transformer, an external oscillator must be gated to the triac to provide the trigger signal. A pulse train of 10 to 15 kHz is adequate to fire the triac each half cycle. This calls for external components and is relatively costly. If isolation associated problems can be tolerated or overcome (dual power supply transformers, direct AC coupling, etc.), a simple buffer may be utilized in triggering the triac. This method is illustrated in *Figure 8*. The National Semiconductor DS8863 display driver is capable of steady state firing of the triac. National offers many buffers capable of driving several hundred milliamps, which are suitable for driving triacs. On the market today there are many suppliers of sensitive gate triacs which may be triggered directly from a COPS device or in conjunction with a smaller external buffer.

The DS8863 display driver is capable of sinking up to 500 mA, which is adequate to drive a standard triac. In the off state the driver will not sink current. When a logic "1" is applied to the input the device will turn on. Keeping the device off (output "1") will prevent the triac from turning on because the buffer does not have the capability of sourcing current. A series resistor limits the current from the triac gate and the diode isolates the negative spikes from the gate. Since the drive circuit will only sink current in this configuration, the triac will be operating in the I- and III- modes.

3.0 Triac Light Intensity Control Code

The following code is not intended to be a final functional program. In order to utilize this program, modifications must be made to specialize the routines. This is intended to illustrate the method and is void of control code to command a response such as intensify or deintensify. The control is up to the user and full understanding of the program must be attained before modifications can be implemented.

This program is a general purpose light intensifying routine which may be modified to suit light dimmer applications. The delay routines require a $4.469 \mu\text{s}$ cycle time which can be attained with a 3.578 MHz crystal (CKI/16 option). This program divides the half cycle of a 60 Hz power line into 16 levels. Intensity is varied by increasing or decreasing the conduction angle by firing the triac at various levels. The program will increase the conduction angle to a maximum specified intensity in a fixed amount of time. The time required to intensify to the maximum level is dependent on the number of fire-times per level that is specified (FINO). This code illustrates a half cycle approach and relies on the parameters specified by the programmer in the control selection.

Zero crossings of the 60 Hz line are detected and software debounced to initiate each half cycle; thus the triac is serviced on every half cycle of the power line. A level/sublevel approach is utilized to vary the conduction angle and provide a prolonged intensifying period. The maximum intensity is specified by the "LEVEL" RAM location and time required to get to that level is specified by the "FINO" RAM location.

Once a level has been specified, the remaining time in the half cycle is then divided into sublevels. The sublevels are increased in steps to the maximum level. The "FINO" RAM location contains the number of times that the triac will be fired per sublevel, thus creating the intensity time base. There are 15 valid sublevels and up to 15 fire-times per sublevel. Both these parameters may be increased to provide better resolution and longer intensify periods. To make the triac de-intensity (dim) the sublevels need only to be decremented rather than incremented. If this is done, the conduction angle will start out at the maximum level and dim by means of stepping down the sublevels. When modifying this routine to incorporate more resolution or increased versatility, care must be taken to account for transfer of control instructions to and from the delay routines.

The following is a schematic diagram of the COPS interface to 120V_{AC} lamps. The program will intensify or de-intensify the lamps under program control.

3.1 TRIAC LIGHT INTENSIFY ROUTINE

This program intensifies a light source by varying the conduction angle applied to the load. The maximum level of intensity is stored in "LEVEL," and the time to get to that level is specified by "FINO." Both these parameters may be altered to suit specific applications. To cause the program to de-intensify the light source, the sublevels must be decremented rather than incremented.

Testing of COP400 Family Devices

National Semiconductor
COP Note 7

Table of Contents

1.0 INTRODUCTION

2.0 PHILOSOPHY

3.0 BUILT-IN TEST FEATURES

- 3.1 Sync between DUT and Tester
- 3.2 Internal Logic Test
- 3.3 RAM Test
- 3.4 ROM Dump

This note will provide some insight into the test mode, the mechanics of testing, and the philosophy of how to implement a test of the COP-400 microcontrollers. Other than the obvious, (verifying that the part meets the specifications), the reason for the test must be considered. Somewhat different criteria may hold, depending on the objective. The manufacturer wafer sort or final test can differ from an incoming inspection at the user's plant, or a field reject test. The first two tests have limited interest as this is not a justification of the testing done on the part during manufacture. Rather, this is a guide for those doing user functional testing.

1.0 INTRODUCTION

Since the introduction of the very first semiconductor devices, testing has been a major problem and expense in their production and use. As the complexity has risen, testing has become a more significant factor. With today's single chip microcontrollers like the COP^{STM} devices this is particularly true as one has a complete computer system in a chip. In order to reduce the testing burden, the facilities to ease the testing have been built into the COPS devices. With the test ability built into the device for production test, the user need only follow set procedures to verify the chip at incoming inspection or field test.

2.0 PHILOSOPHY

The basic test philosophy requires that four major areas be exercised. These areas are:

- 1) Synchronize the device and tester.
- 2) Test the internal logic and I/O.
- 3) Test the RAM.
- 4) Verify the ROM program.

If the devices perform all of these four properly, the device is good. This is a reasonable assumption with a standard device that has a debugged test routine and is ROM programmed. A custom circuit just going into production might not have the accumulated test background. By attacking the problem on a "sum of the parts" approach, one need not do any exhaustive functional test on routine production parts. This will be a major gain where lengthy time consuming or time dependent routines are involved. If one attempts to do a functional test of the chip, a sequence that is unique to the application is needed. Thus, a test program must be written and debugged for each ROM pattern. Further, a test box/board must be designed, built, debugged, documented, and maintained for each one. If testing has been considered from the beginning, the chip will have built-in capabilities to exercise the various parts of it. The different functional parts and instructions are tested to verify proper operation at the voltage and frequency limits.

3.0 BUILT-IN TEST FEATURES

The first step in testing the COP400 devices is to understand the built-in test control features. This will involve the SI/O and the L lines. The SO pin has been designed to be the control node for testing. The pin will normally be in an active low state and when forced high externally, places the chip in the test mode. It should be noted that this output can sink considerable current and one should not force the pin to the V_{CC} rail. By limiting the voltage to the 2.0/3.0V range one can not damage the device where the application of a higher voltage could. When forced into the test mode the SI pin controls the sub mode of the chip. With SI high the data placed on the L port is used as an instruction. When SI is low (and the L output is enabled) the contents of the ROM will be dumped out through the L port. Certain other internal functions have been implemented to allow these modes but these are not part of the basic operation. Included in this category is the activation of the skip signal to prevent the program counter from jumping out of sequence by executing a program control instruction.

3.1 Sync Between Tester and DUT

In order to be able to test a COPS chip, the tester must be in sync with the device under test (DUT). By using an external oscillator the two may be run at the same frequency. This is true regardless of the option or type of oscillator chosen for the chip. Even the RC configuration may be overridden with an external signal that meets the level requirements. In addition to running at the same frequency, the chip and tester must be in sync on a bit basis. See *Figure 1*. The supportive features mentioned above include the condition of the SK signal being a bit (instruction) clock until stopped by software in the program. Hence, one can start the tests based on an edge change of SK. It is important that this be accurate because all data I/O changes will be relative to the SK timing (see the appropriate device data sheet).

It should also be noted that the oscillator frequency is programmed to a rate of 4-32 higher than SK. If one is building a test fixture for more than one device, some method must be available to enter this number. If one is testing a COP420 or COP421 near its upper limit it would be wise to do the SK sync operation at a lower rate and then increase the input frequency. This is desirable because the phase relationship is close to TTL propagation delays at the upper limit. Implementation of the area could be a preset counter that is gated on after a zero to one transition is seen on SK. Continual comparison could be made but once in sync, there should not be any need for the comparison as they should remain in sync.

The basic use of this "sync counter" is to derive the proper timing for loading data and instructions into the chip and verify the outputs. The COP402 data sheet should be used as a guide for these times, modified properly for the L and C parts. For those designing testers, it is suggested that one not attempt to test worse case timing changes as these could be very difficult to implement. Like other parametric tests these should in general be left to the professional test equipment.

3.2 Internal Logic Test

With the device and the tester in sync, actual testing may begin. See the sequence control circuit of *Figure 2*. To place the chip into the test mode the SO output is pulled to a one level (between 2.0 and 3.0 volts). It should be pulled with a circuit that will limit the upper voltage to 3V as this output can have a significant current sink capability. On power up (or after reset) the SO line is set to a zero by the internal logic. An internal sense line will detect the forced condition and provide test control. A delay of 10 ms should be taken after power-up to allow the power on reset circuit to time out before instructions can be executed. If the reset pin is activated in mid-program for some reason, several instructions cycle times should be ignored to insure complete operation.

The tester should at this point force instructions into the L port. These instructions will be executed as if they were from the ROM. The sequence of the instructions is not particularly critical. Table 1 gives an example sequence. The main steps are to be able to detect an output change (OGI) early to verify connection/operation. It is much better to find a problem before going through the steps of loading RAM and then finding that the chip doesn't work. All instructions should be exercised although certain ones should be postponed. Enabling the Q register to the L port is an example. This would interfere with the insertion of instructions on the L port. Another problem is the SO test which could be set up with an XAS and then released from the test mode to check proper data output.

Certain commands will require more effort than others. To check the program counter during JMP's and sub-routine operation will require that known info at the new address be available. One should execute a JSRP at some known address and release the test mode to see that the operation in the subroutine (e.g., SC) is done and that a return is made to $N + 1$. At this point test mode can be re-established to continue the test. The main point to remember is to provide a positive indication of the success of that specific test.

FIGURE 1. Tester Clock Generation and Synchronization Circuit

TL/DD/6940-1

FIGURE 2. Tester Mode Sequencer

TL/DD/6940-2

3.3 RAM Test

The verification of RAM is a part of the internal logic test, but is treated separately here. One must check both the RAM and its address register to find all faults. An example of this testing would be to load RAM with a string of STIL commands. By then going back and reading this data to the outside (through an OMG instruction in a loop) the tester could verify both RAM and address were functional. One could then load RAM with all 6's and 9's (or 5's and 10's) sequentially to insure that all bits were functional and adjacent bits not shorted. Other similar tests could be run at the discretion of the user to do further testing. All of these tests would utilize the output of data via the G ports to validate the data. See the comparator circuit *Figure 3*.

3.4 ROM Dump

Successful operation of the internal logic tests and RAM will lead to the final test phase, ROM comparison. In order to

check the ROM contents, the ROM dump mode must be entered. One should force a JMP to an address near the end of the ROM space (3FF for a 420 chip, 1FF for a 410). A desirable point might be 3FA. The program counter will step ahead on each instruction cycle unless a program control is executed. The next step is to load the Q register with a non-conflicting value so that the enabling of the L outputs will not destroy the second byte of the LEI instruction as control is passed into the ROM dump mode. After going to this address, one should execute an enable of the L lines to the output port (LEI 4). Having done this the external buffers should be disabled and the SI pin taken low. This will allow data out and remove potential level conflicts. By letting the PC step ahead to address zero one can then begin the byte by byte comparison of data. In this mode the controller is not executing the code because the skip line is enabled throughout the sequence. By halting a counter on a failure, one could determine the questionable address.

This test sequence is not to be taken as a recommended test routine and is only shown as an example of what might be done to test various COPS parts. It is also advisable to approach measurements in the test mode with some caution. As stated earlier, one can force a large current into the SO node to place the chip in the test mode. Not only can this current do damage if unlimited, but it can also cause local current overloading such that some I/O conditions may be adversely affected. Obviously this will be more pronounced at higher V_{CC} voltages. A specific example is that the L output current sink test should only be tested at a V_{OUT} of 0.4V and 0.36 mA as the more stringent tests can exceed power limits when combined with the SO current.

MICROWIRE™

National's super-sensible MICROWIRE serial data exchange standard allows interfacing to any number of specialized peripherals using an absolute minimum number of valuable I/O pins; this leaves more I/O lines available for system interfacing and/or may permit the COPS controller to be packaged in a smaller (and even lower cost) package. (MICROWIRE peripherals may also be used with non-COPS controllers). For further applications information, refer to COPS Briefs 8 and 9. MICROWIRE makes sense.

The example below illustrates the power and versatility of MICROWIRE via an extreme example—using one of each type of peripheral with a single controller.

TL/DD/6940-4

COP431 SERIES, 8-BIT A/D CONVERTERS

The COP431 series is an 8-bit successive approximation A/D converter with a serial I/O and configurable input multiplexer with up to 8 channels. The serial I/O is configured to comply with the NSC MICROWIRE serial data exchange standard for easy interface to the COPS family of processors, and can interface with standard shift registers or other μ Ps.

The 2, 4 or 8 channel multiplexers are software configured for single-ended or differential inputs as well as channel assignment.

The differential analog voltage input allows increasing the common-mode rejection and offsetting the analog zero input voltage value. In addition, the voltage reference input can be adjusted to allow encoding any smaller analog voltage span to the full 8 bits of resolution.

COP472-3 LIQUID CRYSTAL DISPLAY CONTROLLER

The COP472-3 Liquid Crystal Display (LCD) Controller drives a multiplexed liquid crystal display directly. Data is loaded serially and is held in internal latches. The COP472-3 contains an on-chip oscillator and generates all the multilevel waveforms for backplanes and segment outputs on a triplex display. One COP472-3 can drive 36 segments multiplexed as 3×12 ($4\frac{1}{2}$ digit display). Two COP472-3 devices can be used together to drive 72 segments (3×24) which could be an $8\frac{1}{2}$ digit display.

NM93C06A 256-BIT SERIAL ELECTRICALLY ERASABLE PROGRAMMABLE MEMORY

The NM93C06A is a 256-bit non-volatile memory. The device contains 256 bits of read/write memory divided into 16 registers of 16 bits each. Each register is serially read or written by the COP400 Family Controller. Written information is stored in a floating gate cell with at least 10 years of retention.

Current Consumption in NMOS COPSTM Microcontrollers

National Semiconductor
Application Brief 3
Len Distaso

Current consumption in the N-channel COPS microcontrollers is a function of manufacturing process variation and three operating condition parameters: temperature, voltage, and frequency. The aforementioned process variation swamps all other variations. Of the operating condition parameters, temperature is by far the most significant. This application brief is intended to provide the user with a guide to approximate the worst-case current consumption of the NMOS COPS microcontroller at a given set of operating conditions and to approximate the current variation with respect to temperature, voltage, and frequency.

Note that this is a guide only. Some approximations in the equations have been made. Only the current values found in the various device data sheets are guaranteed. Values derived by the techniques described here are neither guaranteed nor tested.

PROCESS VARIATION

If a user were to measure the current in two identical COPS microcontrollers under identical operating conditions (i.e., same temperature, voltage, and frequency), the results would probably be different. The reason for this difference is variation in the manufacturing process within its valid range. This variation can be quite substantial; a range of about 3 to 1 can be expected. This variation is essentially a device-to-device variation and basically not related to the operating conditions of the device. The three operating condition parameters (temperature, voltage, and frequency) affect current in the manner described below.

The values for current consumption in the various device data sheets are worst-case maximum values and assume that the processing parameters are at the end of the valid range which will produce maximum current consumption in the device.

THE EFFECT OF FREQUENCY

The frequency effect on current consumption is primarily a device design consideration. The higher the intended operating frequency, the higher the maximum current. However, once the device is designed in this process for a given maximum frequency, there is little variation with operating frequency. To be sure, there is some variation. As might be expected, current consumption is greater at higher frequencies. The variation is, however, slight—typically less than 5%.

THE EFFECT OF VOLTAGE

The operating voltage of the microcontroller has a slightly greater effect on current consumption than the operating current. Current consumption increases with increasing operating voltage. On examining the MOS device equations, one finds that the device current is proportional to the square of a voltage term:

$$I \propto (V_{GS} - V_T)^2$$

where:

I = device current

V_{GS} = device gate to source voltage

V_T = device threshold voltage.

In the N-channel COPS devices, current is consumed primarily by the load devices. Most of these devices, though not all, are depletion mode devices with the gate and source tied together. Thus, V_{GS} is 0. Therefore, the primary mechanism for current consumption as related to voltage is variation in V_T . The depletion mode load devices in the COPS NMOS microcontrollers have geometries (length is much greater than width) which tend to minimize variations in threshold voltage. There are additional second order effects related to operating voltage, such as effective channel lengths shortening due to increased voltage, which affect current consumption. These effects, however, do not have a major impact on current consumption. Note also that the threshold voltage is affected by process variation. This is one of the areas where the process variation contributes to the device-to-device variation in current consumption. The user can typically expect to see a 5% to 10% variation in current due to operating voltage with the maximum current consumption occurring at maximum operating voltage.

THE EFFECT OF TEMPERATURE

Of the three operating parameters affecting current consumption in the NMOS COPS microcontrollers, temperature has by far the greatest impact. The relationship is given by the following simplified, empirical equation:

$$I(T) = I_0(T/T_0)^{-3/2}$$

where:

T_0 = reference junction temperature in °K

T = device junction temperature in °K

I_0 = device current at temperature T_0

$I(T)$ = device current at temperature T .

Although this equation is for a single transistor, it can be applied to the entire microcontroller since all the devices are made with the same process and will exhibit the same

characteristics. It should also be noted that the temperatures involved are device junction temperatures. The junction temperature is essentially a function of two items:

$$T_j = F(T_A, \theta_{jA})$$

where:

T_j = junction temperature

T_A = ambient temperature

θ_{jA} = package thermal characteristic.

The preceding relationship indicates that the package for the device will affect current because the package affects junction temperature. This should not come as a surprise. One need only consider the differences between ceramic and plastic packages to find support for this claim.

For purposes of discussion, it will be assumed that junction temperature is given by the following:

$$T_j = T_A + 25^\circ\text{K}$$

where T_j and T_A are as defined previously. Note that this is an approximation. It is not necessarily true for all packages, or any package. The relationship between junction temperature and ambient temperature is also not necessarily linear. However, the approximation is reasonable and provides a workable framework.

Substituting the junction temperature relationship into the current equation, the following equation results:

$$I(T_A) \cong I_0 \left(\frac{T_A + 25}{T_{AO} + 25} \right)^{-3/2}$$

where:

T_{AO} = reference ambient temperature, °K

T_A = ambient temperature, °K

I_0 = current at ambient temperature T_{AO}

$I(T_A)$ = current at ambient temperature T_A .

AN EXAMPLE

The COP320L has a specified maximum current of 10 mA. In this process, maximum current occurs at minimum temperature, which is -40°C in this case. It is desired to find the maximum current at 25°C . Therefore,

$$T_{AO} = -40^\circ\text{C} = 233^\circ\text{K}$$

$$T_A = 25^\circ\text{C} = 298^\circ\text{K}$$

$$I_0 = 10 \text{ mA}$$

$I(T_A)$ to be determined

$$I(T_A) \cong I_0 \left(\frac{T_A + 25}{T_{AO} + 25} \right)^{-3/2}$$

$$\cong 10 \text{ mA} (323/258)$$

$$\cong 7.14 \text{ mA.}$$

Thus the maximum current for the COP320L at 25°C is approximately 7 mA.

CONCLUSION

A means is provided to the user to approximate the current variation of the NMOS COPS microcontroller over its valid operating range. A given device will consume its maximum current at maximum operating voltage, maximum operating frequency, and minimum operating ambient temperature. Conversely, minimum current will be consumed at minimum operating voltage, minimum operating frequency, and maximum operating ambient temperature.

The user should remember that this document is intended as a guide only. The values produced here are reasonable but they are approximations and are not guaranteed values. The user should also remember that the equations and methods discussed here do not involve process variation. The numbers calculated approximate the worst-case maximum current values at a given set of operating conditions. The user should be prepared to see a wide range of values over the course of volume production.

Further Information on Testing of COPS™ Microcontrollers

National Semiconductor
Application Brief 4
Len Distaso

COP Note 7 describes the basic approach and philosophy for testing COPS microcontrollers. This application brief is intended to complement and expand COP Note 7. It is assumed that the reader is familiar with and has access to COP Note 7.

TEST MODE

On COPS microcontrollers, test mode is entered by forcing the SO output to a logic "1" when it should otherwise be a logic "0". The easiest way to do this is to hold the COPS device in reset, hold the $\overline{\text{RESET}}$ pin low, and pull SO up to a logic "1" level. **WARNING: Do not force more than 3.0V on SO, as damage to the device may occur.** SO should be forced to approximately 2.5V to guarantee entry into test mode and to protect the device from damage.

Once the device is in test mode, the state of the SI input controls the type of test. SI at a logic "1" (high level) conditions the device to accept instructions from an external source via the L port. In test mode, when SI is high, the internal ROM is disabled. SI at a logic "0" (low level) forces the device to dump the internal ROM to the L port where the user can read and verify the ROM contents.

INSTRUCTION INPUT

With the device in test mode and SI at a logic "1", the microcontroller will read the data at the L port as instructions. The instructions must be presented at the beginning of each cycle time and must remain valid during the whole cycle time. The chip SK output is the instruction cycle clock in test mode and can be used as the timing reference. *Figure 1* indicates the timing for instruction input using the chip's SK output as the reference. A new instruction must be valid at the L inputs within approximately 200 ns of the rising edge of SK. The user should make every effort to make this time (t_2 in *Figure 1*) as short as possible.

It is possible to create an external SK signal which more closely duplicates the internal SK. This requires building a divider from CKI and synchronizing the resultant signal with the device under test. This is significant because it is the internal version of the SK signal which is the master timing signal for the microcontroller. The short time from the rising edge of the SK output to instruction valid is necessary because the actual objective is to provide new instructions at the rising edge, or close to it, of the internal timing signal. If the user creates the external timing signal, the 200 ns time is not applicable. A new instruction, or ROM word, would be presented at each rising edge of the external signal. A method for generating and using this external SK is described in COP Note 7.

ROM DUMP

With SI at logic "0" in test mode, the microcontroller will dump the ROM to the L port. ROM will be dumped sequentially, one word at a time, starting at whatever value the

program counter contains. A new ROM word appears at the L lines every falling edge of the chip SK signal. The output timing (t_1 in *Figure 1*) is the L output timing as found in the various device data sheets. The device will remain in ROM dump mode as long as SI is at logic "0" in test mode. The program counter will wrap around from the maximum address to 000 and ROM dump will continue.

To get a ROM dump, the user cannot simply enter test mode and force SI to logic "0". Some conditioning of the device is necessary. This requires that the user first go into instruction input mode and set up the device. The suggested sequence is as follows:

1. Enter test mode—pull $\overline{\text{RESET}}$ low, force SO to about 2.5V.
2. Force SI to logic "1" and force 0s on L lines—RESET still low.
3. Force RESET high and input the following sequence to the device:

```
CLRA
JMP 3FC (modify for ROM size)
LQID
O44H
LEI 4
NOP
```

4. During the NOP, change SI from high to low as shown in *Figure 2*. The ROM dump should start at address 000H at the time shown in *Figure 2*.

Figure 3 presents a general timing diagram for the entire sequence above. The jump instruction (JMP 3FC) in the sequence is used merely to position the program counter so that the ROM dump will begin at a specified location. That jump will be modified to reflect different ROM sizes or different desired starting locations for the ROM dump.

CHANGING BETWEEN INSTRUCTION INPUT AND ROM DUMP

The change from instruction input to ROM dump is accomplished according to the timing in *Figure 2*. It is necessary to do this to perform a valid ROM dump. However, it is not recommended to go the other direction, from ROM dump to instruction input, "on the fly". The instruction input mode should only be entered while the device is reset, RESET line low, to guarantee proper timing.

CONCLUSION

With COP Note 7 and this application brief, the user should be able to create a workable functional test for his COPS microcontroller. The relative timing is presented here and general techniques and sequences are provided in COP Note 7.

COPS™ Interrupts

National Semiconductor
 Application Brief 6
 Jim Murashige

This brief describes in detail the timing requirements pertinent to COPS interrupts. *Figure 1* shows a typical enable-interrupt sequence in relation to the SK (Instruction Cycle) Clock. The SK clock is actually derived from the $\phi 1$ clock which is 180° out of phase with the $\phi 2$ clock. It is the $\phi 1$ and $\phi 2$ clocks to which all operation is referenced but for our purposes the SK will suffice. Program instructions are read on a rising $\phi 1$ edge and executed during the $\phi 1, \phi 2$ cycle time. Here we see the EN register interrupt enable bit EN2 being set with an LEI instruction. Interrupts are actually enabled on the $\phi 2$ leading edge of the second byte of the instruction point ②. Timing for an INTERRUPT DISABLE is essentially the same.

The interrupt line is sampled on the leading edge of $\phi 1$ as shown and interrupts are recognized if the minimum setup and hold times shown are satisfied. Note that the guaranteed times are longer than the typicals. The interrupt signal conditioning circuitry contains a falling edge detection circuit (a one shot) which requires that in addition to meeting the setup and hold times, the enable interrupt bit EN1 must have been turned on sometime before the end of the WINDOW OF OPPORTUNITY shown. If not, the interrupt will be missed and another high to low IN1 transition will be required. EN1 is automatically disabled upon interrupt recognition at point ⑤. Note that although the interrupt is recog-

nized at point ⑤ it will not be acted upon until all successive transfer of control instructions are executed as defined in the data sheets.

Because of gate delays it is doubtful that if an interrupt had been generated in time to meet the leading $\phi 1$ edge at point ② that the EN1 enable bit would have been on in time to meet the WINDOW of OPPORTUNITY.

By doing a worst case analysis one can see that in order to guarantee reception of an asynchronous interrupt IN1 must remain low for at least 2 instruction cycles. The analysis is as follows. Assuming that interrupts had been enabled prior to point ①, if the interrupt arrives a little after point ① it will not satisfy the minimum setup requirements bringing us up to a point ③ our total elapsed time becomes ③ - ① = 2 t_{CYC}.

In a dual COPS the interrupt sequence is the same except that now an instruction cycle time is made up of both a Processor X and a Processor Y instruction execution cycle. With one $\phi 1$ and $\phi 2$ clock per processor execution cycle the instruction cycle time is made up of 2 $\phi 1$'s and $\phi 2$'s. Therefore 1 instruction cycle time in a dual COPS is equivalent to 2 instruction cycle times in a single COPS as far as $\phi 1$'s, $\phi 2$'s and interrupts are concerned.

Protecting Data in Serial EEPROMs

National Semiconductor
Application Brief 15
Paul Lubeck

National offers a broad line of serial interface EEPROMs which share a common set of features:

- Low cost
- Single supply in all modes (+5V ± 10%)
- TTL compatible interface
- MICROWIRE™ compatible interface
- Read-Only mode or read-write mode

This Application Brief will address protecting data in any of National's Serial Interface EEPROMs by using read-only mode.

Whereas EEPROM is non-volatile and does not require V_{CC} to retain data, the problem exists that stored data can be destroyed during power transitions. This is due to either uncontrolled interface signals during power transitions or noise on the power supply lines. There are various hardware design considerations which can help eliminate the problem although the simplest most effective method may be the following programming method.

All National Serial EEPROMs, when initially powered up are in the Program Disable Mode*. In this mode, the EEPROM will abort any requested Erase or Write cycles. Prior to Eras-

ing or Writing it is necessary to place the device in the Program Enable Mode†. Following placing the device in the Program Enable Mode, Erase and Write will remain enabled until either executing the Disable instruction or removing V_{CC}. Having V_{CC} unexpectedly removed often results in uncontrolled interface signals which could result in the EEPROM interpreting a programming instruction causing data to be destroyed.

Upon power up the EEPROM will automatically enter the Program Disable Mode. Subsequently the design should incorporate the following to achieve protection of stored data.

- 1) The device powers up in the read-only mode. However, as a backup, the EWDS instruction should be executed as soon as possible after V_{CC} to the EEPROM is powered up to ensure that it is in the read-only mode.
- 2) Immediately preceding a programming instruction (ERASE, WRITE, ERAL or WRAL), the EWEN instruction should be executed to enable the device for programming; the EWDS instruction should be executed immediately following the programming instruction to return

*EWDS or WDS, depending on exact device.

†EWEN or WEN, depending on exact device.

FIGURE 1. EWEN, EWDS Instruction Timing

TL/D/7085-1

*EWDS must be executed before V_{CC} drops below 4.5V to prevent accidental data loss during subsequent power down and/or power up transients.

FIGURE 2. Typical Instruction Flow for Maximum Data Protection

TL/D/7085-2

the device to the read-only mode and protect the stored data from accidental disturb during subsequent power transients or noise.

- 3) Special care must be taken in designs in which programming instructions are initiated to store data in the EEPROM after the main power supply has gone down. This is usually accomplished by maintaining V_{CC} for the EEPROM and its controller on a capacitor for a sufficient amount of time (approximately 50 ms, depending on the clock rate) to complete these operations. This capacitor

must be large enough to maintain V_{CC} between 4.5 and 5.5 volts for the total duration of the store operation, INCLUDING the execution of the EWDS instruction immediately following the last programming instruction. FAILURE TO EXECUTE THE LAST EWDS INSTRUCTION BEFORE V_{CC} DROPS BELOW 4.5 VOLTS MAY CAUSE INADVERTENT DATA DISTURB DURING SUBSEQUENT POWER DOWN AND/OR POWER UP TRANSIENTS.

A Users Guide to COPSTM Oscillator Operation

National Semiconductor
Application Note 326
Jim Murashige

AN-326

The following discussion is an overview of the COPS oscillator circuits meant to give the reader a working knowledge of the circuits. Although the descriptions are very general and light on detail; a background in complex frequency analysis is necessary. For additional information the references cited should be consulted as well as the many works on oscillator theory.

There are 2 basic circuits from which all of the COPS oscillator options are provided. (See option lists in individual data sheets.) The first and simplest in description is the astable one shot of *Figure 1* which gives us our RC oscillator option. A1 and A2 are inverters with A1 possessing a Schmitt trigger input. T1 is a large N channel enhancement MOS FET. Operation with the external R-C shown is as follows. Assuming C is initially discharged the CKI pin is low forcing T1 off. As C charges through R the trigger point of A1 is eventually reached at which time T1 is turned on discharging C and beginning a new cycle. Although almost any combination of R-C could be chosen, we would ideally like to have as short a discharge time as possible thereby eliminating the high variability in T1 drain current from device to device as a timing factor. For this reason R is chosen very large and C very small. This choice also leads to minimum R-C power dissipation. For the CKI Schmitt trigger clock input option the T1 MOS FET is merely mask disabled from the oscillator circuit.

FIGURE 1. R-C Oscillator

TL/DD/5139-1

The second oscillator circuit is the classic phase shift oscillator depicted in *Figure 2*. Found not only on COPS but on most other microprocessor circuits it is the simplest oscillator in terms of component complexity but the most difficult to analyze.

FIGURE 2. Phase Shift Oscillator

TL/DD/5139-2

The conditions under which the circuit will oscillate are described by the Barkhausen Criterion which states that oscillation will occur at the frequency for which the total loop phase shift from x_i to x_f is 0° or a multiple of 360° (i. e., x_f is identical to x_i). In addition the total loop gain must be > 1 to insure self propagation. The inverting amplifier shown between x_i and x_o provides 180° of phase shift thus leaving the feedback network to supply the other $\pm 180^\circ$. The feedback network can be comprised of active or passive components but highly effective oscillators are possible using only passive reactive components and the general configuration of *Figure 3*.

If you work out the feedback loop equations for *Figure 3* it can be shown that in order to achieve $\pm 180^\circ$ phase shift:

$$X_1 + X_2 + X_3 = 0 \quad (1)$$

X_1 and X_2 must both be inductors or capacitors (2)

therefore X_3 is inductive if X_1 is capacitive and vice versa if X_1 and X_2 are capacitors it is a Colpitts Oscillator

X_1 and X_2 are inductors it is a Hartley Oscillator

FIGURE 3. Typical Feedback Configuration

TL/DD/5139-3

3

The Colpitts configuration is commonly shown in microprocessor oscillator circuits (Figure 5) with the inductive X3 replaced by a crystal for reasons we shall soon see. The equivalent electrical model of a crystal is shown in Figure 4b and a plot of its Reactance versus Frequency shown in Figure 4c. R-L-C represent the electro-mechanical properties of the crystal and C₀ the electrode capacitance. There are 2 important points on the reactance curve labeled f_a and f_b.

$$\text{At } f_a = \frac{1}{2\pi} \sqrt{\frac{1}{LC}}$$

the crystal is at series resonance with L and C canceling each other out leaving only a nonreactive R for 0 phase shift. This mode of operation is important in oscillator circuits where a non-inverting amplifier is used and 0° phase shift must be preserved.

$$\text{At } f_b = \frac{1}{2\pi} \sqrt{\frac{1}{LC} + \frac{1}{LC_0}}$$

which is just a little higher than f_a the crystal is at parallel resonance and appears very inductive or capacitive. Note that the crystal will only appear inductive between f_a and f_b and that it becomes highly inductive very quickly. In addition f_b is only a fraction of a percent higher than f_a. Therefore the only time that the crystal will satisfy the X3 = -(X1 + X2) condition in the Colpitts configuration of Figure 5 is when the circuit is oscillating between f_a and f_b. The exact frequency will be the one which gives an inductive reactance large enough to cancel out:

$$X1 + X2 = \frac{1}{\omega C1} + \frac{1}{\omega C2} = \frac{1}{\omega} \left[\frac{1}{C1} + \frac{1}{C2} \right] = \frac{1}{2\pi f} \left[\frac{1}{C_L} \right]$$

Therefore by varying C1 or C2 we can trim slightly the oscillator frequency.

FIGURE 4. Quartz Crystal

FIGURE 5. Colpitts Oscillator

The Q of a circuit is often bounced around in comparing different circuits and can be viewed graphically here as the slope of the reactance curve between f_a and f_b . Obviously the steeper the curve the smaller the variation in f necessary to restore the Barkhausen Phase Shift Criterion. In addition a lower Q (more R) means that the reactance curve won't peak as high at f_b , necessitating a smaller X1 + X2. When selecting crystals the user should be aware that the frequency stamped on the cans are for either parallel or series resonance, which, although very close, may matter significantly in the particular application.

An actual MOS circuit implementation of *Figure 5* is shown in *Figure 6*. It consists of a MOS inverter with depletion load and the crystal π network just presented. External to the COPS chips are the R_f and R_g resistors. R_f provides bias to the MOS inverter gate $V_g = V_0$. Since the gate draws no current R_f can be very large (M Ω) and should be, since we do not wish it to interact with the crystal network. R_g increases the output resistance of the inverter and keeps the crystal from being over driven.

FIGURE 6. MOS Oscillator

TL/DD/5139-8

Of course the feedback network doesn't have to have the configuration of *Figure 3* and can be anything so long as the Barkhausen Phase Shift Criterion is satisfied. One popular configuration is shown in *Figure 7* where the phase shift will be 180°

$$\text{at } f = \frac{1}{(2\pi RC\sqrt{6})}$$

Implementing an 8-Bit Buffer in COPS™

National Semiconductor
Application Note 329
David Pointer

AN-329

Sometimes a COP microcontroller must input and/or output 8-bit data; for instance, when handling ASCII data. In some applications, the processor must also provide temporary storage for 8-bit data before it is output. The COP instruction set and RAM structure lend themselves very nicely to providing a 32 digit, 8-bit buffer for a solution to these applications.

Such a large buffer is possible using a COP440 or a COP444L. The other members of the COP400 family with half as much RAM as these two would provide a 16 digit 8-bit buffer using the techniques described in this example.

Four adjacent RAM registers (16 digits each) are required. Referring to *Figure 1*, registers 4, 5, 6, and 7 are used for the buffer. Each RAM location contains 4 bits, so 2 locations will be used to store a byte of data. But these RAM locations are not adjacent to each other. You will note that the MSD of digit number 0A hex is in RAM location (4, A) while the LSD of the same digit is in RAM location (6, A).

The 2 RAM locations CHARM and CHARL are used for temporary storage of an 8-bit value.

In addition, 4 RAM locations are used for buffer pointers: those labelled IPM and IPL are the MSD and LSD of the

input pointer, and those labelled OPM and OPL are the MSD and LSD of the output pointer. Each pointer's function is to store an 8-bit counter whose value ranges from 00 hex thru 1F hex. The input pointer's value is used for storing the temporary storage buffer contents into the digit with the same number. For example, if the input pointer equals 14 hex, then the contents of CHARM would be stored in RAM location (5, 4) and the contents of CHARL would be stored in RAM location (7, 4). The output pointer's value is used for retrieving a digit from the buffer and putting it in CHARM and CHARL. For instance, if the output pointer equals 05 hex, then the contents of RAM location (4, 5) would be transferred to CHARM and the contents of RAM location (6, 5) would be transferred to CHARL.

A simple example of one possible application of the buffer is flowcharted in *Figure 2*. In this example, data is input to CHARM and CHARL, then stored in the buffer. An output device (a printer) is checked to see if it is ready to receive data. If it is, data is brought out of the buffer and put in CHARM and CHARL for output to the printer.

Pages 3 and 4 contain a listing of the subroutines needed to perform the data transfers in the 32-digit, 8-bit buffer.

Designing with the NM93C06 A Versatile Simple to Use E² PROM

National Semiconductor
Application Note 338
Masood Alavi

This application note outlines various methods of interfacing an NM93C06 with the COPST[™] family of microcontrollers and other microprocessors. Figures 1-6 show pin connections involved in such interfaces. Figure 7 shows how parallel data can be converted into a serial format to be inputted to the NM93C06; as well as how serial data outputted from an NM93C06 can be converted to a parallel-format.

The second part of the application note summarizes the key points covering the critical electrical specifications to be kept in mind when using the NM93C06.

The third part of the application note shows a list of various applications that can use a NM93C06.

GENERIC CONSIDERATIONS

A typical application should meet the following generic criteria:

1. Allow for no more than 10,000 E/W cycles for optimum and reliable performance.
2. Allow for any number of read cycles.
3. Allow for an erase or write cycle that operates in the 10-30 ms range, and not in the tens or hundreds of ns range as used in writing RAMs. (Read vs write speeds are distinctly different by orders of magnitude in E²PROM, not so in RAMs.)

4. No battery back-up required for data-retention, which is fully non-volatile for at least 10 years at room-ambient.

SYSTEM CONSIDERATIONS

When the control processor is turned on and off, power supply transitions between ground and operating voltage may cause undesired pulses to occur on data, address and control lines. By using WEEN and WEDS instructions in conjunction with a LO-HI transition on CS, accidental erasing or writing into the memory is prevented.

The duty cycle in conjunction with the maximum frequency translates into having a minimum HI-time on the SK clock. If the minimum SK clock high time is greater than 1 μ s, the duty cycle is not a critical factor as long as the frequency does not exceed the 250 kHz max. On the low side no limit exists on the minimum frequency. This makes it superior to the COP499 CMOS-RAM. The rise and fall times on the SK clock can also be slow enough not to require termination up to reasonable cable-lengths.

Since the device operates off of a simple 5V supply, the signal levels on the inputs are non-critical and may be operated anywhere within the specified input range.

PA0 → SK
 PA1 → DI/DO } Common to all 9306's
 PA2-7 → 6CS for 6-9306's

- * SK is generated on port pins by bit-set and bit-clear operations in software. A symmetrical duty cycle is not critical.
- * CS is set in software. To generate 10-30 ms write/erase the timer/counter is used. During write/erase, SK may be turned off.

t_{CSH} 0		ns
t_{PD0}		2 μ s
t_{PD1}		2 μ s

THE NM93C06A

Extremely simple to interface with any μ P or hardware logic. The device has six pins for the following functions:

Pin 1	CS*	HI enabled
Pin 2	SK	Serial Clock input
Pin 3	DI	For instruction or data input
Pin 4	DO**	For data read, TRI-STATE® otherwise
Pin 5	GND	
Pin 8	V_{CC}	For 5V power
Pins 6-7	No Connect	No termination required

*Following an E/W instruction feed, CS is also toggled low for 10 ms (typical) for an E/W operation. This internally turns the VPP generator on (HI-LO on CS) and off (LO-HI on CS).

**DI and DO can be on a common line since DO is TRI-STATE[®] when unselected DO is only on in the read mode.

USING THE NM93C06

The following points are worth noting:

- SK clock frequency should be in the 0-250 kHz range. With most μ Ps this is easily achieved when implemented in software by bit-set and bit-clear instructions, which take 4 instructions to execute a clock or a frequency in the 100 kHz range for standard μ P speeds. Symmetrical duty cycle is irrelevant if SK HI time is $\geq 2 \mu$ s.
- CS low period following an E/W instruction must not exceed the 30 ms max. It should best be set at typical or minimum spec of 10 ms. This is easily done by timer or a software connect. The reason is that it minimizes the 'on time' for the high V_{PP} internal voltage, and so maximizes endurance. SK-clock during this period may be turned off if desired.
- All E/W instructions must be preceded by EWEN and should be followed by an EWDS. This is to secure the stored data and avoid inadvertent erase or write.
- A continuously 'on' SK clock does not hurt the stored data. Proper sequencing of instructions and data on DI is essential to proper operation.

- Stored data is fully non-volatile for a minimum of ten years independent of V_{CC} , which may be on or off. Read cycles have no adverse effects on data retention.
- Up to 10,000 E/W cycles/register are possible. Under typical conditions, this number may actually approach 1 million. For applications requiring a large number of cycles, redundant use of internal registers beyond 10,000 cycles is recommended.
- Data shows a fairly constant E/W Programming behavior over temperature. In this sense E²PROMs supersede EPROMs which are restricted to room temperature programming.
- As shown in the timing diagrams, the start bit on DI must be set by a ZERO - ONE transition following a CS enable (ZERO - ONE), when executing any instruction. ONE CS enable transition can only execute ONE instruction.
- In the read mode, following an instruction and data train, the DI can be a don't care, while the data is being outputted i.e., for next 17 bits or clocks. The same is true for other instructions after the instruction and data has been fed in.
- The data-out train starts with a dummy bit 0 and is terminated by chip deselect. Any extra SK cycle after 16 bits is not essential. If CS is held on after all 16 of the data bits have been outputted, the DO will output the state of DI till another CS LO-HI transition starts a new instruction cycle.
- When a common line is used for DI and DO, a probable overlap occurs between the last bit on DI and start bit on DO.
- After a read cycle, the CS must be brought low for 1 SK clock cycle before another instruction cycle can start.

All commands, data in, and data out are shifted in/out on rising edge of SK clock.

Write/erase is then done by pulsing CS low for 10 ms.

All instructions are initiated by a LO-HI transition on CS followed by a LO-HI transition on DI.

READ — After read command is shifted in DI becomes don't care and data can be read out on data out, starting with dummy bit zero.

WRITE — Write command shifted in followed by data in (16 bits) then CS pulsed low for 10 ms minimum.

INSTRUCTION SET

Instruction	SB	Opcode	Address	Data	Comments
READ	01	10xx	A3A2A1A0		Read Register A3A2A1A0
WRITE	01	01xx	A3A2A1A0	D15-D0	Write Register A3A2A1A0
ERASE	01	11xx	A3A2A1A0		Erase Register A3A2A1A0
EWEN	01	0011	XXXX		Erase/Write Enable
EWDS	01	0000	XXXX		Erase/Write Disable
ERAL	01	0010	XXXX		Erase All Registers
WRAL	01	0001	XXXX	D15-D0	Write All Registers

NM93C06 has 7 instructions as shown. Note that MSB of any given instruction is a "1" and is viewed as a start bit in the interface sequence. The next 8 bits carry the op code and the 4-bit address for 1 of 16, 16-bit registers.

X is a don't care state.

A Study of the Crystal Oscillator for CMOS-COPS™

National Semiconductor
Application Note 400
Abdul Aleaf

INTRODUCTION

The most important characteristic of CMOS-COPS is its low power consumption. This low power feature does not exist in TTL and NMOS systems which require the selection of low power IC's and external components to reduce power consumption.

The optimization of external components helps decrease the power consumption of CMOS-COPS based systems even more.

A major contributor to power consumption is the crystal oscillator circuitry.

Table I presents experimentally observed data which compares the current drain of a crystal oscillator vs. an external squarewave clock source.

The main purpose of this application note is to provide experimentally observed phenomena and discuss the selection of suitable oscillator circuits that cover the frequency range of the CMOS-COPS.

Table I clearly shows that an unoptimized crystal oscillator draws more current than an external squarewave clock. An RC oscillator draws even more current because of the slow rising signal at the CKI input.

Although there are few components involved in the design of the oscillator, several effects must be considered. If the requirement is only for a circuit at a standard frequency which starts up reliably regardless of precise frequency stability, power dissipation and etc., then the user could directly consult the data book and select a suitable circuit with proper components. If power consumption is a major requirement, then reading this application note might be helpful.

WHICH IS THE BEST OSCILLATOR CIRCUIT?

The Pierce Oscillator has many desirable characteristics. It provides a large output signal and drives the crystal at a low power level. The low power level leads to low power dissipation, especially at higher frequencies. The circuit has good short-term stability, good waveforms at the crystal, a frequency which is independent of power supply and temperature changes, low cost and usable at any frequency. As compared with other oscillator circuits, this circuit is not disturbed very much by connecting a scope probe at any point in the circuit, because it is a stable circuit and has low impedance. This makes it easier to monitor the circuit without any major disturbance. The Pierce oscillator has one disadvantage. The amplifier used in the circuit must have high gain to compensate for high gain losses in the circuitry surrounding the crystal.

TABLE I

A. Crystal oscillator vs. external squarewave COP410C change in current consumption as a function of frequency and voltage, chip held in reset, CKI is ÷ 4.

I = total power supply current drain (at V_{CC}).

Crystal

V_{CC}	f_{ckl}	Inst. cyc. time	$I_{\mu A}$
2.4V	32 kHz	125 μs	8.5
5.0V	32 kHz	125 μs	83
2.4V	1 MHz	4 μs	199
5.0V	1 MHz	4 μs	360

External Squarewave

V_{CC}	f_{ckl}	Inst. cyc. time	I
2.4V	32 kHz	125 μs	4.4 μA
5.0V	32 kHz	125 μs	10 μA
2.4V	1 MHz	4 μs	127 μA
5.0V	1 MHz	4 μs	283 μA

WHAT IS A PIERCE OSCILLATOR?

The Pierce is a series resonant circuit, and its basic configuration is shown below.

FIGURE 1

TL/DD/8439-1

For oscillation to occur, the Barkhausen criteria must be met: (1) The loop gain must be greater than one. (2) The phase shift around the loop must be 360° .

Ideally, the inverting amplifier provides 180° , the R_1C_1 integration network provides a 90° phase lag, and the crystal's impedance which is a pure resistance at series resonance together with C_2 acts as a second integration network which provides another 90° phase lag. The time constants of the two RC phase shifting networks should be made as big as possible. This makes their phase shifts independent of any changes in resistance or capacitance values. However, big RC values introduce large gain losses and the selected amplifier should provide sufficient gain to satisfy gain requirement. CMOS inverters or discrete transistors can be used as amplifiers. An experimental evaluation of crystal oscillators using either type of amplifier is given within this report.

CRYSTAL OSCILLATORS USING CMOS-IC

The use of CMOS-IC's in crystal oscillators is quite popular. However, they are not perfect and could cause problems. The input characteristics of such IC's are good, but they are limited in their output drive capability.

The other disadvantage is the longer time delay in a CMOS-inverter as compared to a discrete transistor. The longer this time delay the more power will be dissipated. This time delay is also different among different manufacturers.

As a characteristic of most CMOS-IC's the frequency sensitivity to power supply voltage changes is high. As a group, IC's do not perform very well when compared with discrete transistor circuits.

But let us not be discouraged. Low component count which leads to low cost is one good feature of IC oscillators.

As a rule, IC's work best at the low end of their frequency range and poorest at the high end.

Several types of crystal oscillators using CMOS-IC's have been found to work satisfactorily in some applications.

CMOS—TWO INVERTER OSCILLATOR

The two inverter circuit shown in *Figure 2* is a popular one. The circuit is series resonant and uses two cascaded inverters for an amplifier.

FIGURE 2

TL/DD/8439-2

Each inverter has a DC biasing resistor which biases the inverter halfway between the logic "1" and "0" states. This will help the inverters to amplify when the power is applied and the crystal will start oscillation.

The 74C family works better as compared with other CMOS-IC's. Will oscillate at a higher frequency and is less sensitive to temperature changes. The CMOS-COPS data sheet states that a crystal oscillator will typically draw $100 \mu\text{A}$ more than an external clock source. However, the crystal oscillator described above will draw approximately as much

current as an external squarewave clock. The experimental data presented below shows the comparison:

Chip held in Reset, $V_{CC} = +5.0\text{V}$

$f = 455 \text{ kHz}$, COP444C, CKI is $\div 8$

Instruction cycle time = $17.5 \mu\text{s}$

I = total power supply (V_{CC}) current drain

Oscillator Type	I (current drain)
Crystal Osc. (data sheet)	$950 \mu\text{A}$
Crystal Osc. (two inverter)	$810 \mu\text{A}$
Ext. Clock	$790 \mu\text{A}$

PIERCE IC OSCILLATOR

Figure 3 shows a Pierce oscillator using CMOS inverter as an amplifier.

FIGURE 3

TL/DD/8439-3

The gain of CMOS inverter is low, so the resistor R_1 should be made small. This reduces gain losses. The output resistance of the inverter (R_o) can be the integrating resistor for the R_oC_1 phase lag network.

Omitting R_1 or with a small value of R_1 , the crystal will be driven at a much higher voltage level. This will increase power dissipation.

For lower frequencies (i.e., 32 kHz), R_1 must be large enough so that the inverter won't overdrive the crystal. Also, if R_1 is too large we won't get an adequate signal back at the inverter's input to maintain oscillation. With large values of R_1 the inverter will remain in its linear region longer and will cause more power dissipation. Typically for 32 kHz, R_1 should be constrained by the relation.

$$\frac{1}{2\pi R_1 C_1} \ll 32 \text{ kHz}$$

At higher frequencies, selection of R_1 is again critical. In order to drive a heavy load at high frequency, the amplifier output impedance must be low. In order to isolate the oscillator output from C_1 so it can drive the following logic stages, then R_1 should be large. But again, R_1 must not be too large, otherwise it will reduce the loop gain.

The value of R_1 is chosen to be roughly equal to the capacitive reactance of C_1 at the frequency of operation, or the value of load impedance Z_L .

$$\text{Where } Z_L = \frac{X_{C1}}{R_L}$$

$R_L = R_S =$ series resistance of crystal

The small values of C_1 and C_2 will help minimize the gain reduction they introduce.

typically: $C_1 = C_2 = 220$ pF at 1 MHz
 $C_1 = C_2 = 330$ pF at 2 MHz

DISCRETE TRANSISTOR OSCILLATOR

As mentioned earlier, a discrete transistor circuit performs better than an IC circuit. The reason for this is that in a discrete transistor circuit it is easier to control the crystal's source and load resistances, the gain and signal amplitude. A discrete transistor circuit has shorter time delay, because it uses one or two transistors. This time delay should always be minimized, since it causes more power dissipation and shifts frequency with temperature changes. *Figure 4* shows a basic Pierce oscillator using a transistor as an amplifier.

FIGURE 4

TL/DD/8439-4

The basic phase shift network consists of C_{A1} , C_{B2} and the crystal which looks inductive and is series resonant with C_{A1} and C_{B1} . The phase shift through the transistor is 180° and the total phase shift around the loop is 360° . The condition of a unity loop gain must also be satisfied.

$$\frac{V_A}{V_B} = - \left(\frac{C_B}{C_A} \right)$$

$$\frac{V_A}{V_B} = - \left(\frac{X_{CA}}{X_{CB}} \right)$$

For oscillation to occur, the transistor gain must satisfy the relation

$$G \left(\frac{V_A}{V_B} \right) \geq 1$$

where $G = -g_{fe}Z_L$

g_{fe} is the transconductance of the transistor

Z_L is the load seen by the collector

$$Z_L = \frac{X_B^2}{R_e}, \quad X_B = - \frac{1}{\omega C_B}$$

R_e is the crystal's effective series resistance.

The crystal's drive level

$$P_d = \frac{V_B^2 R_e}{X_B^2}$$

This drive level should not exceed the manufacturer's spec. Certain biasing conditions might cause collector saturation. Collector saturation increases oscillator's dependence on the supply voltage and should be avoided.

The circuit of *Figure 5* has been tested and has a very good performance.

FIGURE 5

TL/DD/8439-5

This circuit will oscillate over a wide range of frequencies 2–20 MHz.

$$\text{Voltage } (V_1) = \frac{(5)(1.5)}{1.5 + 4.7} = 1.21V$$

$$\text{Base Current} = \frac{1.21 - V_{BE}}{39k} = 15.6 \mu A$$

At Saturation ($V_{CE} = 0$)

$$I_C (\text{SAT}) = \frac{5}{1.2} = 4.2 \text{ mA}$$

FIGURE 6

TL/DD/8439-6

Having $15.6 \mu\text{A}$ of base current, for saturation to occur

$$h_{FE} = \frac{4.2 \text{ mA}}{15.6 \mu\text{A}} = 269$$

The DC beta for 3904 at 1 mA is 70 to 210, so no problem with saturation, even at lower supply voltages.

The current consumption (power supply V_{CC} current drain) of COP444C using the above oscillation circuit is around $267 \mu\text{A}$.

The circuit of *Figure 6* is another configuration of discrete transistor oscillator.

The performance of above circuit is also good. The only drawback is that it does not provide larger output signal.

CONCLUSION

As discussed within this report, a discrete transistor circuit gives better performance than an IC circuit. However, oscillators using discrete transistors are more expensive than those using IC's when assembly labor costs are included. So, the selection of either circuit is a trade-off between better performance and cost.

The data and circuits presented here are intended to be used only as a guide for the designer. The networks described are generally simple and inexpensive and have all been observed to be functional. They only provide greater flexibility in the oscillator selection for CMOS-COPS systems.

Selecting Input/Output Options On COPS™ Microcontrollers

National Semiconductor
Application Note 401
Abdul Aleaf

AN-401

INTRODUCTION

There are a variety of user selectable input and output options available on COPS when the ROM is masked. These options are available to help the user tailor the I/O characteristics of the Microcontroller to the application. This application note is intended to provide the user a guide to the options: What are they? When and how to use which ones? The paper is generally written without reference to a specific device except when examples are given. It must be remembered that any given generic COPS Microcontroller has a subset of all the possible options available and that a given pin might not have all possible options. A reference to the device data sheet will determine which options are available for a specific device and a specific pin of that device.

INPUT/OUTPUT OPTIONS

Table I summarizes the I/O capability of NMOS-COPS, in general. However, some of the options have different configuration in CMOS-COPS. Data sheets provide information on the I/O options associated with the CMOS-COPS.

I. OUTPUTS

The following discussion provides detailed information on the capabilities of the mask-programmable output options available on COPS.

A. STANDARD OUTPUT

This option is a simple, straightforward, logic compatible output used for simple logic interface. It is available on SO, SK and all D and G outputs. It is recommended to be used as a default option for all but SO, SK outputs.

FIGURE 1. Standard Output

Figure 1 shows the standard output configuration. The enhancement mode device to ground is good at sinking current (sinks 1–2 mA) and is compatible with the

sinking requirement of 1 TTL load (1.6 mA at 0.4V). It will meet the "low" voltage requirement of CMOS logic. All output options use this device (device #1) for current sinking. On the other hand, the relatively high impedance depletion-mode device (device #2) to V_{CC} provides low current sourcing capability (100 μA at 2.4V). This pullup is sufficient to provide the source current for a TTL high level and will go to V_{CC} to meet the "high" voltage requirements of CMOS logic. An external resistor to V_{CC} may be required to interface to other external devices requiring higher sourcing capability.

An interface example to a common emitter NPN transistor is given below:

FIGURE 2

TL/DD/8440-2

R_B is needed to limit transistor's base current if I_{source} > I_{B(max)}.

R_P helps generate base drive if the I_{source} is not sufficient. The disadvantage of R_P is the introduction of more power dissipation. The temperature effects on the reverse saturation current I_{CB0} causes I_C to shift. I_{CB0} approximately doubles for every 10°C temperature rise. The effect of changes in I_{CB0} reduces off state margin and increases power dissipation in the off state.

However, in a typical device, the current supplied by R_P will swamp out any effects on I_{CB0}. Another parameter found to be decreasing linearly with temperature is V_{BE}:

$$\Delta V_{BE} = V_{BE2} - V_{BE1} = -k(T_2 - T_1)$$

where k ≈ 2 mV/°C, T in °C.

Now let's consider a practical example:

LOW SOURCE CURRENT OUTPUT:

Standard output, COP420, device #2.

The selected transistor is 2N3904.

DESIGN CONSIDERATIONS:

- Q is in saturation during ON-state.
- Q's collector current I_C = 100 mA

TABLE I

	Default	Standard	Push-Pull	High Sink	Very High Sink	LED	Hi-Current LED	TRI-STATE® Push-Pull	Hi Current TRI-STATE Push-Pull	Open Drain

c. Assuming a "forced" β of 10 for Q. This is a standard value for β to insure saturation.

For an $I_C = 100$ mA, $\beta = 10$, we have $I_B \geq 10$ mA. The low current standard output certainly cannot provide $I_B \geq 10$ mA. Therefore, a pullup resistor (R_P) is required.

d. Now we need to select the minimum allowed value for R_P . The sinking ability of COPS output will determine R_P . We must sink the pullup current to a $V_{OUT} < V_{BE}$ in order to hold Q off. Also, note that

$$\frac{\Delta V_{BE}}{\Delta T} = -2 \text{ mV}/^\circ\text{C}.$$

e. Assuming the worst case is at V_{CC} (max) and High-temperature (let $\Delta T = 20^\circ\text{C} \Rightarrow \Delta V_{BE} = -40$ mV). From $V_{BE(ON)}$ Vs. I_C curve, Figure 3:

TL/DD/8440-3

FIGURE 3. 2N3904 I/V

at 100 mA, 25°C , $V_{BE} \approx 0.85$ V.

So, our $V_{BE(45^\circ\text{C})} = 0.85 - 0.04 \approx 0.81$ V.

There is not margin here for process V_{BE} variations so we can allow 200 mV of slope,

$$V_{BE} = 0.61 \text{ V (worst case)}$$

f. Having $V_{BE} = 0.61$ V, we go to COPS sink graph and draw a vertical line at $V_{OUT} = V_{BE} = 0.61$ V. Figure 4 below:

TL/DD/8440-4

FIGURE 4

This will tell us, at $V_{OUT} = V_{BE}$, how much current can be sunk to keep Q "OFF". The intersection of $V_{CC} = 6.3$ (MIN) and $V_{BE} = 0.61$ V gives us $I_{sink} = 4$ mA.

g. Now calculate R_P .

$$R_P \geq \frac{6.3 - 0.61}{4} \text{ k} \geq 1.42 \text{ k}$$

$$\text{the actual standard } R_P (\pm 10\%) = \frac{1.42}{0.9} = 1.6 \text{ k} \pm 10\%$$

h. Using the value of R_P , let's calculate the current through R_P at $V_{CC} = 4.5$ V (MIN).

$$I_{R_P} = \frac{4.5 - 0.61}{1.42} \text{ mA} = 2.74 \text{ mA}$$

Which is less than sink ability of device (3 mA from Figure 4) at $V_{CC} = 4.5$ V, $V_{OUT} = 0.61$ V.

i. Now calculate the available source current. Here we use $V_{BE(max)}$ which is the worst case, and low temperature.

Let T (ambient) = 10°C .

From V_{BE} vs. I_C curve, Figure 3:

$$V_{BE} \approx 0.83 \text{ V at } 25^\circ\text{C}$$

$$V_{BE} \approx 0.83 + 2 \text{ mV}/^\circ\text{C} \times 15 = 0.86 \text{ V at } 10^\circ\text{C}.$$

Using this value of V_{BE} , we go to COP420 Standard Output source current curve (Figure 5), and draw a vertical line at $V_{BE} = 0.86$ V. The intersection of this line and $V_{CC} = 4.5$ (MIN) gives an $I_{source} = 325 \mu\text{A}$.

TL/DD/8440-5

FIGURE 5

This is low but typical of N-channel low current standard output.

Contribution of R_P

$$I_{R_P} = \frac{4.5 - 0.86}{(1.6)(1.1)} = 2.07 \text{ mA}$$

$$I_B(\text{min}) \approx 2.07 + 0.325 = 2.3 \text{ mA}$$

This is our worst case base drive, but we needed 10 mA.

What can we do to get the base drive we need?

1. We can use above design and allow Q to come out of saturation. The disadvantage is that Q's power dissipation increases.
2. Or use a Darlington configuration (Process 05). In such a configuration only first stage of Darlington can be saturated (not output stage). This will introduce a slightly higher power dissipation. Note that for a process 05 transistor, the forced β is 1000.
3. Use a high source type output such as TRI-STATE output. If we draw a vertical line at $V_{BE} = 0.86$, we get a source current of ≈ 6 mA at $V_{CC} = 4.5(\text{MIN})$ Figure 6, which gives us a worst case

FIGURE 6

CAUTION On TRI-STATE graph the intersection of $V_{\text{out}} = V_{BE} = 0.86\text{V}$ and $V_{CC} = 6.3\text{V}(\text{MAX})$ curve (Figure 6) would result in an $I_{B(\text{MAX})} = 50\text{--}60 \text{ mA}$, which is way too much to handle. In this case there is a need for a series current limiting R_B to kill some of the worst case $I_{B(\text{max})}$.

4. There is a high current Standard-L option on some COPS (i.e., COP4XL, L-port) which provides sufficient source current.
5. N-channel output can generally sink better than source. PNP transistor can be used instead of NPN. The same analysis applies and in general will show better overdrive capabilities.

As shown in Figure 7, the D_0 output option, is driving the base of the PNP transistor. Assuming $V_{CC} = 4.5\text{V}$ (for COP402), $V_{BE} = 1.0\text{V}$, and a worst case base drive requirement of 3.0 mA . We see that we must supply $200 \mu\text{A}$ to the base-emitter resistor to turn the transistor on:

$$1.0\text{V}/5.1\text{k} = 200 \mu\text{A}$$

FIGURE 7. PNP Drive

From the output sink current curve on the COP402 data sheet, we find that, at 1.0V the D-line can sink 3.2 mA . To calculate the value of the current limiting resistor,

$$R = (V_{CC} - V_{BE} - V_{D0})/I$$

When $V_{CC} = 6.3\text{V}$, the D_0 output can sink more than enough current at 0.3V , and if the $V_{BE} = 0.7\text{V}$, we can calculate the maximum D_0 output current:

$$I = (V_{CC} - V_{BE} - V_D)/R \\ = (6.3 - 0.7 - 0.3)/780 = 6.3 \text{ mA.}$$

Using the Standard Output Option for Bidirectional I/O (G-port)

The standard output is good at sinking current, but rather weak at sourcing it. Therefore, by using the Standard Drive configuration and outputting 1's to the port, an external source may easily overdrive the port drivers with the added bonus of a built-in pullup. While the depletion-mode device provides sufficient current for a TTL high level, yet can be pulled low by an external source, thus allowing the same pin to be used as an input and output. Data written to the ports is statically latched and remains unchanged until rewritten. As inputs the lines are non-latching (Figure 8).

FIGURE 8. G Port Characteristics

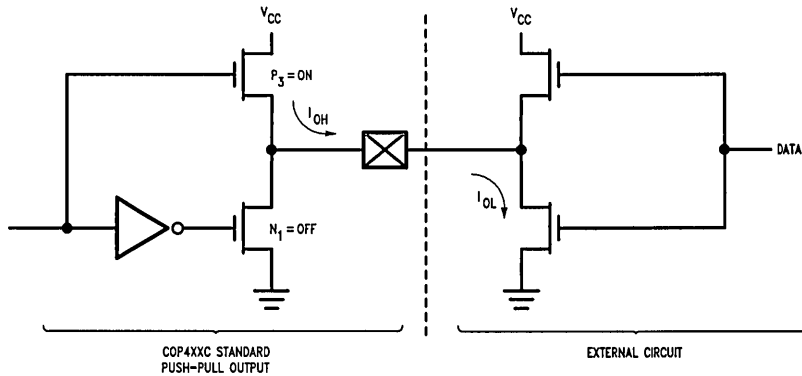

FIGURE 9

TL/DD/8440-9

When writing a "0" to the port, the enhancement-mode device to ground overcomes the high pullup and provides TTL current sinking capability. While writing a "1" the depletion-mode device behaves as internal pullup maintaining the "1" level indefinitely. In this situation, an input device capable of overriding the small amount of current supplied by the pull-up device can be read. This feature provides maximum user flexibility in selecting input/output lines with minimum external components.

In CMOS-COPS the low current push-pull output has even much weaker source current capability and this make it easier to be overridden.

Referring to *Figure 9*.

Note that $I_{OL} > I_{OH}$, otherwise transistors or buffers must be used.

For COP424C/444C, standard push-pull

$$\begin{aligned} @ V_{CC} = 4.5V, V_{out} = 0V, I_{OH(min)} &= 30 \mu A \\ I_{OH(max)} &= 330 \mu A \end{aligned}$$

$$\begin{aligned} @ V_{CC} = 2.4V, V_{out} = 0V, I_{OH(min)} &= 6 \mu A \\ I_{OH(max)} &= 80 \mu A \end{aligned}$$

While in NMOS (COP420L), Standard output:

$$\begin{aligned} @ V_{CC} = 4.5V, V_{OH} = 2.0V, I_{OH(min)} &= 30 \mu A \\ I_{OH(max)} &= 250 \mu A \end{aligned}$$

$$\begin{aligned} @ V_{CC} = 6.3V, V_{OH} = 2.0V, I_{OH(min)} &= 75 \mu A \\ I_{OH(max)} &= 480 \mu A \end{aligned}$$

As we see, both in CMOS and NMOS it is easier to override I_{OH} . Note that the standard output option is available with standard, high, or very high sink current capability ("L" parts only). The pull-down device is bigger for the high/very high current standard output. The sourcing current is the same. These three choices provide some control over current capability.

B. OPEN-DRAIN OUTPUT

This option uses the same enhancement-mode device to ground as the standard output with the same current sinking capability. It does not contain a load device to V_{CC} , allowing external pullup as required by the user's application. The sinking ability of device # 1 determines the minimum allowed external pullup. The analysis discussed earlier for Standard Output options equally applies here. Available on SO, SK, and all D, G, and L outputs.

TL/DD/8440-10

FIGURE 10. Open-Drain Output

The open-drain option makes the ports G and L very easy to drive when they are used as inputs. This option is commonly used for high noise margin inputs, unusual logic level inputs as from a diode isolated keyboard, analog channel expansion, and direct capacitive touch-panel interface. Available with standard, high or very high sink capability ("L" parts only).

C. PUSH-PULL OUTPUT

The push-pull output differs from the standard output configuration in having an enhancement-mode device in parallel with the depletion-load device to V_{CC} , providing greater current sourcing capability (better drive) and faster rise and fall times when driving capacitive loads.

TL/DD/8440-11

FIGURE 11. Push-Pull Output

If a push-pull output is interfaced to an external transistor, a current-limiting resistor must be placed in series with the base of the transistor to avoid excessive source current flow out of the push-pull output. This option is generally for MICROWIRE Serial Data exchange.

It is available on SO, SK only and is recommended to be used as a default option for these outputs. A few points must be kept in mind when using SO, SK for MICROWIRE interface.

The data sheet specifies the propagation delay for a certain test condition (i.e., $V_{CC} = 5V$, $V_{OH} = 0.4V$, Loading = 50 pF, etc.).

In practice, actual delay varies according to actual input capacitive loading (typical 7–10 pF per IC input), total wire capacitance and PCB stray capacitance connected to the SI input. Thus, if actual total capacitive loading is too large to satisfy the delay time relationships ($t_d = t_{SK} - t_r$; t_d = actual delay time, t_{SK} = the instruction cycle time, t_r = the finite SK rise time), either slow down SK cycle time or add a pullup resistor to speed up SK "0" to "1" transition or use an external buffer to drive the large load. Besides the timing requirement, system supply and fan-out/fan-in requirements have to be considered, too.

If devices of different types are connected to the same serial interface, the output driver of the controller must satisfy all the input requirements of each device. Briefly, for devices that have incompatible input levels or source/sink requirements to exchange data, external pullups or buffers are necessary to provide level shifting or driving. Unreliable operation might occur during data transfer, otherwise. For a 100 pF load, a standard COPS Microcontroller may use a 4.7k external resistor, with the output "low" level increased by less than 0.2V. For the same load the low power COPS may use a 22k resistor; with the SO, SK output "low" level increased by less than 0.1V.

D. STANDARD L OUTPUT

Same as Standard Output, but may be disabled. Available on L-outputs only.

TL/DD/8440-12

FIGURE 12. Standard L Output

When this option is implemented on the L-port and the L-drivers are disabled to use the L lines as inputs, the disabled depletion-mode device cannot be relied on to source sufficient current to pull an input to a logic high. There are two ways to use L lines as inputs (having standard L option):

The first method requires that the drivers be disabled. In this case the lines are floating in an undefined state. The external circuitry must provide good logic levels both high and low to the input pins. The inputs are then read by the INL instruction. The second method is similar to the technique used for the G-port. The drivers are enabled and a "1" must be written to the Q register.

The external circuitry will then be required only to pull the lines low to a logic "0". The line will pull up to a "1" itself. The INL instruction is used as before to read the lines.

E. LED DIRECT DRIVE OUTPUT

In this configuration, the depletion-load device to V_{CC} is paralleled by an enhancement-mode device to V_{CC} to allow for the greater current sourcing capacity required by the segments of an LED display. Source current is clamped to prevent excessive source current flow.

TL/DD/8440-13

FIGURE 13. LED (L output) NMOS-COPS

This configuration can be disabled under program control by resetting bit 2 (EN^2) of the enable register to provide simplified display segment blanking.

However, while both enhancement-mode devices are turned off in the disabled mode, the depletion-load device to V_{CC} will still source up to 0.125 mA. As in the case of Standard L output, again this current is not sufficient to pull an input to a logic "1".

The drivers must be disabled and the lines must be pulled high and low externally, whenever they are used as inputs.

Example #1:

When COPS outputs are used to drive loads directly, the power consumed in the outputs must be considered in the maximum power dissipation of the package.

Figure 14 shows an LED segment obtaining its source current from L_0 output and D_0 sinking the current. In this configuration all the power required to drive the LED with the exception of the portion consumed by the LED itself, is consumed within the chip. Assuming COP404L is the driving device:

TL/DD/8440-14

FIGURE 14. LED Drive

If we assume the V_{source} is not inserted, the device has a V_{CC} of 9.5V, and that the voltage drop across the LED is 2.0V.

We can calculate the power dissipation in these outputs. The minimum current that D_0 can sink at 1.0V is 35 mA (COP404L data sheet). L_0 can source up to 35 mA at 3.0V. Therefore, the power dissipation for the L_0 output could be: $(9.5 - 3.0)(0.035) = 227$ mW. The power in the D_0 output is $(1)(0.035) = 35$ mW.

Now let us calculate the current limiting resistor. Referring to COP404L L_0-L_7 output source current curves, at $V_{CC} = 9.5V$ the minimum current curve peaks at $I = 6.0$ mA and $V_{source} = 4.8V$. The current curve is actually very flat between 4.0 and 5.0 volts. For maximum current, we need to set the voltage on the L pin equal to 4.8V at 6.0 mA. The D line will sink this current at 0.4V. Therefore, the resistor and LED must make up the difference:

$$V_I = V_D + IR + V_{LED}$$

$$4.8 = 0.4 + 0.006R + 2.0$$

$$R = 400\Omega$$

At the other end of the curve, when the L line sources the maximum current, assume the LED and the D line will have the same voltage drop.

$$V_I = 0.4 + IR + 2.0$$

$$V_I = 2.4 + IR$$

From the current curve, we see that at 6.4V the L line will source 10 mA. Therefore: $V_I = 2.4 + (0.01)(400) = 6.4V$.

Example #2:

Let's consider a different configuration.

FIGURE 15. LED DRIVE

Now we calculate the series current limiting resistor R . The circuit has two non-linear devices to be considered; the output device and the LED.

The LED in this example is NSC5050. Looking at I/V curve, the device has a threshold 1.6V. Also, note that for $V_{LED} > 1.6V$ the I/V curve is very linear (Figure 17). Because of this, the LED characteristic can be modeled as a sharp threshold device with a non-zero source resistance (normally I/V curve is LOG looking).

From ON part of curve,

$$R_S = \frac{1.9 - 1.7}{0.05} = 4\Omega$$

We can neglect R_S as well (only $R_S \ll R$). Our model is simply a voltage source for the LED when

$$I = 0 \text{ for } V_{LED} < V_{TH}$$

$$I = \infty \text{ for } V_{LED} > V_{TH}$$

Design Procedure:

$$1. I_{LED(min)} = \frac{V_S(min) - (V_{LED(max)} + V_{OUT(max)})}{R(max)}$$

We need endpoints of the load line.

$$a. @V_{out} = 0 \Rightarrow I_{LED(min)} = \frac{V_S(min) - V_{LED(max)}}{R(max)}$$

$$b. @V_{out} + V_{LED(max)} = V_S \Rightarrow I = 0$$

$$(V_{LED(max)} = 2V)$$

2. Plot a and b

Assuming an $I_{min} = 7$ mA, $V_S(min) = 4.5V$ from 1 $R(max) = 357\Omega$

Draw the load line with slope $-1/357$ crossing

$$V_{out} = V_S - V_{LED(max)} = 4.5 - 2 = 2.5V.$$

(Figure 16).

FIGURE 16. COP420

FIGURE 17. LED I/V Characteristic

The intersection of this load line and $V_{CC} = 4.5V$ (min) curve, we find an actual value of $I_{(min)} = 4.25$ mA. To determine I_{max} (at $R = 357\Omega$) we draw a parallel load line intersecting $V_{out} = 6.3 - 2.0 = 4.3V$ and find that @ $V_{CC} = 6.3V$, $I_{(max)} = 13$ mA.

3. From above calculations we observe that our $I_{(min)}$ (actual) is way off. Let's try to rotate our first load line around $V_{out} = 2.5V$ to increase I_{min} and then check I_{max} and R . (Figure 18).

Let's go for an I_{min} (actual) = 6 mA. This will give us $R = 89\Omega$ and the max. plot goes off the graph to = 36 mA.

FIGURE 18. COP420

Comments:

1. The design must be a compromise between the two extremes (battery life should also be considered).
2. The lower the LED threshold the better. (The load line moves further up the device curve.)

F. TRI-STATE PUSH-PULL OUTPUT

This option is specifically available to meet the specifications of National's MICROBUS, outputting data over the data bus to a host CPU. It has two enhancement-mode devices to ground and V_{CC} .

FIGURE 19. TRI-STATE Push Pull (L output)

The TRI-STATE logic can disable both enhancement-mode devices to free the MICROBUS data lines for input operation.

CAUTION Never try to pull against the TRI-STATE Output (too much source current) with the drivers enabled and Q register previously loaded with "1". The choices we have are mentioned earlier. Either TRI-STATE L-port or use Standard L output option.

II. INPUTS

COPS inputs may be programmed either with a depletion load device to V_{CC} or floating (Hi-Z input). All inputs are TTL/CMOS compatible. Hi-Z inputs should not be left floating; they should be connected to the output of a "high" and "low" driving device if active or to V_{CC} and ground if unused. Especially when using CMOS COPS (very high impedance inputs), the open inputs can float to any voltage. This will cause incorrect logic function and more power dissipation. Also, the CMOS inputs are more susceptible to static charge which causes gate oxide rupture and destroys the device. Unlike inputs, the outputs should be left open to allow the output switch without drawing any DC current. Another precaution is powering up the device. Never apply power to inputs or TRI-STATE outputs before both V_{CC} and ground are connected. This will forward bias input protection diodes, causing excessive diode currents. It will also power the device.

Special care must be practiced when interfacing a CMOS-COPS input to an analog IC, powered by different supply voltages. Avoid overvoltage conditions resulting

FIGURE 20

TL/DD/8440-20

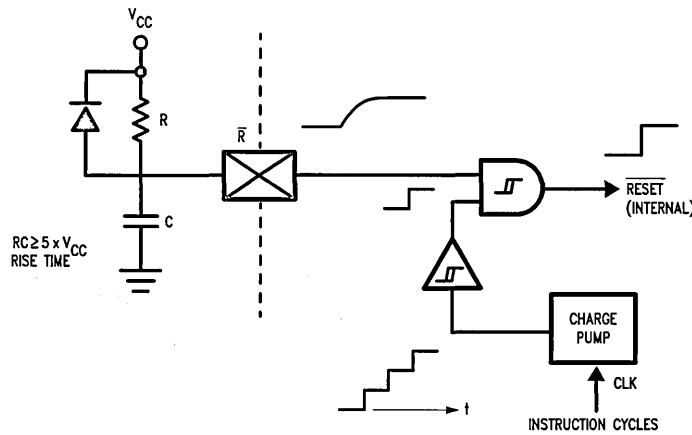

FIGURE 21

TL/DD/8440-21

from such situations. As an example, consider the interface of a CMOS-COPS with the LF111 voltage comparator:

When the low level “-5V” appears on the comparator’s output, the COPS input is pulled low below “logic low” of “0V”. This will cause damage if the comparator sinks enough current. The use of a current-limiting resistor in series with the input is helpful. A better solution is to use a voltage divider as shown in *Figure 20*. Any time a low level appears on the comparator’s output, a total voltage drop of 10V will appear across both resistors each dropping 5V, causing the input to sit at 0V. Whenever the output goes high, the resistors will not drop any voltage (no current through the resistors) and a logic high of 5V will appear on the input. To reduce power dissipation introduced by resistors, the resistor value must be high (> 100k), because the CMOS inputs have very high input impedance.

RESET INPUT

All COPS Microcontroller have internal reset circuitry. Internally there is an AND gate with one input coming from the RESET input, and the second input connected to a charge pump circuit. In the Charge pump circuit, a tiny capacitor is being charged upon execution of each internal instruction cycle. When the voltage across this inter-

nal capacitor reaches a high logic level, the second input of the AND gate is released.

The Reset logic will initialize (clear) the device upon power-up if the power supply rise time is less than 1 ms and greater than 1 μ s. With a slowly rising power supply, the part may start running before V_{CC} is within the guaranteed range. In this case, the user must provide an external RC network and diode shown in *Figure 21* above. The external RC network is there to hold the RESET pin below V_{IL} until V_{CC} reaches at least $V_{CC(min)}$. The desired response is shown in *Figure 22*.

FIGURE 22

TL/DD/8440-22

t = 500-600 instruction cycles (8 msec)
for COPxxxL
t = 900-1000 instruction cycles (4 msec)
for COPxxxC

The diode is included in the reset circuitry to cause a "forced Reset" when the power supply goes away and recovers quickly. In such a situation the diode helps discharge the capacitor quickly. Otherwise, if the power failure occurs for a short time, the capacitor will not be fully discharged and the chip will continue operation with incorrect data.

Note that on the CMOS COPS, the internal charge pump circuitry can be disabled when using a very slow clock (<32 kHz) [option 23 = 1]. This is necessary, because one can run from DC to 4 μs instruction cycle time (fully static). In such a situation external RC network discussed earlier must be used.

INPUT PROTECTION DEVICES

All inputs and I/O pins have input protection circuitry. This circuitry is there regardless of any option selected. It is the first circuitry encountered at the pin.

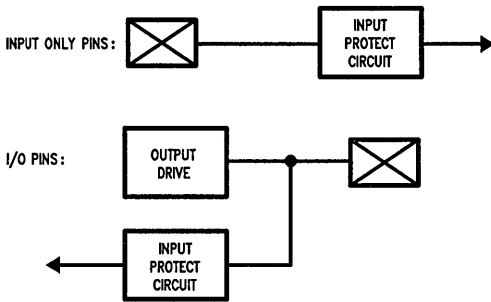

FIGURE 23

TL/DD/8440-23

For NMOS and XMOS devices, the circuits are of the form:

TL/DD/8440-24

FIGURE 24

This is a standard circuit defined for the process. R₁ is on the order of 200Ω. R₂ is around 300Ω (note that the R values are not precise).

This circuit is functionally equivalent to:

TL/DD/8440-25

FIGURE 25

The zener breakdown is around 10-15V; the gate breakdown is 50V.

CONCLUSION

All COPS Microcontrollers have a number of I/O options necessary to implement dedicated control functions in a wide variety of applications. The flexibility to select different options allows the user to tailor within limits, the I/O characteristics of the Microcontroller to the system. Thus, the user can optimize COPS for the system, thereby achieving maximum capability and minimum cost. This application note deals with the basic functionality of COPS I/O characteristics and does not address electrical differences among the various COPS devices.

New CMOS Vacuum Fluorescent Drivers Enable Three Chip System to Provide Intelligent Control of Dot Matrix VF Display

National Semiconductor
Application Note 440
Tom Markman

INTRODUCTION

Vacuum Fluorescent (VF) displays are becoming more and more common in a variety of applications. Manufacturers of everything from Automobiles to Video Recorders have taken advantage of these easy to read displays. VF displays are available in a wide variety of configurations; clock displays, calculator displays, multi-segment, and dot matrix displays are readily available at a low cost. This application note develops and covers in some detail a small CMOS system consisting of a single chip microcontroller and two display drivers which control a 20 character, 5 x 7 dot matrix VF display.

Figure 1 shows the schematic of the system. The microcontroller, a COPSM 424C, receives a character in ASCII form from the host system, stores the ASCII value of the character in its onboard RAM, converts the ASCII value to a 5 byte data word suitable for the display drivers and displays it on the VF display. The COPS also refreshes the display continuously while performing character update, much like a dumb terminal. Not including the address decoding logic, this application requires only the on-board RAM and ROM of the COPS424C, and National's MM58341 and MM58348 VF display drivers. If a steady message or a scrolling sentence is desired, only small changes in the COPS software are re-

quired. In this case the messages could be stored in the ROM of the COPS and the need for a host system would be eliminated.

VF DISPLAY AND VF DISPLAY DRIVER REQUIREMENTS

The display used in this application was an Itron #DC205G2. This 20 segment, 5 x 7 dot matrix, multiplexed display required a filament voltage of 5.7 Vac and a filament current of 37 mAac. The anode and grid voltages were supplied by the display drivers. The voltage and current requirements vary considerably for different displays depending on the size and number of characters, and the configuration (dot matrix, 7 segment, 14 segment, etc.). To determine the voltage requirements for a particular display, a simple calculation can be made. If maximum possible brightness of the display is desired, the following equation must be true:

$$E_t \geq E_b + E_k + (I_b)(R_{on}) \text{ where:}$$

E_t is the total Voltage of the display driver or $|V_{dis}| + V_{dd}$

E_k is the display Cathode Bias Voltage

$E_b = E_c$ is the typical Anode or Grid Voltage (V_{p-p})

I_b is the typical anode current (mA-p-p)

R_{on} is the display driver output impedance (Ω)

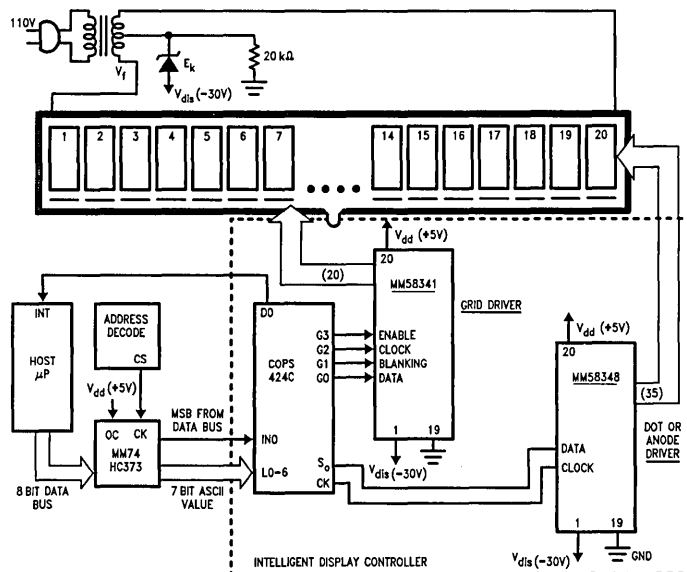

FIGURE 1. System Diagram Showing the Basic 3-Chip Display Controller and the Interface to a Microprocessor System

TL/F/8683-1

If the maximum brightness is not desired, the following equation can be used: $(E_t)(1.2) \geq E_b + E_k + (I_b)(R_{on})$. In this application, the calculated E_t was 42.25V, however, the display was legible under normal lighting conditions, with an E_t as low as 25V. If your display requires more than the 35V output of the MM58341 and MM58348, pin for pin compatible 60V VF Display Drivers (MM58241, MM58248) are available.

Figure 2 shows the relationship between the required VF display voltages. The cut-off voltage (E_k) is set by the Zener diode on the center tap of the filament transformer. This value is given in the VF display data sheet.

Avoiding Flicker and Pulsing

There are two different conditions which may cause the display to appear to flicker. The first is the refresh rate. This is particularly a problem on displays where the micro-controller must up-date more than 25 characters. Since the human

eye begins to notice flicker at about 40 Hz, a display with a refresh rate less than that will appear to be flashing on and off.

The second type of flicker occurs when the refresh rate is between 40 Hz and 90 Hz. In this case, the display will appear to be rolling rather than flashing. This condition occurs when the refresh rate and the filament frequency are close together. If a character is only on during the time when the filament voltage is negative, it will appear to be slightly brighter than the character next to it which may only be on during the positive cycle of the filament voltage. If this is the case, as it was in this application, the simplest solution is to increase the frequency of the filament. A DC oscillator circuit, such as the one shown in Figure 3, can be used to replace the AC voltage source. The filament frequency can be easily adjusted to eliminate this condition.

FIGURE 2. Voltage Levels for VF Display

FIGURE 3. Filament Oscillator Circuit

TL/F/8683-3

VF Display Drivers

Two high voltage display drivers were needed to control the VF display. A MM58341, was used to control the grids and a MM58348 was used to control the individual pixels or anodes. Both of these drivers receive serial information and output 32 and 35 segments of data respectively.

The MM58341 has three control pins which make it ideal for controlling the grids of a VF display. The blanking control pin will turn off all segments of the display when a logic '1' is applied to this pin. This is particularly important for reducing ghosting, and controlling brightness. Ghosting is a condition where the last characters shadow appears behind the character being displayed. The enable pin acts as an envelope for the input signal. Only while it is at a logic '1' level will the circuit accept clock inputs. When the pin goes low, all the data is latched and displayed. A data out pin is also provided for cascading. If the display has more than 32 grids, a second grid driver can be cascaded by connecting the data out pin to the input data for the second grid driver.

The MM58348 is a 35 bit shift register and latch which is used to control each pixel or dot. When a leading 1, fol-

lowed by 35 bits of data, is received, the data is latched and displayed. The chip is automatically reset upon power up.

MULTIPLEXED DISPLAY REFRESH TIMING

Considering first the digit driver (MM58341), it becomes clear that the digits must be enabled or refreshed sequentially and that this process must be continuous regardless if the display data has changed. The data for the MM58341 is simply a 1 followed by 19 zeroes where the 1 is shifted through the internal registers of the MM58341. As each digit is enabled, the corresponding segment data is displayed. To insure that no ghosting effects are seen during the transition between digits, the blanking control is activated just before the data is latched into the dot or anode driver and deactivated just after the data has been latched. During this time when the blanking control is activated, the grid driver is clocked shifting the 1 to the next location. *Figure 4* shows the micro-controller waveforms and the resultant display waveforms for the 20 character display.

FIGURE 4. Timing Diagram

TL/F/8683-4

In between digit strobes, the segment data is updated. The first 34 bits of segment data are set up in the dot driver and the blanking signal is activated to disable all 20 digits. The 35th bit of data is clocked in, updating the segments. Since the MM58348 resets its internal shift register each time the data is latched, it can accept all but the final data bit while still displaying the previous digit. The digit driver is then clocked, shifting the digit strobe to the next position. The enable is then brought low, enabling the next digit. Finally blanking control is deactivated and the data displayed.

During the time which the blanking control is high, the order in which the segments or the digits are updated is not critical. Since this occurs while the display is blank. The digit driver may be clocked first, or the segments could be changed first. In general, the philosophy for driving this VF multiplexed display is outlined in *Figure 5*.

HOST INTERFACE AND PROGRAMMING

With a minimal amount of address decoding and an eight bit latch, COPS can be interfaced with a common microprocessor bus. When a character has been input into the host to be displayed, the ASCII value of that character is latched into the eight bit latch (MM74HC373) and is read on the L port (L0-6) of the COPS. The MSB of the ASCII value must be a logic 1. This MSB is the signal to the COPS that a new character is being presented. Once the character has been stored, an interrupt is sent from the COPS to the host through the D-0 port. The COPS checks for a new character being input every 200 μ s. If a character is being sent, 1 ms is required to store that character in the RAM of the COPS. With the COPS controlling the display, the host microprocessor is not being tied down with character look-up and display refresh. A simple flowchart of the host requirements is shown in *Figure 6*.

COPS SOFTWARE

There are four main sections of the COPS software. The first section, the initialization of the RAM, sets up the RAM as shown in *Figure 7*. A '0' is stored in all of the LSB positions and a '2' is stored in all of the MSB positions. Since the COPS is in a constant display loop, this is necessary to insure a blank display. 20H is the ASCII value of a space. With the RAM set up in this way, a maximum of 28 characters can be stored in RAM. Since the display in this application is only 20 characters long, RAM locations M1,4 to M1,11 and M3,4 to M3,11 are not used. RAM locations 1,12 to 1,15 and 3,12 to 3,15 are used as temporary storage throughout the program and cannot be used for character storage.

The second part of the program, stores the new characters sent by the host CPU in RAM. Once a character has been sent, this section of the program checks the ASCII value of that character to see if it is a control character or a display character. If it is a display character, the character is stored in RAM and an interrupt is sent to the host. There are three control characters which the COPS program will recognize. Cursor forward (ASCII value 08H) moves the cursor forward without destroying the data, cursor backwards (ASCII value 0CH) moves the cursor backwards without destroying the data, and return (ASCII value 0DH) will clear the display and put the cursor at the beginning of the display. To recognize and store a character, 1 ms is required.

The third part of the program, the display loop, is the heart of the program. Unless a new character has been detected, the program is always in this loop. This section does the

FIGURE 8

character font look-up, shifts the character data out the COPS serial port to the MM58348, and controls the MM58341 through the four bit parallel port (G0-4). Because the most significant nibble of the program counter is used as part of some COPS instructions, it is important that parts of the program are located at specific locations in ROM.

The final part of the program is the data. Each character is represented by a 5 byte data word. Each byte of the data word is stored at a different location in ROM. Fonts for characters with the ASCII values from 20H-5AH have already been stored in ROM. These characters can be changed or more characters can be added. The only limitation to the number of characters is the amount of available ROM.

CREATING THE 5 BYTE DATA WORD

Any number or combination of pixels or dots can be turned on at a time. To create a new character, it is easiest to first create a binary string which represents the character. A '1' in the binary string will turn on the pixel, a '0' will turn it off. To create this string, start in the upper left corner of the matrix and go down the columns.

The letter 'A' (Figure 9) would have a binary string shown in Figure 8. The data must be padded to make it an even 5 bytes in length. The pad at the beginning of the data (0001) is used as the leading 1 for the MM58348. The one bit pad at the end of the binary string must be a 0. If a 1 were sent as the pad, it would be used as the start bit for the next character.

The 5 byte data word that would be stored in ROM and represent the letter 'A' would then be 13EA24283E.

STORING THE DATA IN ROM

The 5 bytes of data are stored in 5 different locations in ROM. The first byte of data will be stored, LSB first, at location 200H plus the ASCII value of the character. For example, the ASCII value of the letter 'A' is 41H. The first byte of data for the letter 'A' would be stored, least significant bit first, at 241H. The second byte of data is stored at the location of the first data byte plus 60H or in this case at 2A1H. The location of the third byte is 40H plus the location of the

second byte. In this case, the third byte of data would be stored at 2E1H. The fourth byte of data is stored at 300H plus the ASCII value of the character or at 341H for the letter 'A'. The final byte of data is stored 40H from the fourth byte or at 381H. Remember the LSB of each byte is stored first. Table 1 shows the locations in ROM and the values stored in them for the letter 'A'.

This application shows a VF display controller designed with a minimum number of IC's. If additional information about VF displays or VF display drivers is required, refer to Application Note AN-371 (The MM58348/342/341/248/242/241 direct drive Vacuum Fluorescent (VF) Displays.

MICROWIRE™ Serial Interface

National Semiconductor
Application Note 452
Abdul Aleaf

AN-452

INTRODUCTION

MICROWIRE is a simple three-wire serial communications interface. Built into COPS™, this standardized protocol handles serial communications between controller and peripheral devices. In this application note are some clarifications of MICROWIRE logical operation and of hardware and software considerations.

LOGICAL OPERATION

The MICROWIRE interface is essentially the serial I/O port on COPS microcontrollers, the SIO register in the shift register mode. SI is the shift register input, the serial input line to the microcontroller. SO is the shift register output, the serial output line to the peripherals. SK is the serial clock; data is clocked into or out of peripheral devices with this clock.

It is important to examine the logical diagram of the SIO and SK circuitry to fully understand the operation of this I/O port (Figure 1).

The output at SK is a function of SYNC, EN0, CARRY, and the XAS instruction. If CARRY had been set and propagated to the SKL latch by the execution of an XAS instruction, SYNC is enabled to SK and can only be overridden by EN0 (Figure 2). Trouble could arise if the user changes the state of EN0 without paying close attention to the state of the latch in the SK circuit.

If the latch is set to a logical high and the SIO register enabled as a binary counter, SK is driven high. From this state, if the SIO register is enabled as a serial shift register, SK will output the SYNC pulse immediately, without any intervening XAS instruction.

The SK clock (SYNC pulse) can be terminated by issuing an XAS instruction with CARRY = 0 (Figure 3).

FIGURE 1. Logical Diagram of SK Circuit

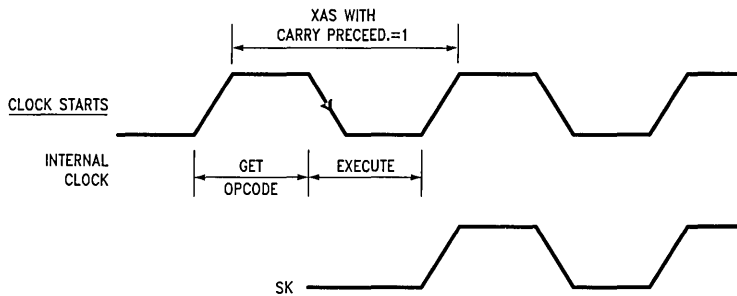

FIGURE 2. SK Clock Starts

TL/DD/8796-2

FIGURE 3. SK Clock Stops

TL/DD/8796-3

The SIO register can be compared to four master-slave flip-flops shown in Figure 4. The masters are clocked by the rising edges of the internal clock. The slaves are clocked by the falling edges of the internal clock. Upon execution of an XAS, the outputs of the masters are exchanged with the contents of the accumulator (read and overdrive) in such a way that the new data are present at the inputs of the four slaves when the falling edge of the internal clock occurs. The content of the accumulator is, therefore, latched respectively in the four slave flip-flops and bit 3 appears directly on SO.

This means that:

- a) SO will be shifted out upon the falling edges of SK and will be stable during rising edges of SK.

- b) SI will be shifted in upon the rising edge of SK, and will be stable when executing, i.e., an XAS instruction.

The shifting function is automatically performed on each of the four instruction cycles that follow an XAS instruction (Figure 5).

When the SIO register is in the shift register mode (EN0 = 0), it left shifts its contents once each instruction cycle. The data present on the SI input is shifted into the least significant bit (bit 0) of the serial shift register. SO will output the most significant bit of the SIO register (bit 3) if EN3 = 1. Otherwise, SO is held low. The SK is a logic controlled clock which issues a pulse each instruction cycle. To ensure that the serial data stream is continuous, an XAS instruction must be executed every fourth time. Serial I/O timing is related to instruction cycle timing in the following way:

FIGURE 4

TL/DD/8798-4

FIGURE 5. XAS Sequence

TL/DD/8796-5

FIGURE 6. Serial I/O Timing

TL/DD/8796-6

FIGURE 7. MICROWIRE Serial Data Exchange Timing

TL/DD/8796-7

To write to device: $t_{ns} > t_{setup}$

To read from device: $t_d \ll t_{SK} - t_r$; $t_{RS} > t_{SK}/4$

Where: t_{ws} is MICROWIRE write data-in (DI) setup time,

t_{setup} is device data sheet min data setup time to latch in valid data,

t_{SK} is system clock (SK) cycle time (Recommended 50% duty cycle),

t_r is rise time (10% to 70% bout) of system clock (SK),

t_d is device actual delay time before data-out (DO) valid and

t_{RS} is minimum data setup time for controller to shift-in valid data

The first clock rising edge of the instruction cycle triggers the low-to-high transition of SYNC output via SK. At this time, the processor reads the state of SI into SIO bit 0, shifting the current bits 0–2 left. Halfway through the cycle (shown in *Figure 6* as the eight clock rising edge), SK is reset low and the new SIO bit 3 is outputted via SO.

INTERFACING CONSIDERATIONS

To ensure data exchange, two aspects of interfacing have to be considered: 1) serial data exchange timing; 2) fan-out/fan-in requirements. Theoretically, infinite devices can access the same interface and be uniquely enabled sequentially in time. In practice, however, the actual number of devices that can access the same serial interface depends on the following: system data transfer rate, system supply requirement capacitive loading on SK and SO outputs, the fan-in requirements of the logic families or discrete devices to be interfaced.

HARDWARE INTERFACE

Provided an output can switch between a HIGH level and a LOW level, it must do so in a predetermined amount of time for the data transfer to occur. Since the transfer is strictly synchronous, the timing is related to the system clock (SK) (*Figure 7*). For example, if a COPS controller outputs a value at the falling edge of the clock and is latched in by the peripheral device at the rising edge, then the following relationship has to be satisfied:

$$t_{\text{DELAY}} + t_{\text{SETUP}} \leq t_{\text{CK}}$$

where t_{CK} is the time from data output starts to switch to data being latched into the peripheral chip, t_{SETUP} is the setup time for the peripheral device where the data has to be at a valid level, and t_{DELAY} is the time for the output to read the valid level. t_{CK} is related to the system clock provided by the SK pin of the COPS controller and can be increased by increasing the COPS instruction cycle time.

The maximum t_{SETUP} is specified in the peripheral chip data sheets. The maximum t_{DELAY} allowed may then be derived from the above relationship.

Most of the delay time before the output becomes valid comes from charging the capacitive load connected to the output. Each integrated circuit pin has a maximum load of 7 pF. Other sources come from connecting wires and connection from PC boards. The total capacitive load may then be estimated. The propagation delay values given in data sheets assume particular capacitive loads (e.g. $V_{\text{CC}} = 5\text{V}$, $V_{\text{OH}} = 0.4\text{V}$, loading = 50 pF, etc.).

If the calculated load is less than the given load, those values should be used. Otherwise, a conservative estimate is to assume that the delay time is proportional to the capacitive load.

If the capacitive load is too large to satisfy the delay time criterion, then three choices are available. An external buffer may be used to drive the large load. The COPS instruction cycle may be slowed down. An external pullup resistor may be added to speed up the LOW level to HIGH level transition. The resistor will also increase the output LOW level and increase the HIGH level to LOW level transition time, but the increased time is negligible as long as the output LOW level changes by less than 0.3V. For a 100 pF load, the standard COPS controller may use a 4.7k external resistor, with the output LOW level increased by less than

0.2V. For the same load, the low power COPS controller may use a 22k resistor, with the SO and SK LOW levels increased by less than 0.1V.

Besides the timing requirements, system supply and fan-out/fan-in requirements also have to be considered when interfacing with MICROWIRE. For the following discussion, we assume single supply push-pull outputs for system clock (SK) and serial output (SO), high-impedance input for serial input (SI).

To drive multi-devices on the same MICROWIRE, the output drivers of the controller need to source and sink the total maximum leakage current of all the inputs connected to it and keep the signal level within the valid logic "1" or logic "0". However, in general, different logic families have different valid "1" and "0" input voltage levels. Thus, if devices of different types are connected to the same serial interface, the output driver of the controller must satisfy all the input requirements of each device. Similarly, devices with TRI-STATE® outputs, when connected to the SI input, must satisfy the minimum valid input level of the controller and the maximum TRI-STATE leakage current of all outputs.

So, for devices that have incompatible input levels or source/sink requirements, external pull-up resistors or buffers are necessary to provide level-shifting or driving.

SOFTWARE INTERFACE

The existing MICROWIRE protocol is very flexible, basically divided into two groups:

1) 1AAA.....ADD.....D

where leading 1 is the start bit and leading zeroes are ignored.

AAA.....A is device variable instruction/address word.

DDD.....D is variable data stream between controller and device.

2) No start bit, just bit stream, i.e., bbb.....b

where b is a variable bit stream. Thus, device has to decode various fields within the bit stream by counting exact bit position.

SERIAL I/O ROUTINES

Routines for handling serial I/O are provided below. The routines are written for 16-bit transmissions, but are trivially expandable up to 64-bit transmissions by merely changing the initial LBI instruction. The routines arbitrarily select register 0 as the I/O register. It is assumed that the external device requires a logic low chip select. It is further assumed that chip select is high and SK and SO are low on entry to the routines. The routines exit with chip select high, SK and SO low. GO is arbitrarily chosen as the chip select for the external device.

SERIAL DATA OUTPUT

This routine outputs the data under the conditions specified above. The transmitted data is preserved in the microcontroller.

The code for reading serial data is almost the same as the serial output code. This should be expected because of the nature of the SIO register and the XAS instruction.

MICROWIRE STANDARD FAMILY

A whole family of off-the-shelf devices exists that is directly compatible with MICROWIRE serial data exchange standard. This allows direct interface with the COPS family of microcontrollers.

Table I provides a summary of the existing devices and their functions and specifications.

TYPICAL APPLICATION

Figure 8 shows pin connection involved in interfacing an E²PROM with the COP420 microcontroller.

FIGURE 8. NM93C06A COP420 Interface

The following points have to be considered:

1. For NM93C06A the SK clock frequency should be in the 0 kHz–250 kHz range. This is easily achieved with COP420 running at 4 μs–10 μs instruction cycle time (SK period is the COP420 instruction cycle time). Since the minimum SK clock high time is greater than 1 μs, the duty cycle is not a critical factor as long as the frequency does not exceed the 250 kHz max.
2. CS low period following an E/W instruction must not exceed 30 ms maximum. It should be set at typical or minimum spec of 10 ms. This is easily done in software using the SKT timer on COP420.

FIGURE 9. NM93C06A Timing

3. As shown in WRITE timing diagram, the start bit on DI must be set by a “0” to “1” transition following a CS enable (“0” to “1”) when executing any instruction. One CS enable transition can only execute one instruction.
4. In the read mode, following an instruction and data train, the DI can be a “don’t care,” while the data is being outputted, i.e., for the next 17 bits or clocks. The same is true for other instructions after the instruction and data has been fed in.
5. The data-out train starts with a dummy bit 0 and is terminated by chip deselect. Any extra SK cycle after 16 bits is not essential. If CS is held on after all 16 of the data bits have been outputted, the DO will output the state of DI until another CS LO to HI transition starts a new instruction cycle.
6. After a read cycle, the CS must be brought low for one SK clock cycle before another instruction cycle starts.

INSTRUCTION SET

Commands	Opcode	Comments
READ	1000A3A2A1A0	Read Register 0–15
WRITE	1100A3A2A1A0	Write Register 0–15
ERASE	1010A3A2A1A0	Erase Register 0–15
EWEN	111000 0 0 1	Write/Erase Enable
ENDS	111000 0 1 0	Write/Erase Disable
***WRAL	111000 1 0 0	Write All Registers
ERAL	111000 1 0 1	Erase All Registers

All commands, data in, and data out are shifted in/out on rising edge of SK clock.

Write/erase is then done by pulsing CS low for 10 ms.

All instructions are initiated by a LO-HI transition on CS followed by a LO-HI transition on DI.

READ— After read command is shifted in DI becomes don’t care and data can be read out on data out, starting with dummy bit zero.

WRITE— Write command shifted in followed by data in (16 bits) then CS pulsed low for 10 ms minimum.

ERASE

ERASE ALL—Command shifted in followed by CS low.

WRITE ALL—Pulsing CS low for 10 ms.

WRITE

ENABLE/DISABLE—Command shifted in.

*** (This instruction is not speeded on Data sheet.)

SOFTWARE DEBUG OF SERIAL REGISTER FUNCTIONS

In order to understand the method of software debug when dealing with the SIO register, one must first become familiar with the method in which the COPS MOLE™ (Development System) BREAKPOINT and TRACE operations are carried out. Once these operations are explained, the difficulties which could arise when interrogating the status of the SIO register should become apparent.

SERIAL OUT DURING BREAKPOINT

When the MOLE BREAKPOINTS, the COPS user program execution is stopped and execution of a monitor-type program, within the COP device, is started. At no time does the COP part "idle." The monitor program loads the development system with the information contained in the COP registers.

Note also that single-step is simply a BREAKPOINT on every instruction.

If the COP chip is BREAKPOINTed while a serial function is in progress, the contents of the SIO register will be destroyed.

By the time the monitor program dumps the SIO register to the MOLE, the contents of the SIO register will have been written over by clocking in SI. To inspect the SIO register using BREAKPOINT, an XAS must be executed prior to BREAKPOINT; therefore, the SIO register will be saved in the accumulator.

An even more severe consequence is that the monitor program executes an XAS instruction to get the contents of the SIO register to the MOLE. Therefore, the SK latch is dependent on the state of the CARRY prior to the BREAKPOINT. In order to guarantee the integrity of the SIO register, one must carefully choose the position of the BREAKPOINT address.

As can be seen, it is impossible to single-step or BREAKPOINT through a serial operation in the SIO register.

SERIAL OUT DURING TRACE

In the TRACE mode, the user's program execution is never stopped. This mode is a real-time description of the program counter and the external event lines; therefore, the four external event lines can be used as logic analyzers to monitor the state of any input or output on the COPS device. The external event lines must be tied to the I/O which is to be monitored.

The state of these I/O (external event lines) is displayed along with the TRACE information. The safest way to monitor the real-time state of SO is to use the TRACE function in conjunction with the external event lines.

CONCLUSIONS

National's super-sensible MICROWIRE serial data exchange standard allows interfacing to any number of specialized peripherals using an absolute minimum number of valuable I/O pins; this leaves more I/O lines available for system interfacing and may permit the COPS controller to be packaged in a smaller package.

Automotive Multiplex Wiring

National Semiconductor
Application Note 454
Abdul H. Aleaf

INTRODUCTION

The evolutionary development of vehicle electronic systems has rapidly increased the number of individual wires in the vehicle. The conventional wiring harness will not provide solutions to the problems such as reducing size and weight in addition to meeting cost and reliability objectives. Several approaches have been taken to provide long term solutions. None has succeeded. Miniaturization of cables and wires is one example of a temporary solution.

Multiplexing on the other hand has been regarded as a technique which allows considerable savings to be made in the size and cost of the harness. It can also enhance reliability by reducing the number of electrical connections.

In a multiplex system the control functions will be distributed around the vehicle and complex interconnections between diagnostic terminals, sensors, instruments and switches will not add to the harness complexity. With all its advantages it has not been implemented on a production car yet. The reason has been economical feasibility and lack of suitable semiconductor components for power switching. But, with the rapid technology advances in power FETs and introduction of low cost microcomputers, multiplex wiring can be regarded as a logical successor to conventional wiring systems. Extended development efforts are necessary to introduce a reliable system at reasonable cost.

The Microcontroller Applications Group at National Semiconductor has taken a step towards this goal. A low end multiplex wiring system focusing on asynchronous serial communication in a multi node network has been developed. This paper describes the development of this system on an abstract model which forms the basis for analysis of communication protocol and various node functions.

SYSTEM CONFIGURATION

Figure 1 presents a general view of the system. The system is a centralized single master multiple slave-node scheme. All units are connected together by a balanced twisted pair. The expandable interconnection of different subsystems is achieved with 9600 Baud communication over a standard UART bus. The bus handles the interface between a master controller and the intelligent nodes.

The approach to have a centralized control system offers several advantages as compared against a non-centralized system. It prevents the problem of bus monopolization by a faulty node and is potentially cheaper due to the need for only one complex node (master). The master-slave architecture also prevents bus contention problems.

The master is a COP420L. The COP420L is a 4-bit microcontroller with a software UART that handles asynchronous communication with other processors at speeds up to 9600 Baud.

The use of 4-bit 49¢ microcontrollers (COP413L) at the nodes not only provides intelligence which reduces the required bus bandwidth, it also reduces the incremental cost associated with automotive multiplexing. All standard nodes

are identical. One standard program is used. This uniformity contributes to the system flexibility and expandability. External standard nodes may be added to the system to control additional functions. Node types and addresses are selected via external wire jumpers or switches. The slave nodes consist of four remote units to handle functions such as headlamps, tail lamps, etc. These nodes are the front right, front left, rear right and rear left nodes. Incorporated into the system are also a keyboard node, a EIC node and a display node.

The keyboard node may call for a control action at any time. This node is being continuously monitored by the master controller which receives status and processes the command or information.

Overall system intelligence and flexibility is increased by dedicating a node to NS455 the Terminal Management Processor. This node takes the responsibility to display information on a 4" flat CRT display.

An Electronic Instrument Cluster (EIC) system is a completely independent system. It typically performs all functions associated with the automobile dashboard such as vehicle speed, odometers to accumulate mileage, gauges to display engine temperature, fuel level and so on. It also indicates error conditions such as high engine temperatures, low fuel level etc. The multiplex wiring system uses a standard slave node as a bridge between the two independent systems. The slave node monitors error conditions from the EIC system and passes them to the master node upon request. It becomes relatively simple to allow the master to access all activity in the EIC system via additional commands to the slave node serving the EIC system:

THE COMMUNICATION PROTOCOL

The master unit addresses the remote units sequentially and receives a status reply from each individual node. Data communication is via the standard UART format. It has a start bit, eight data bits, an even parity bit and one stop bit. Information to be transmitted from the master to a slave node is organized as a frame. Each frame contains the address of destination and command or data. The information in a frame is transmitted as byte format. Address/data differentiation is done by means of a flag. The byte is an address byte if the MSB is set ("1"), otherwise it is a data byte.

Two different types of addressing schemes have been incorporated into the communication protocol; node addressing and class addressing. A class of nodes is formed by grouping together slave nodes with common functions. Commands may be executed either by specific individual nodes or by slave classes. All nodes of the same class execute the command simultaneously. The system implementation at National involved four classes with seven slave nodes per class. So, the total number of nodes possible in this system is 28.

FIGURE 1. Block Diagram

TL/DD/8799-1

The partitioning between the class address and node address reduces the density of bus traffic significantly by eliminating repetitive command transmission to individual node class. Lower bus traffic implies that lower transmission bit rate can be used, allowing additional noise immunity. Another advantage of the class addressing is the provision of synchronization for control signals such as HAZARD, LEFT/RIGHT turns.

Error correction is incorporated into the communication protocol. The UART error flags such as PARITY and FRAMING ERRORS protect the system at the physical layer. At the system level, the nodes simply avoid sending an acknowledgement to the master when an error is detected. The master times out and sends the command again.

THE MASTER NODE

The master controller is the heart of the system. Its responsibility is to generate the controlling commands and synchronize the system. It transmits to the remote units and listens to them to get the vehicle status and acts accordingly. Circuit complexity is reduced by implementing extensive software programming in the master controller. This means that the burden is essentially on the master and must be engineered to very high standards of reliability. The device used in the implementation as the master is the COP1430. It is a cost effective 4-bit single chip microcontroller. It features on chip UART which handles asynchronous communications at speeds up to 9600 Baud.

THE SLAVE NODES

The standard slave nodes are based upon the COP413L. The COP413L is a low cost 4-bit microcontroller which may be customized in production. A system such as multiplex wiring requires power consumption to be absolutely minimal. Another basic requirement is that the system should be cost effective. These two facts directed us to use the COP413L at the standard slave node. The COP413L is a low cost (49¢) low power microcontroller from NSC drawing less

than 7 mA at 4.5V to 5.5V. The device contains an 8-bit bidirectional I/O port and a serial expansion port. The CMOS version of COP413L will also be available.

THE DISPLAY NODE

This node can serve as a condition monitoring unit for the vehicle. A considerable quantity of diagnostic information collected from transducers, switches, sensors and various loads are fed to this unit to be displayed on a CRT display. The node is based on a Terminal Management Processor the NS455. The NS455 is a CRT controller on chip. The messages are updated over the serial I/O line by the master controller. The communication format is:

- a) The node receives the address.
- b) If address matches the local node address, send the copy command
- c) Receive new address and execute.

OUTPUT STAGES

The power FETs used for local switching throughout the system are IRF541 (4). These N-channel FETs provide much better drive circuit specification as compared to bipolar output stages. They also feature all of the well established advantages of MOSFET such as voltage control, very fast switching, and very low on state resistance. Another advantage is the lower cost as compared to comparably rated p-channel devices.

TRANSMISSION MEDIUM

A balanced twisted pair is used for bus medium which provides high noise immunity. The transceiver selected for the bus is DS3695 (Figure 2). This device is a high speed differential TRI-STATE® Bus/line transceiver designed to meet EIA standard for multipoint bus transmission. Bus contention or fault situations that cause excessive power dissipation within the device are handled by a standard thermal shutdown circuit, which forces the driver outputs into the high impedance state.

TL/DD/8799-3

FIGURE 2. Bus Interface

CONCLUSIONS

Multiplex wiring system potentially seems to be a good replacement for conventional wiring system. Reduced complexity, increased flexibility and diagnostic capability could be achieved by incorporating microcontroller devices at nodes within the wiring system. The 4-bit microcontrollers selected are available in a price range, as low as 49¢, that will allow multiplex wiring to compare favorably on a cost-performance basis with the conventional harness.

Dual Tone Multiple Frequency (DTMF)

National Semiconductor
Application Note 521
Verne H. Wilson

The DTMF (Dual Tone Multiple Frequency) application is associated with digital telephony, and provides two selected output frequencies (one high band, one low band) for a duration of 100 ms. A benchmark subroutine has been written for the COP820C/840C microcontrollers, and is outlined in detail in this application note. This DTMF subroutine takes 110 bytes of COP820C/840C code, consisting of 78 bytes of program code and 32 bytes of ROM table. The timings in this DTMF subroutine are based on a 20 MHz COP820C/840C clock, giving an instruction cycle time of 1 μ s.

The matrix for selecting the high and low band frequencies associated with each key is shown in *Figure 1*. Each key is uniquely referenced by selecting one of the four low band frequencies associated with the matrix rows, coupled with selecting one of the four high band frequencies associated with the matrix columns. The low band frequencies are 697, 770, 852, and 941 Hz, while the high band frequencies are 1209, 1336, 1477, and 1633 Hz. The DTMF subroutine assumes that the key decoding is supplied as a low order hex digit in the accumulator. The COP820C/840C DTMF subroutine will then generate the selected high band and low band frequencies on port G output pins G3 and G2 respectively for a duration of 100 ms.

The COP820C/840C each contain only one timer. The problem is that three different times must be generated to satisfy the DTMF application. These three times are the periods of the two selected frequencies and the 100 ms duration period. Obviously the single timer can be used to generate any one (or possibly two) of the required times, with the program having to generate the other two (or one) times.

The solution to the DTMF problem lies in dividing the 100 ms time duration by the half periods (rounded to the nearest micro second) for each of the eight frequencies, and then examining the respective high band and low band quotients and remainders. The results of these divisions are detailed in Table I. The low band frequency quotients range from 139 to 188, while the high band quotients range from 241 to 326. The observation that only the low band quotients will each fit in a single byte dictates that the high band frequency be produced by the 16 bit (2 byte) COP820C/840C timer running in PWM (Pulse Width Modulation) Mode.

FIGURE 1. DTMF Keyboard Matrix

TL/DD/9662-1

The solution then is to use the program to produce the selected low band frequency as well as keep track of the 100 ms duration. This is achieved by using three programmed register counters R0, R2, and R3, with a backup register R1 to reload the counter R0. These three counters represent the half period, the 100 ms quotient, and the 100 ms remainder associated with each of the four low band frequencies.

The theory of operation in producing the selected low band frequency starts with loading the three counters with values obtained from a ROM table. The half period for the selected frequency is counted out, after which the G2 output bit is toggled. During this half period countout, the quotient counter is decremented. This procedure is repeated until the quotient counter counts out, after which the program branches to the remainder loop. During the remainder loop, the remainder counter counts out to terminate the 100 ms. Following the remainder countout, the G2 and G3 bits are both reset, after which the DTMF subroutine is exited. Great care must be taken in time balancing the half period loop for the selected low band frequency. Furthermore, the toggling of the G2 output bit (achieved with either a set or reset bit instruction) must also be exactly time balanced to maintain the half period time integrity. Local stall loops (consisting of a DRSZ instruction followed by a JP jump back to the DRSZ for a two byte, six instruction cycle loop) are embedded in both the half period and remainder loops. Consequently, the ROM table parameters for the half period and remainder counters are approximately only one sixth of what otherwise might be expected. The program for the half period loop, along with the detailed time balancing of the loop for each of the low band frequencies, is shown in *Figure 2*.

The DTMF subroutine makes use of two 16 byte ROM tables. The first ROM table contains the translation table for the input hex digit into the core vector. The encoding of the hex digit along with the hex digit ROM translation table is shown in Table II. The row and column bits (RR, CC) representing the low band and high band frequencies respectively of the keyboard matrix shown in *Figure 1*, are encoded in

TABLE I. Frequency Half Periods, Quotients, and Remainders

	Freq. Hz	Half Period 0.5P	Half Period in μ s	100 ms/0.5P	
				Quotient	Remainder
Low Band Freq.'s	697	717.36	717	139	337
	770	649.35	649	154	54
	852	586.85	587	170	210
	941	531.35	531	188	172
High Band Freq.'s	1209	413.56	414 (256 + 158)	241	226
	1336	374.25	374 (256 + 118)	267	142
	1477	338.52	339 (256 + 83)	294	334
	1633	306.18	306 (256 + 50)	326	244

the two upper and two lower bits of the hex digit respectively. Consequently, the format for the hex digit bits is RRCC, so that the input byte in the accumulator will consist of 0000RRCC. The program changes this value into 1101RRCC before using it in setting up the address for the hex digit ROM translation table.

The core vectors from the hex digit ROM translation table consist of a format of XX00TT00, where the two T (Timer) bits select one of four high band frequencies, while the two X bits select one of four low band frequencies. The core vector is transformed into four different inputs for the second ROM table. This transformation of the core vector is shown in Table III. The core vector transformation produces a timer vector 1100TT00 (T), and three programmed coun-

ter vectors for R1, R2, and R3. The formats for the three counter vectors are 1100XX11 (F), 1100XX10 (Q), and 1100XX01 (R) for R1, R2, and R3 respectively. These four vectors produced from the core vector are then used as inputs to the second ROM table. One of these four vectors (the T vector) is a function of the T bits from the core vector, while the other three vectors (F, Q, R) are a function of the X bits. This correlates to only one parameter being needed for the timer (representing the selected high band frequency), while three parameters are needed for the three counters (half period, 100 ms quotient, 100 ms remainder) associated with the low band frequency and 100 ms duration. The frequency parameter ROM translation table, accessed by the T, F, Q, and R vectors, is shown in Table IV.

0xCF	83	F

In summary, the input hex digit selects one of 16 core vectors from the first ROM table. This core vector is then transformed into four other vectors (T, F, Q, R), which in turn are used to select four parameters from the second ROM table. These four parameters are used to load the timer, and the respective half period, quotient, and remainder counters. The first ROM table (representing the hex digit matrix table) is arbitrarily placed starting at ROM location 01D0, and has a reference setup with the ADD A,#0D0 instruction. The second ROM table (representing the frequency parameter table) must be placed starting at ROM location 01C0 (or 0xC0) in order to minimize program size, and has reference setups with the OR A,#0C3 instruction for the F vector and with the OR A,#0C0 instruction for the T vector.

The three parameters associated with the two X bits of the core vector require a multi-level table lookup capability with the LAID instruction. This is achieved with the following section of code in the DTMF subroutine:

```

LD      B, #R1
LD      X, #R4
X       A, [X]
LUP:   LD      A, [X]
        LAID
X       A, [B+]
DRSZ   R4
IFBNE  #4
JP     LUP

```

This program code loads the F frequency vector into R4, and then decrements the vector each time around the loop. This successive loop decrementation of the R4 vector changes the F vector into the Q vector, and then changes the Q vector into the R vector. This R4 vector is used to access the ROM table with the LAID instruction. The X pointer references the R4 vector, while the B pointer is incremented each time around the loop after it has been used to store away the three selected ROM table parameters (one per loop). These three parameters are stored in sequential RAM locations R1, R2, and R3. The IFBNE test instruction is used to skip out of the loop once the three selected ROM table parameters have been accessed and stored away.

The timer is initialized to a count of 15 so that the first timer underflow and toggling of the G3 output bit (with timer PWM mode and G3 toggle output selected) will occur at the same time as the first toggling of the G2 output bit. The half period counts for the high band frequencies range from 306 to 414, so these values minus 256 are stored in the timer section of the second ROM table. The selected value from this frequency ROM table is then stored in the lower half of the timer autoreload register, while a 1 is stored in the upper half. The timer is selected for PWM output mode and started with the instruction LD [B],#0B0 where the B pointer is selecting the CNTRL register at memory location 0EE.

The DTMF subroutine for the COP820C/840C uses 110 bytes of code, consisting of 78 bytes of program code and 32 bytes of ROM table. A program routine to sequentially call the DTMF subroutine for each of the 16 hex digit inputs is supplied with the listing for the DTMF subroutine.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be down loaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

MICROWIRE/PLUS™ Serial Interface for COP800 Family

National Semiconductor
Application Note 579
Ramesh Sivakolundu
Sunder Velamuri

AN-579

INTRODUCTION

National Semiconductor's COP800 family of full-feature, cost-effective microcontrollers use a new 8-bit single chip core architecture fabricated with M²CMOS process technology. These high performance microcontrollers provide efficient system solutions with a versatile instruction set and high functionality.

The COP800 family of microcontrollers feature the MICROWIRE/PLUS mode of serial communication. MICROWIRE/PLUS is an enhancement of the MICROWIRE™ synchronous serial communications scheme, originally implemented on the COP400 family of microcontrollers. The MICROWIRE/PLUS interface on the COP800 family of microcontrollers enables easy I/O expansion and interfacing to several COPS peripheral devices (A/D converters, EEPROMs, Display drivers etc.), and interfacing with other microcontrollers which support MICROWIRE/PLUS or SPI* modes of serial interface.

MICROWIRE/PLUS DEFINITION

MICROWIRE/PLUS is a versatile three wire, SI (serial input), SO (serial output), and SK (serial clock), bidirectional serial synchronous communication scheme where the COP800 is either the Master providing the Shift Clock (SK) or a slave accepting an external Shift Clock (SK). The COP800 MICROWIRE/PLUS system block diagram is shown in Figure 1. The MICROWIRE/PLUS serial interface utilizes an 8-bit memory mapped MICROWIRE/PLUS serial shift register, SIOR, clocked by the SK signal. As the name suggests, the SIOR register serves as the shift register for serial transfers. SI, the serial input line to the COP800 microcontroller, is the shift register input. SO, the shift register output, is the serial output to external devices. SK is the serial synchronous clock. Data is clocked into and out of the

peripheral devices with the SK clock. The SO, SK and SI are mapped as alternate functions on pins 4, 5, and 6 respectively of the 8-bit bidirectional G Port.

MICROWIRE/PLUS OPERATION

In MICROWIRE/PLUS serial interface, the input data on the SI pin is shifted high order first into the Least Significant Bit (LSB) of the 8-bit SIOR shift register. The output data is shifted out high order first from the Most Significant Bit (MSB) of the shift register onto the SO pin. The SIOR register is clocked on the falling edge of the SK clock signal. The input data on the SI pin is shifted into the LSB of the SIOR register on the rising edge of the SK clock. The MSB of the SIOR register is shifted out to the SO pin on the falling edge of the SK clock signal. The SK clock signal is generated internally by the COP800 for the master mode of MICROWIRE/PLUS operation. In the slave mode, the SK clock is generated by an external device (which acts as the master) and is input to the COP800.

The MSEL (MICROWIRE Select) flag in the CNTRL register is used to enable MICROWIRE/PLUS operation. Setting the MSEL flag enables the gating of the MICROWIRE/PLUS interface signals through the G port. Pins G4, G5, and G6 of the G port are used for the signals SO, SK and SI, respectively. It should be noted that the G port configuration register must be set up appropriately for MICROWIRE/PLUS operation. Table I illustrates the G-port configurations. In the master mode of MICROWIRE/PLUS operation, G4 and G5 need to be selected as outputs for SO and SK signals. Alternatively, in the slave mode of operation, G5 needs to be configured as an input for the external SK. The SI signal is a dedicated input on G6 and therefore no further setup is required.

TABLE I. G Port Configurations

G4 (SO) Config. Bit	G5 (SK) Config. Bit	G4 Fun.	G5 Fun.	Operation
1	1	SO	Int. SK	MICROWIRE Master
0	1	TRI-STATE	Int. SK	MICROWIRE Master
1	0	SO	Ext. SK	MICROWIRE Slave
0	0	TRI-STATE	Ext. SK	MICROWIRE Slave

The SL1 and SL0 (S1 and S0 in COP820C and COP840C) bits of the CNTRL register are used to select the clock division factor (2, 4, or 8) for SK clock generation in MICROWIRE/PLUS master mode operation. A clock select table for these bits of the CNTRL register along with the CNTRL register is shown in Table II. The counter associated with

TL/DD/10252-1

*only in COP88XX series

FIGURE 1. MICROWIRE/PLUS Block Diagram

3

the master mode clock division factor is cleared when the MICROWIRE/PLUS BUSY flag is low. The clock division factor is relative to the instruction cycle frequency. For example, if the COP800 is operating with an internal clock of 1 MHz, the SK clock rate would be 500 kHz, 250 kHz, or 125 kHz for SL1 and SL0 values of 00, 01 and 10 (or 11) respectively.

TABLE II

CNTRL Register (Address X'00EE)

The Timer1 (T1) and MICROWIRE control register contains the following bits:

- SL1 & SL0 Select the MICROWIRE clock divide by (00 = 2, 01 = 4, 1X = 8)
- IEDG External Interrupt Edge Polarity Select (0 = Rising Edge, 1 = Falling Edge)
- MSEL Selects G5 and G4 as MICROWIRE Signals SK and SO Respectively
- T1C0 Timer T1 Start/Stop Control in Timer Modes 1 and 2
Timer T1 Underflow Interrupt Pending Flag in Timer Mode 3
- T1C1 Timer T1 Mode Control Bit
- T1C2 Timer T1 Mode Control Bit
- T1C3 Timer T1 Mode Control Bit

Bit 7				Bit 0			

SL1	SL0	SK
0	0	2 x t _C
0	1	4 x t _C
1	x	8 x t _C

Where t_C is the instruction cycle clock

MICROWIRE/PLUS MASTER MODE OPERATION

In the MICROWIRE/PLUS master mode, the BUSY flag of PSW (Processor Status Word) is used to control the shifting

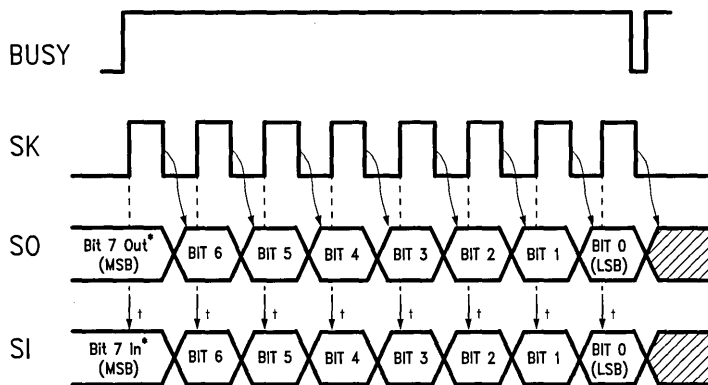

of the MICROWIRE/PLUS 8-bit shift register. Setting the BUSY flag causes the SIOR register to shift out 8 bits of data from SO at the high order end of the shift register. During the same time, 8 new bits of data from SI are shifted into the low order end of the SIOR register. The BUSY flag is automatically reset after the 8 bits of data have been shifted (Figure 2). The COP888XX series of microcontrollers provide a vectored maskable interrupt when the BUSY goes low indicating the end of an 8-bit shift. Input data is clocked into the SIOR register from the SI pin with the rising edge of the SK clock, while the MSB of the SIOR is shifted onto the SO pin with the falling edge of the SK clock. The user may reset the BUSY bit by software to allow less than 8 bits to shift. However, the user should ensure that the software BUSY resets only occurs when the SK clock is low, in order to avoid a narrow SK terminal clock.

MICROWIRE/PLUS SLAVE MODE OPERATION

In the MICROWIRE/PLUS Slave mode of operation the SK clock is generated by an external source. Setting the MSEL bit in the CNTRL register enables the SO and SK functions onto the G Port. The SK pin must be configured as an input and the SO pin configured as an output by resetting and setting the appropriate bits in the Port G configuration register. The user must set the BUSY flag immediately upon entering the Slave mode. After eight clock pulses the Busy flag will be cleared and the sequence may be repeated. However, in the Slave mode the COP888 series does not shift data if the BUSY flag is reset, whereas the COP820C and COP840C continues to shift regardless of the BUSY flag, if the SK clock is active.

MICROWIRE/PLUS ALTERNATE SK MODE

The COP888XX series of microcontrollers also allow an additional Alternate SK Phase Operation. In the normal mode data is shifted in on the rising edge of the SK clock and data is shifted out on the falling edge of the SK clock (Figure 2). The SIOR register is shifted on each falling edge of the SK clock. In the alternate SK phase operation, data is shifted in on the falling edge of the SK clock and data is shifted out on the rising edge of the SK clock (Figure 3).

*This bit becomes valid immediately after loading the SIOR register of the transmitting device.

†Arrows indicate points at which SI is sampled.

FIGURE 2. MICROWIRE/PLUS Timing

TL/DD/10252-2

TL/DD/10252-3

↑ Arrows indicates points at which SI is sampled.

FIGURE 3. Alternate Phase SK Clock Timing

A control flag, SKSEL, allows either the normal SK clock or alternate SK clock to be selected. Resetting SKSEL selects the normal SK clock and setting SKSEL selects the alternate SK clock for the MICROWIRE/PLUS logic. The SKSEL flag is mapped into the G6 configuration bit. The SKSEL flag is reset after power up, selecting the normal SK clock signal. The alternate mode facilitates the usage of the MICROWIRE/PLUS protocol for serial data transfer between peripheral devices which are not compatible with the normal SK clock operation, i.e., shifting data out on the falling edge of the SK clock and shifting in data on the rising edge of the SK clock.

MICROWIRE/PLUS SAMPLE PROTOCOL

This section gives a sample MICROWIRE/PLUS protocol using a COP888CL and COP840C. The slave mode operating procedure for this sample protocol is explained, and a timing illustration of the protocol is provided.

1. The MSEL bit in the CNTRL register is set to enable MICROWIRE; G0 (\overline{CS}) and G5 (SK) are configured as inputs and G4 (SO) as an output. G6 (SI) is always an input.
2. Chip Select line (\overline{CS}) from master device is connected to G0 of the slave device. An active-low level on \overline{CS} line causes the slave to interrupt.
3. From the high-to-low transition on the \overline{CS} line, there is no data transfer on the MICROWIRE until time "T" (See Figure 4).
4. The master initiates data transfer on the MICROWIRE by turning on the SK clock.
5. A series of data transfers take place between the master and slave devices.
6. The master pulls the \overline{CS} line high to end the MICROWIRE operation. The slave device returns to normal mode of operation.

SLAVE MODE OPERATING PROCEDURE

1. The MSEL bit in the CNTRL register is set to enable MICROWIRE; G0 (\overline{CS}) and G5 (SK) are configured as inputs and G4 (SO) as an output. G6 (SI) is always an input.
2. Normal mode of operation until interrupted by \overline{CS} going low.

3. Set the BUSY flag and load SIOR register with the data to be sent out on SO. (The shift register shifts 8 bits of data from SO at the high order end of the shift register. During the same time, 8 new bits of data from SI are loaded into the low order end of the shift register.)
4. Wait for the BUSY flag to reset. (The BUSY flag is automatically reset after 8 bits of data have been shifted.)
5. If data is being read in, the user should save contents of the SIOR register.
6. The prearranged set of data transfers are performed.
7. Repeat steps 3 through 6. The user must ensure steps 3 through 6 are performed in time "T" (See Figure 4) as agreed upon in the protocol.

DIFFERENCES BETWEEN COP888 AND COP820/COP840

The COP888 series MICROWIRE/PLUS feature differs from that of the COP820/COP840 in some respects. The COP888 series can be configured to interrupt the processor after the completion of a MICROWIRE/PLUS operation indicated by the BUSY flag going low. The COP888 series supports a vectored interrupt scheme. Two bytes of program memory space are reserved for each interrupt source. The user would do any required context switching and then program a VIS (Vector Interrupt Select) instruction in order to branch to the interrupt service routine of the highest priority interrupt enabled and pending at the time of the VIS instruction. The addresses of the different interrupt service routines are chosen by the user and stored in a table starting at 0yE0 where "y" depends on the 256 byte block (0y00 to 0yFF) in which the VIS instruction is located. The vector address for the MICROWIRE/PLUS interrupt is 0yF2-0yF3.

Secondly, the COP888 series supports the alternate SK phase mode of MICROWIRE/PLUS operation. This feature facilitates the usage of the MICROWIRE/PLUS protocol for serial data transfer between peripheral devices which are not compatible with the normal SK clock operation, i.e., shifting data out on the falling edge of SK clock and shifting in data on the rising edge of the SK clock.

FIGURE 4. MICROWIRE/PLUS Sample Protocol Timing Diagram

TL/DD/10252-4

INTERFACE CONSIDERATIONS

To preserve the integrity of data exchange using MICROWIRE/PLUS, two aspects have to be considered:

1. Serial data exchange timing.
2. Fan-out/fan-in requirements.

Theoretically, infinite devices can access the same interface and be uniquely enabled sequentially in time. In practice, however, the actual number of devices that can access the same serial interface depends on the following: System data transfer rate, system supply requirement, capacitive loading on SK and SO outputs, the fan-in requirements of the logic families or discrete devices to be interfaced.

HARDWARE INTERFACE

For proper data transfer to occur the output should be able to switch between a HIGH level and a LOW level in a predetermined amount of time. The transfer is strictly synchronous and the timing is related to the MICROWIRE/PLUS system clock (SK). For example, if a COPS controller outputs a value at the falling edge of the clock and is latched in by the peripheral device at the rising edge, then the following relationship has to be satisfied:

$$t_{\text{DELAY}} + t_{\text{SETUP}} \leq t_{\text{CK}}$$

where t_{CK} is the time from data output starts to switch to data being latched into the peripheral chip, t_{SETUP} is the setup time for the peripheral device where the data has to be at a valid level, and t_{DELAY} is the time for the output to read the valid level. t_{CK} is related to the system clock provided by the SK pin of the COPS controller and can be increased by increasing the COPS instruction cycle time.

Besides the timing requirements, system supply and fan-out/fan-in requirements also have to be considered when interfacing with MICROWIRE/PLUS. To drive multi-devices on the same MICROWIRE/PLUS, the output drivers of the controller need to source and sink the total maximum leakage current of all the inputs connected to it and keep the signal level within the valid logic "1" and "0" input voltage levels. Thus, if devices of different types are connected to the same serial interface, output driver of the controller must satisfy all the input requirements of each device. Similarly, devices with TRI-STATE® outputs, when connected to the SI input, must satisfy the minimum valid input level of the controller and the maximum TRI-STATE® leakage current of all outputs.

So, for devices that have incompatible input levels or source/sink requirements, external pull-up resistors or buffers are necessary to provide level-shifting or driving.

TYPICAL APPLICATIONS

A whole family of off-the-shelf devices exist that are directly compatible with MICROWIRE/PLUS protocol. This allows direct interface with the COP800 family of microcontrollers. Table III provides a summary of the existing devices, their function and specification.

NMC9306-COP888CG INTERFACE

The pin connection involved in interfacing an NMC9306 (COP494), a 256 bit E²PROM, with the COP888CG microcontroller is shown in Figure 5. Some notes on the NMC9306 interface requirements are:

1. The SK clock frequency should be in the 0 kHz–250 kHz range.
2. \overline{CS} low period following an Erase/Write instruction must not exceed 30 ms maximum. It should be set at typical or minimum specification of 10 ms.

FIGURE 5. NMC9306-COP888CG Interface

TL/DD/10252-5

Instruction Set

Commands	Start Bit	Opcode	Address	Comments
READ	1	0000	A3A2A1A0	Read Register 0–15
WRITE	1	1000	A3A2A1A0	Write Register 0–15
ERASE	1	0100	A3A2A1A0	Erase Register 0–15
EWEN	1	1100	00 01	Write/Erase Enable
ENDS	1	1100	00 10	Write/Erase Disable
***WRAL	1	1100	01 00	Write All Registers
ERAL	1	1100	01 01	Read All Registers

Where A3A2A1A0 corresponds to one of the sixteen 16-bit registers.

All commands, data in, and data out are shifted in/out on the rising edge of the SK clock.

Write/Erase is then done by pulsing \overline{CS} low for 10 ms.

All instructions are initiated by a LO–HI transition on \overline{CS} followed by a LO–HI transition on DI.

READ— After read command is shifted in DI becomes don't care and data can be read out on data out, starting with dummy bit zero.

WRITE— Write command shifted in followed by data in (16 bits) the \overline{CS} pulsed low for 10 ms minimum.

3. The start bit on DI must be set by a "0" to "1" transition following a \overline{CS} enable ("0" to "1") when executing any instruction. One \overline{CS} enable transition can only execute one instruction.

4. In the read mode, following an instruction and data train, the DI can be a "don't care", while the data is being outputted, i.e., for the next 17 bits or clocks. The same is true for other instructions after the instruction and data has been fed in.

5. The data out train starts with a dummy bit 0 and is terminated by chip deselect. Any extra SK cycle after 16 bits is not essential.

If \overline{CS} is held on after all 16 of the data bits have been outputted, the DO will output the state of DI until another \overline{CS} LO to HI transition starts a new instruction cycle.

6. After a read cycle, the \overline{CS} must be brought low for one SK clock cycle before another instruction cycle starts.

ERASE/ERASE ALL— Command shifted in followed by \overline{CS} low.

WRITE ALL— Pulsing \overline{CS} low for 10 ms.

ENABLE/DISABLE— Command shifted in.

A detailed explanation of the E²PROM timing diagrams, instruction set and the various considerations could be found in the NMC9306 data sheet. A source listing of the software to interface the NMC9306 with the COP888CG is provided.

COP472-COP820 Interface

The pin connection required for interfacing COP472-3 Liquid Crystal Display (LCD) Controller with COP820C microcontroller is shown in Figure 6. The COP472-3 drives a multiplexed liquid crystal display directly. Data is loaded serially and is held in internal latches. One COP472-3 can drive 36 segments and two or more COP472-3's can be cascaded to drive additional segments as long as the output loading capacitance does not exceed specifications.

The COP472-3 requires 40 information bits: 36 data and 4 control. The function of each control bit is described briefly. Data is loaded in serially, in sets of eight bits. Each set of segment data is in the following format:

SA	SB	SC	SD	SE	SF	SG	SH
----	----	----	----	----	----	----	----

Data is shifted into an eight bit shift register. The first bit of data is for segment H, digit 1, and the eight bit is for segment A, digit 1. A set of eight bits are shifted in and then

loaded into the digit one latches. The second, third, and fourth set is then loaded sequentially. The fifth set of data bits contain special segment data and control data in the following format:

SYNC	Q7	Q6	X	SP4	SP3	SP2	SP1
------	----	----	---	-----	-----	-----	-----

The first four bits shifted in contain the special character segment data. The fifth bit is not used. The sixth and seventh bits program the COP472-3 as a stand alone LCD driver or as a master or slave for cascading COP472-3's. The Table IV summarizes the function of bits six and seven.

The eight bit is used to synchronize two COP472-3's to drive an 8½ digit display. A detailed explanation of the various timing diagrams, loading sequence and segment/backplane multiplex scheme can be found in the data sheets of COP472-3. The source listing of the software used in the interface is provided.

TL/DD/10252-11

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be downloaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162

Voice (408) 721-5582

For Additional Information, Please Contact Factory

OVERVIEW

This application note discusses the various arithmetic operations for National Semiconductor's COP800 family of 8-bit microcontrollers. These arithmetic operations include both binary and BCD (Binary Coded Decimal) operation. The four basic arithmetic operations (add, subtract, multiply, divide) are outlined in detail, with several examples shown for both binary and BCD addition and subtraction. Multiplication, division, and BCD conversion algorithms are also provided. Both BCD to binary and binary to BCD conversion subroutines are included, as well as the various multiplication and division subroutines.

Four sets of optimal subroutines are provided for

1. Multiplication
2. Division
3. Decimal (Packed BCD) to binary conversion
4. Binary to decimal (Packed BCD) conversion

One class of subroutines is optimized for minimal COP800 program code, while the second class is optimized for minimal execution time in order to optimize throughput time.

This application note is organized in four different sections. The first section outlines various addition and subtraction routines, including both binary and BCD (Binary Coded Decimal). The second section outlines the multiplication algorithm and provides several optimal multiply subroutines for 1, 2, 3, and 4 byte operation. The third section outlines the division algorithm and provides several optimal division subroutines for 1, 2, 3, and 4 byte operation. The fourth section outlines both the decimal (Packed BCD) to binary and binary to decimal (Packed BCD) conversion algorithms. This section provides several optimal subroutines for these BCD conversions.

The COP800 arithmetic instructions include the Add (ADD), Add with Carry (ADC), Subtract with Carry (SUBC), Increment (INCR), Decrement (DECR), Decimal Correct (DCOR),

Clear Accumulator (ACC), Set Carry (SC), and Reset Carry (RC). The shift and rotate instructions, which include the Rotate Right through Carry (RRC) and the Swap Accumulator Nibbles (SWAP), may also be considered as arithmetic instruction variations. The RRC instruction is instrumental in writing a fast multiply routine.

1.0 BINARY AND BCD ADDITION AND SUBTRACTION

In subtraction, a borrow is represented by the absence of a carry and vice versa. Consequently, the carry flag needs to be set (no borrow) before a subtraction, just as the carry flag is reset before an addition. The ADD instruction does not use the carry flag as an input, nor does it change the carry flag. It should also be noted that both the carry and half carry flags (bits 6 and 7, respectively, of the PSW control register) are cleared with reset, and remain unchanged with the ADD, INC, DEC, DCOR, CLR and SWAP instructions. The DCOR instruction uses both the carry and half carry flags. The SC instruction sets both the carry and half carry flags, while the RC instruction resets both these flags.

The following program examples illustrate additions and subtractions of 4-byte data fields in both binary and BCD (Binary Coded Decimal). The four bytes from data memory locations 24 through 27 are added to or subtracted from the four bytes in data memory locations 16 through 19. The results replace the data in memory locations 24 through 27.

These operations are performed both in Binary and BCD. It should be noted that the BCD pre-conditioning of Adding (ADD) the hex 66 is only necessary with the BCD addition, not with the BCD subtraction. The (Binary Coded Decimal) DCOR (Decimal Correct) instruction uses both the carry and half carry flags as inputs, but does not change the carry and half carry flags. Also note that the #12 with the IFBNE instruction represents $28 - 16$, since the IFBNE operand is modulo 16 (remainder when divided by 16).

      IFBNE  #12    ; IF STILL IN DATA FIELD
      JF     LOOP   ; JUMP BACK TO REPEAT LOOP
      IFC    ; IF TERMINAL CARRY
      JF     OVFLOW ; JUMP TO OVERFLOW

```

BCD SUBTRACTION:

```

LD      X,#16      ; NO LEADING ZERO
LD      B,#24      ; INDICATES DECIMAL
C      ;
LOOP:  LD      A,[X+] ; [X] TO ACC
      SUBC   A,[B]  ; SUBTRACT [B] FROM ACC
      DCOR   A      ; DECIMAL CORRECT RESULT
      X      A,[B+] ; RESULT TO [B]
      IFBNE  #12    ; IF STILL IN DATA FIELD
      JF     LOOP   ; JUMP BACK TO REPEAT LOOP
      IFNC   ; IF TERMINAL BORROW
      JF     NEGRSLT ; JUMP TO NEGATIVE RESULT

```

The astute observer will notice that these previous additions and subtractions are not "adding machine" type arithmetic operations in that the result replaces the second operand rather than the first. The following program examples illus-

trate "adding machine" type operation where the result replaces the first operand. With subtraction, this entails the result replacing the minuend rather than the subtrahend. Note that the B and X pointers are now reversed.

BINARY ADDITION:

        IFNC   ; IF TERMINAL BORROW
        JP     NEGRSLT ; JUMP TO NEGATIVE RESULT

```

Let us now consider a hybrid arithmetic example, where we wish to add five successive bytes of a data table in ROM program memory to a two byte sum, and then subtract the SUM result from a two byte total TOT. Let us further assume

that the ROM table is located starting at program memory address 0401, while SUM and TOT are at RAM data memory locations [1, 0] and [3, 2] respectively, and that we wish to encode the program as a subroutine.

ROM Table:

```
. = 0401
. Byte 102
. Byte 41
. Byte 31
. Byte 26
. Byte 5
```

ROM Table Accessed Top Down

```
SUMLO = 0
SUMHI = 1
TOTLO = 2
TOTHI = 3
```

```
ARITH1: LD      X,#5          ; SET UP ROM TABLE POINTER

        RET    ; RETURN FROM SUBROUTINE
```

2.0 MULTIPLICATION

The COP800 multiplications are all based on starting the multiplier in the low order end of the double length product space. The high end of the double length product space is initially cleared, and then the double length product is shifted right one bit. The bit shifted out from the low order end represents the low order bit of the multiplier. If this bit is a "1", the multiplicand is added to the high end of the double length product space. The entire shifting process and the conditional addition of the multiplicand to the upper end of the double length product is then repeated. The number of shift cycles is equal to the number of bit positions in the multiplier plus one extra shift cycle. This extra terminal shift cycle is necessary to correctly align the resultant product.

Note that an M byte multiplicand multiplied by an N byte multiplier will result in an M + N byte double length product. However, these multiplication subroutines will only use 2M + N + 1 bytes of RAM memory space, since the multiplier initially occupies the low order end of the double length product. The one extra byte is necessary for the shift counter CNTR.

The minimal code (28 byte) general multiplication subroutine is shown with two different examples, MY2448 and MY4824. Both examples multiply 24 bits by 48 bits. The MY2448 subroutine uses the 48-bit operand as the multiplier, and consequently uses minimal RAM as well as minimal program code. The MY4824 subroutine uses the 24-bit operand as the multiplier, and consequently executes considerably faster than the minimal RAM MY2448 subroutine.

3.0 DIVISION

The COP 800 divisions are all based on shifting the dividend left up into a test field equal in length to the number of bytes in the divisor. The divisor is resident immediately above this test field. After each shift cycle of the dividend into the test field, a trial subtraction is made of the test field minus the divisor. If the divisor is found equal to or less than the contents of the test field, then the divisor is subtracted from the test field and a 1's quotient digit is recorded by setting the low order bit of the dividend field. The dividend and test field left shift cycle is then repeated. The number of left shift cycles is equal to the number of bit positions in the dividend. The quotient from the division is formed in the dividend field, while the remainder from the division is resident in the test field.

Note that an M byte dividend divided by an N byte divisor will result in an M byte quotient and an N byte remainder.

These division algorithms will use $M + 2N + 1$ bytes of RAM memory space, since the test field is equal to the length of the divisor. The one extra byte is necessary for the shift counter CNTR.

In special cases where the dividend has an upper bound and the divisor has a lower bound, the upper bytes of the dividend may be used as the test field. One example is shown (DV2815), where a 28 bit dividend is divided by a 15-bit divisor. The dividend is less than $2^{**}28$ (upper nibble of high order byte is zero), while the divisor is greater than $2^{**}12$ (4096) and less than $2^{**}15$ (32768). In this case, the upper limit for the quotient is $2^{**}28/2^{**}12$, which indicates a 16-bit quotient ($2^{**}16$) and a 15-bit remainder. Consequently, the upper two bytes of the dividend may be used as the test field for the remainder, since the divisor is greater than the test field (upper two bytes of the 28-bit dividend) initially.

The minimal code (40 byte) general division subroutine is shown with the example DV3224, which divides a 32 bit dividend by a 24 bit divisor.

DECBIN—Decimal (Packed BCD) to Binary

This 24 byte subroutine represents very minimal code for translating a packed BCD decimal number of any length to binary.

ALGORITHM:

The binary result is resident just below the packed BCD decimal number. During each cycle of the algorithm, the decimal operand and the binary result are shifted right one bit position, with the low order bit of the decimal operand shifting down into the high order bit position of the binary field. The residual decimal operand is then tested for a high order bit in each of its nibbles. A three is subtracted from each nibble in the BCD operand space that is found to contain a high order bit equal to one. (This process effectively right shifts the BCD operand one bit position, and then corrects the result to BCD format.) The entire cycle is then repeated, with the total number of cycles being equal to the number of bit positions in the decimal field.

16 Bit: Binary IN [1,0]

Packed BCD in [3, 2]

24 Bit: Binary in [2, 1, 0]

Packed BCD in [5, 4, 3]

32 Bit: Binary in [3, 2, 1, 0]

Packed BCD in [7, 6, 5, 4]

24 Bytes

1030 Instruction Cycles (16 Bit)

BINDEC—Binary to Decimal (Packed BCD)

This 25 byte subroutine represents very minimal code for translating a binary number of any length to packed BCD decimal.

ALGORITHM:

The packed BCD decimal result is resident just above the binary number. A sufficient number of bytes must be allowed for the BCD result. During each cycle of the algorithm the binary number is shifted left one bit position. The packed BCD decimal result is also shifted left one bit position, with the high order bit of the binary field being shifted up into the low order bit position of the BCD field. The shifted result in the BCD field is decimal corrected by using the DCOR instruction. Note that for addition an "ADD A, #066" instruction must be used in conjunction with the DCOR (Decimal Correct) instruction. The entire cycle is then repeated, with the total number of cycles being equal to the number of bit positions in the binary field.

16 Bit: Binary in [1, 0]
 Packed BCD in [4, 3, 2]
 24 Bit: Binary in [2, 1, 0]
 Packed BCD in [6, 5, 4, 3]
 32 Bit: Binary in [3, 2, 1, 0]
 Packed BCD in [8, 7, 6, 5, 4]

25 Bytes

856 Instructions Cycles (16 Bit)

VFBTOD—VERY FAST BINARY TO DECIMAL (PACKED BCD)

Algorithm: Decimal (Packed BCD) result is equal to summation in BCD of powers of two corresponding to 1's bits present in binary number.

Note that binary field (2 bytes) is initially one's complemented by program, in order to facilitate bypass branching when a tested bit in the binary field is found equal to zero.

Binary in [1, 0]
BCD in [4, 3, 2]

189 Bytes

Pulse Width Modulation A/D Conversion Techniques with COP800 Family Microcontrollers

National Semiconductor
Application Note 607
Kevin Daugherty

1.0 BASIC TECHNIQUE

This application note describes a technique for creating an analog to digital converter using a microcontroller with other low cost components. Many applications do not require the speed associated with a dedicated hardware A/D converter and it is worth evaluating a more cost effective approach.

With a high speed CMOS microcontroller an eight bit A/D can be implemented that converts in approximately 10 ms. This method is based on the fact that if a repetitive waveform is applied to an RC network, the capacitor will charge to the average voltage, provided that the RC time constant is much larger than the pulse widths. The basic equation for computing the analog to digital result is:

$$V_{in} = V_{ref} [T_{on} / (T_{on} + T_{off})] \quad (1)$$

With this equation it is necessary to precisely measure several time periods within both the T_{on} and T_{off} in order to achieve the desired resolution. Additionally, the waveform would have to be gradually adjusted to allow for the large RC time constant to settle out. This results in a relatively long conversion cycle. Modifying the equation and technique slightly, significantly speeds up the process. This technique works by averaging several pulses over a fixed period of time and is based on the following equation:

$$V_{in} = V_{ref} [\text{Sum of } T_{on} / (\text{Sum of } (T_{on} + T_{off}))] \quad (2)$$

2.0 IMPLEMENTATION

Figure 1 describes the basic circuit schematic that uses a National Semiconductor COP822C microcontroller, a low cost LM2901 comparator, two 100k resistors, and a 0.047 mfd film capacitor. The CMOS COP822C microcontroller provides a squarewave signal with logic levels very close to GND and V_{CC} . This generates a small ramp voltage on the capacitor for the LM2901 quad comparator input.

FIGURE 1. Basic Circuit

TL/DD/10407-1

To minimize error, a tradeoff must be made when selecting the resistor. The microcontroller output (L1) should have a large resistor to minimize the output switching offset (V_{os}), and the comparator should have a small resistor due to error caused by I_{bos} (input bias offset current).

Once the resistor is determined, the capacitor should be chosen so that the RC time constant is large enough to provide a small incremental voltage ramp. This design has a sample time of 20 μ s and has a 4.7 ms time constant with a 0.047 mfd film type capacitor which has low leakage current to prevent errors. Since a 100k resistor is used in the RC network for one comparator input, another 100k resistor is required for the V_{in} input to balance the offset voltage caused by the comparator I_b (input bias current).

Figure 2 illustrates the relationship between the microcontroller squarewave output and the capacitor charge and discharge. Every 20 μ s the comparator is sampled. If the capacitor voltage (V_c) is below V_{in} the RC network will receive a positive pulse. The inverse is true if V_c is above V_{in} at sample time. Note that with this approach, the PWM waveform is broken up into several small pulses over a fixed period instead of having a single pulse represent the duty cycle; thus a relatively small RC time constant can be used.

Mathematical Analysis:

let n = total number of T_{on} pulses and

m = total number of T_{off} pulses

then $V_c(t) = V_c + n[(V_{out} - V_c)(1 - e^{-t/RC})] - m[(V_c - V_o)(1 - e^{-t/RC})]$

let $V_c = V_{in}$ at start of conversion and

$$K = (1 - e^{-t/RC})$$

then $V_{in} = V_{in} + K_n V_{out} - K_n V_{in} - K_m V_{in} + K_m V_o$

$$0 = K_n V_{out} + K_m V_o - K V_{in} (n + m)$$

let $V_{out} = V_{ref} - V_{os}$

solving for V_{in} :

$$V_{in} = nV_{ref}/(n + m) - (nV_{os} - mV_o)(1/(n + m)) \quad (3)$$

Note that the RC value drops out of the equation and therefore is not an error factor.

FIGURE 2. PWM Signal

3.0 SOFTWARE DESCRIPTION

Single Channel

Referring to the flow chart in *Figure 3*, and the code listed in *Figure 4*, the software counters T_{ON} and TOTAL are first preloaded with the FF. The accumulator and register 0F1 are then loaded with 2 to provide for an initialization and final conversion cycle. Next, the L port is configured to complete the initialization of the microcontroller.

The comparator output is checked with the IFBIT 0,0D2 instruction. This will determine whether the RC network will receive a positive (V_{ref}) or ground pulse. You can think of the microcontroller as part of the feedback path of the comparator. The microcontroller uses the comparator output to decide what level output on L1 is required to keep the capacitor equal to the unknown input voltage. Each time the negative or GND pulse is applied, the T_{ON} counter is decremented by DRSZ. Similarly, each time a sample loop is completed the TOTAL counter is decremented by DRSZ. Note that NOP instructions are used in the high and low loops. These are necessary to provide exactly the same cycles for a high or low L1 output pulse.

Once the TOTAL register is decremented to zero, the initialization loop is completed. Immediately afterwards, the L1 output is put in TRI-STATE® mode to minimize capacitor voltage variations while other instructions are completed. After the first conversion, the IFEQ A,0F1 instruction will be true and the T_{ON} and TOTAL registers will be reloaded with FF. Following this, the L1 pin is restored as a high output and the 0F1 multiplier is decremented.

At this point the capacitor is equal to V_{in} and the actual conversion is started. When the TOTAL register is decremented to zero (255 samples later), the conversion is complete. T_{ON} will not be reloaded since 0F1 was decremented and IFEQ A,0F1 will no longer be true. The accumulator is then loaded with T_{ON} and stored in RAM location 00 with X A,00.

The final two instructions (RBIT 1,LCONF & RBIT 1[B]) are optional depending on the application and the amount of additional code required. This will prevent the capacitor from decaying appreciably between conversions and allow for a much quicker capacitor initialization time. Otherwise more time may be required, or a diode speed-up circuit as shown in *Figure 7d* is required to fully charge the capacitor prior to starting the actual conversion.

Eight Channel

This is basically the same as that for the single channel. Referring to the flow chart in *Figure 5* and the code in *Figure 6*, the differences are in the front and back ends. Before the

conversions are started, the X register is initialized to 00 for RAM location 00. The accumulator is then loaded with the current RAM pointer (LD A,X), OR'ed with the LDATA (OR A,LDATA), and finally the LDATA register is modified to provide for the proper output select (X A,LDATA).

Following the actual conversion cycle, the result is stored at the current RAM pointer (X A,[X+]) which also auto-increments the X register. The next conversion will use this to select the next channel and determine where to store the result. Once the eighth channel is converted, the IFEQ A,X instruction will be true and the RAM pointer will be reset (LD X,#00) before the next conversion is started.

FIGURE 6. 8-Channel PWM A/D Listing

4.0 ACCURACY AND CIRCUIT CONSIDERATIONS

The basic circuit will provide 8 bits ± 1 LSB accuracy depending on the choice of comparator, and passive components. With this type of design several tradeoffs and error sources should be considered. First of all, conversion equation 2 assumes that the microcontroller output switches exactly to GND and V_{CC} (or V_{ref}). The COP822C will typically switch between 10 mV and 20 mV from GND and V_{CC} with a light load. This will cause an error equal to the offset voltage times the duty cycle (equ. 3). Fortunately, the offsets tend to cancel each other at mid range voltages. At near GND and V_{CC} input voltages the offsets are minimal due to the very small voltage drop across the resistor. If the error is undesirable, the offset voltage can be reduced by paralleling outputs with the same levels together, or by using a CMOS buffer such as a 74HC04 to drive the RC network (see Figure 7 for suggested circuits).

Another possible source of error is with the LM2901 worst case input bias offset current of 200 nA over temperature. This will cause an error equal to $R_{in} \times I_{bos}$, which equals 20 mV with a 100k resistor. Either the resistor or the I_{bos} can be reduced to improve the error. If the resistor is reduced then the L port offset voltages will increase so the preferred approach is to select a comparator with lower I_{bos} such as the LP339 which has an I_{bos} of only ± 15 nA. The comparator V_{os} may also introduce error. The LM2901 V_{os} is ± 9 mV, the LP339 V_{os} is only ± 5 mV. An added benefit of using the LP339 is that since the I_{bos} is so small, the resistor for the RC network can be larger. In addition, one RC network could be used for several comparator input channels (refer to Figure 7A).

By using the LM604 (Figure 7B) the basic software can be easily extended for converting several channels. This will only require a control line to be selected before a conversion is started. Since the LM604 needs to be powered from a higher voltage than the input voltage range, the output voltage will also be higher than the microcontroller supply. This requires a current limiting resistor to be used in series

between the LM604 output and the COP8XX. Note that two or more LM604's can be paralleled for providing several more A/D channels by utilizing the EN control input that can TRI-STATE the LM604 output when high.

When more than 4 channels of analog signals are required to be measured, the circuit in Figure 7(d) is recommended. This circuit utilizes an inexpensive CD4051 8:1 multiplexer with a single comparator (which could be on-board the micro). When measuring several input voltages that can vary, TRI-STATING the output driving the RC between conversions is not possible. It is necessary to provide 6x RC time constants to charge the capacitor to within 0.25%. Note that there are two 1N4148's across the comparator inputs. The diodes provide a quick capacitor charge path providing that the total input resistance is much smaller than the resistor used in the RC network (a 2k resistor will meet the requirements within 255 sample times). Once the capacitor is charged to within about 0.6V, the diodes will start turning off. At this point the microcontroller will start dominating the charge/discharge of the capacitor. After the initialization cycle is complete, the capacitor is very close to the unknown V_{in} and the diodes are effectively out of the circuit.

Depending on the speed and accuracy requirements, the total number of counts used in the conversion can be changed. Increasing the counts will give more accuracy with the practical limit of about 9–10 bits. With increased resolution, the capacitor ramp voltage per sample time should be decreased so that the capacitor can be initialized to within 1 LSB prior to conversion. This can be done by either increasing the RC time constant, or by using an initialization routine with a shorter sample time. The conversion time will depend on the total counts and the microcontroller oscillator frequency as described below:

$$T_{con} = \text{Total counts} \times (20 \text{ cycles}) \times (\text{instruction cycle time})$$

Another factor to consider is when a non-ratiometric conversion is required, the reference voltage must have the tolerance to match the desired accuracy.

5.0 CONCLUSION

The PWM A/D technique described in this application note provides a relatively fast discrete implementation with substantial cost savings compared to a dedicated hardware A/D. Minimal microcontroller I/O and software is required to interface with a comparator and RC network. Depending on the application requirements, the designer can tailor the basic 8-bit A/D a number of ways. By varying the total software counts, the desired speed and resolution can be adjusted. The number of A/D channels will determine the number of comparators used. In choosing the comparator, it is recommended that the designer refer to the data sheets and match the I_{bos} and V_{os} to the desired accuracy.

When other than a $1 \mu s$ instruction cycle is used, the RC time constant of 4.7 ms should be scaled to provide for

a maximum peak-peak ramp voltage of <1 LSB of the desired accuracy. For example, if 8-bit accuracy is desired and the instruction cycle time is now $4 \mu s$ instead of $1 \mu s$, multiply 4.7 ms by 4 to calculate the new RC.

Keep in mind that the comparator input voltage is limited so that you do not get erroneous/nonlinear results. Another possible problem is during development. When doing in-circuit emulation with the development equipment, note that there will be ground loops in the cable thus causing errors in your measurements. You can reduce this by connecting an extra GND and V_{CC} wire between your prototype and development system power and GND. It is still possible to see offsets in the sockets holding the COP8XX in the development board, however this should be relatively small. The best test is to take accurate measurements with an emulator in the actual prototype circuit.

COP800 Based Automated Security/Monitoring System

National Semiconductor
Application Note 662
Ramesh Sivakolundu

INTRODUCTION

National Semiconductor's COP800 family of full-feature, cost effective, fully static, single chip micro CMOS micro-controllers provide efficient system solutions with a versatile instruction set and high functionality. The heart of the ASM System prototype is a COP800 family member with at least the following features: 4k bytes of on-board program memory, 192 bytes of on-board data memory, memory mapped I/O, fourteen multi-sourced vectored interrupts and a versatile instruction set. The family member used is the COP888CG microcontroller.

This application note describes the implementation of a Security/Monitoring System using the COP888CG microcontroller. The COP888CG contains features such as:

- Low power HALT and IDLE modes
- MICROWIRE/PLUS™ serial communication
- Multiple multi-mode general purpose timers
- Multi-input wakeup/interrupt
- WATCHDOG™ and Clock monitor
- Maskable vectored interrupt scheme
- UART

In addition to these features common to the COP888 sub-family of microcontrollers, COP888CG has a full duplex, double buffered UART and two Differential Comparators.

The COP888CG based Automated Security/Monitoring (ASM) System consists of several features:

- Automatic Telephone Dialing
- Real Time Clock
- Non-Volatile storage of real time information of events
- Continuous display of events on the terminal
- Battery operated remote sensors and transmitters
- Exit and Entry delays
- Expandable to add new features

SYSTEM OVERVIEW

Figure 1 gives the block diagram of the ASM System prototype hardware. The application consists of following major blocks:

- Central Controlling Unit
- Receiver
- Sensors and Transmitters
- Keypad Unit
- Auto-Dialer Unit
- Data Storage Unit
- Display Terminal Unit
- LED Display Unit

The implementation allows easy expansion of the ASM System features by adding new blocks to the Central Controlling Unit.

COP888CG is the workhorse of the ASM System and provides the processing power to scan the keypad, service the Receiver interrupts, update the real time clock, serially communicate with the LED display unit and Data Storage Unit, activate the Auto-Dialer Unit and use the full-duplex double buffered UART to interface with the Display Terminal Unit. System capabilities may be enhanced or scaled down by simply changing the processor's algorithm. The subsequent sections describe each of the units and their interface with the COP888CG.

FIGURE 1. Block Diagram of Security/Monitoring System

TL/DD/10607-1

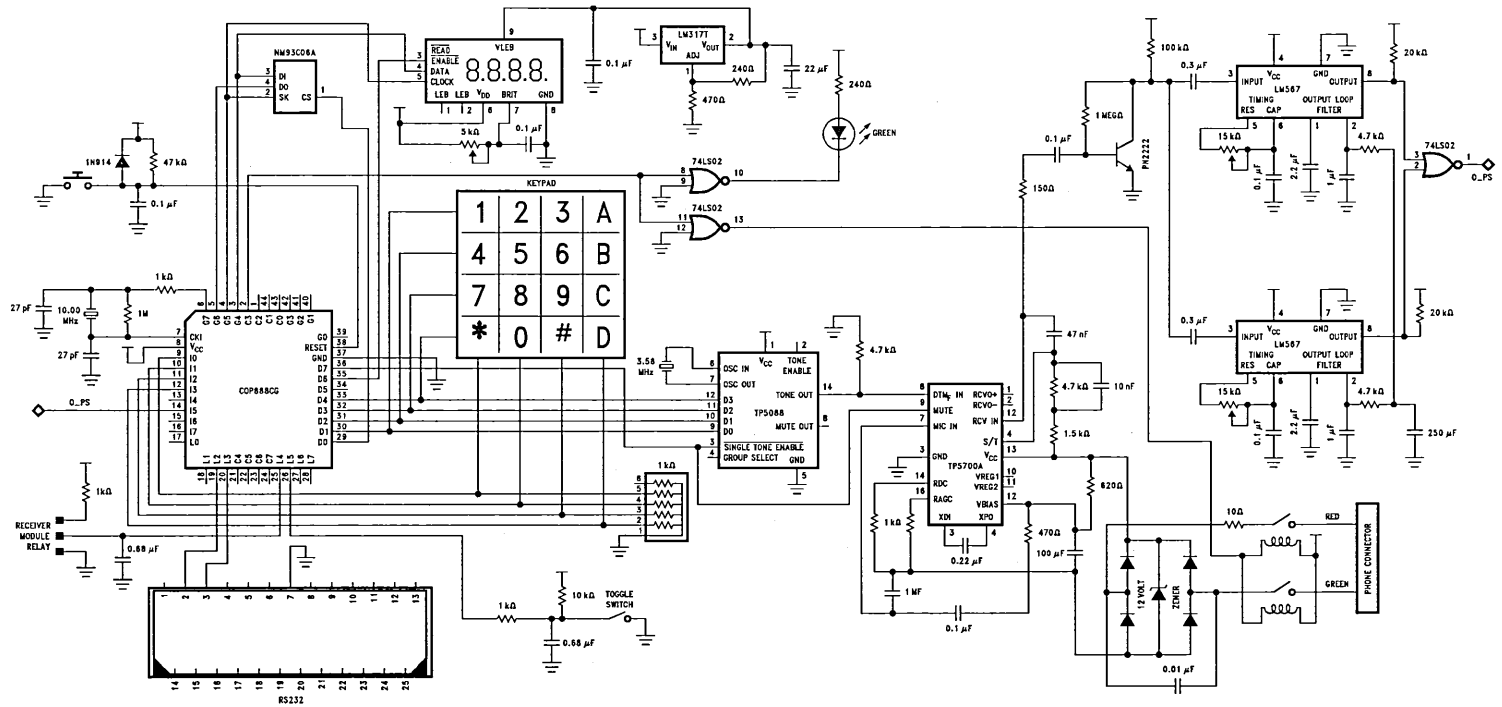

FIGURE 2. Schematic of the ASM System Prototype

TL/DD/10607-2

HARDWARE DESCRIPTION

This section describes the various blocks in the ASM System briefly and highlights the hardware considerations in the design of the System.

Receiver Unit

The Receiver Unit operates with the Sensors and Transmitter Unit. An eight-key dip switch makes it possible to select 256 different digital codes. A detector LED indicates the level of the radio frequency (RF) energy detected by the receiver and enables the user to determine the best locations for the transmitter(s) and receiver, assuring reliable operation.

Figure 2 shows the interface between the COP888CG and the Receiver Unit on the bi-directional I/O Port L capable of functioning as Multi-Input WakeUp (MIWU). In this implementation the WR-200 series of receivers manufactured by Visonic Ltd was used. These receivers are designed to operate with Visonic standard transmitters. The receiver operates on 12 VDC. When RF signal from the transmitter(s) is detected, the receiver activates a relay which in turn interrupts the microcontroller. The output of the relay is connected to the Port L of the COP888CG whose alternate function includes, the Multi-Input WakeUp feature. The COP888CG, after a time delay of 10 seconds, activates the Auto-Dialer Unit. The microcontroller turns on a LED to indicate an alarm signal was detected and is being processed.

Sensors and Transmitters

This unit has a built-in reed switch which can be used with a magnet to activate the transmitter. An eight-key dip switch forms the code selector and each key can be set to either ON or OFF position to create a unique code. This code should match with the code selected on the receiver unit.

Model WR-100 Universal Wireless Transmitter, manufactured by Visonic Ltd. was used in the implementation of the Security/Monitoring System.

Keypad Unit

The Keypad Unit consists of 4 x 4 matrix keyboard. The *Figure 2* shows the keyboard matrix interface to COP888CG. The keyboard is scanned periodically by addressing a column in the keyboard matrix. The program senses the key closure in that column by testing the Port I lines (I0 to I3) which are connected to the rows of the keyboard matrix. Thus, each key is associated with the conjunction of one Port D output line and one Port I input line only.

The keypad unit is used to program the real time clock in order to set the time and date. The telephone number to be dialed in case of a security breach can also be programmed through the keypad as well as the terminal keyboard in the Terminal Unit.

Auto-Dialer Unit

The Auto-Dialer Unit dials the number programmed by the user upon detection of RF signal by the Receiver from the Sensors and Transmitter Unit. The unit consists of two ICs and some peripheral circuitry. National Semiconductor's TP5700A is the Telephone Speech Circuit and TP5088 is the DTMF generator. These two chips are interfaced to the COP888CG as in *Figure 2*. The COP888CG outputs the digit to be dialed to TP5088 and the output of the DTMF generator is inputted to the Speech Circuit. The Speech Circuit interfaces with the telephone lines.

TP5088 is a low cost CMOS device that provides the toning capability in microprocessor-controlled telephone applications. TP5700A is a linear bipolar device which includes the functions required to build the speech circuit of a telephone. It replaces the hybrid transformer, compensation circuit and sidetone network used traditional designs.

Data Storage Unit

The Data Storage Unit stores the real time data of events that the Receiver Unit detects and informs the Central Controlling Unit. The storage is non-volatile and can be archived for later references. The Terminal Unit can request the Central Controlling Unit to display the events and the data stored in the Storage Unit. The telephone number to be dialed by the Auto-Dialer Unit is also stored in this unit. This unit interfaces with the COP888CG using the MICROWIRE/PLUSTM serial communication protocol.

In this implementation the COP888CG microcontroller interfaces with NM93C06A Serial EEPROM Memory. The NM93C06A contains 256 bits of read/write EEPROM organized as 16 registers of 16 bits each. Written information has a retention period of at least 10 years. *Figure 2* shows the interface between COP888CG and NMC9306.

Any sequentially accessible memory device that is compatible with the MICROWIRE/PLUSTM serial communication protocol can be used as a Data Storage Unit. The Central Controlling Unit checks for the availability of memory and informs the user of the same if memory is full. Upon receipt of memory full prompt, the user can decide to overwrite or replace the memory device.

Display Terminal Unit

The Display Terminal Unit interfaces with the COP888CG through the full-duplex, double buffered UART. The COP888CG is interrupted by the terminal and the microcontroller decodes the ASCII character sent and services the corresponding request. The terminal keyboard can be used to program the telephone number to be dialed by the Auto-Dialer Unit. The real time clock is displayed on the terminal screen. The user can request the Central Controlling Unit to display the history of events monitored by the AMS System. The Central Controlling Unit retrieves the information from the Date Storage Unit and displays it on the screen.

The ASM System utilized a Visual 550 terminal. The terminal employs two independent display memories: alphanumeric and graphics. The alphanumeric functions of the V550 is ANSI X3.64 compatible and the graphics functions are fully compatible with Tectronix Plot 10® software.

With slight modification of the Central Controlling Unit's algorithm it is possible to make the ASM System interface with any other terminal unit.

LED Display Unit

The LED Display Unit is used to display the time and date information. *Figure 2* shows the interface between COP888CG and the Display Terminal Unit. The COP888CG communicates with this unit serially using the MICROWIRE/PLUS protocol.

The NSM4000A LED Display with Driver is used in the ASM System. The NSM4000A is a 4-digit 0.3" height LED display with serial data-in parallel data-out LED driver designed to operate with minimal interface to the data source. The Cen-

tral Controlling Unit does not update the display when it is servicing the Receiver Unit. The APS System has a toggle switch that enables toggling the display between Hours-Minutes to Seconds-1/80th of Seconds. The Keypad Unit is used to toggle the display between time and date.

Central Controlling Unit

This is the main unit in the application and is responsible for the efficient operation of the various units in the ASM System. The unit consists of COP888CG and the application software. The next section describes the application software in detail. The COP888CG interfaces with the various units described in the previous sections (*Figure 2*).

The application is a real time system and is totally interrupt driven with some of the tasks being executed in the background. The various units that interface with the COP888CG can be considered as tasks and the Central Controlling Unit executes these tasks based on their priority and the sequence of occurrence. The real time clock counter is given the highest priority. The Receiver Unit uses the Multi-Input Wakeup/Interrupt feature of the COP888CG to wakeup the microcontroller and service the Alarm routine. The Display Unit has a display toggle switch which also uses the Multi-Input Wakeup/Interrupt to toggle the display between Hours-Minutes and Seconds-1/80th of Seconds.

The COP888CG communicates with the Terminal Unit through the on-board, full duplex, double buffered UART. The terminal keyboard can be used to interrupt the COP888CG to program the phone number to dial in case of an emergency. The COP888CG uses the MICROWIRE/PLUSTM serial communication protocol to display the time and date information on the LED display and also to store real time information of events in the non-volatile data storage unit. Thus the MICROWIRE/PLUS protocol is time shared between the Display Unit and Data Storage Unit.

The Keypad Unit is a 4 x 4 array of keys and the COP888CG periodically polls the keypad. The input/output ports of the COP888CG is used to read the key pressed and is decoded by the software. The Auto-Dialer Unit is driven by the input/output lines and the interface between COP888CG. This unit is activated by the COP888CG 10 seconds after the Receiver Unit interrupts the microcontroller. This delay is used to disarm the Alarm routine.

SOFTWARE DESCRIPTION

The instruction set of the COP800 family of microcontrollers provide easy optimization of program size and throughput efficiency. Most of the instructions of the COP800 family are single-byte, single-cycle instructions (approximately 60%). The COP800 family of microcontrollers has three memory mapped registers (B, X and SP). The B and X registers can be used as data store memory pointers for register indirect addressing with optional auto post incrementing or decrementing of the associated pointer. This allows greater efficiency in cycle time and program code. The COP800 family allows true bit-manipulation i.e., the ability to set, reset or test any individual bit in data memory including the memory mapped I/O ports.

The architecture of COP800 family is based on a modified Harvard type architecture, where the Control Store Program (in ROM) is separated from the Data Store Memory (in RAM). Both types of memory have their own separate addressing space and separate address busses. This architecture allows the overlap of ROM and RAM memory accesses which is not possible with single-address bus Von Neumann-style architecture. The modified Harvard architecture allows access to ROM data tables which is not possible with the classical Harvard architecture.

The COP888 sub-family of microcontrollers support a total of sixteen vectored interrupts, of which fourteen are maskable interrupts and two high-priority, non-maskable interrupts. A 2-byte interrupt vector is reserved for each of these sixteen interrupts and they are stored in a user-defined 32-byte program memory (ROM) table. Please refer to the COP888 users manual or the Microcontrollers Databook for more detailed information on interrupts.

The MIWU feature, which utilizes the Port L, of the COP888 sub-family can be used to wakeup the microcontroller from the two power saving modes, i.e., HALT or IDLE modes. Alternately, the MIWU/Interrupt allows the user to generate eight additional edge selectable external interrupts. Three 8-bit memory mapped registers (WKEDG, WKEN and WKPND) are used to implement the MIWU/Interrupt. The three control registers each contain an associated pin for each L port pin. The WKEN register is used to select which particular Port L inputs will be used. The user can select whether the trigger condition on a selected L port pin is to be a positive edge (low to high transition) or a negative edge (high to low transition). This selection is made through the WKEDG register. The occurrence of the selected trigger condition for MIWU/Interrupt is latched into the associated bit of the Wakeup Pending Register (WKPND).

The COP800 family has the ability to detect various illegal conditions resulting from coding errors, transient noise, power supply voltage drops, runaway programs, etc. Reading an undefined ROM location gets zeroes, which results in a non-maskable software interrupt thus signalling an illegal condition has occurred. In addition to this, the COP888 sub-family supports both WATCHDOG™ and Clock Monitor. The WATCHDOG™ is used to monitor the number of instruction cycles between WATCHDOG™ services in order to avoid runaway programs or infinite loops. The Clock Monitor is used to detect the absence of a clock or a very slow clock below a specified rate. These features of the COP800 family provide easy implementation of real time applications where the proper execution of the software plays a crucial role.

The major features of the software written for the ASM System implementation are described on the flow chart *Figure 3*. The main program flow is to detect the flags set, service the flags and scan the Keypad. The rest of the software is interrupt driven. The program is real time and the interrupts are serviced as and when they occur. Some of the routines are running in the background all the time, such as, Time Keeping Routine and Keypad Scan Routine. *Figures 4 and 5* gives the flow of the various interrupt service routines. The following sub-sections briefly describe each module of software connected to the units described earlier.

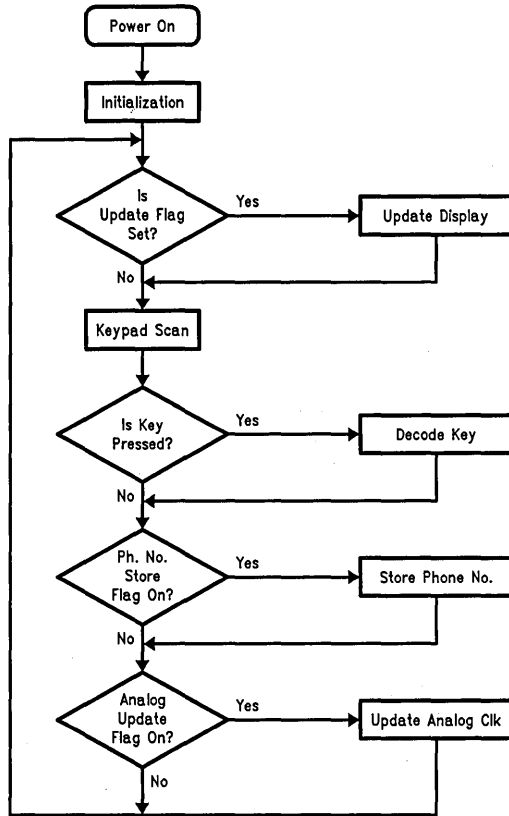

FIGURE 3. ASM System Program Flow

TL/DD/10607-3

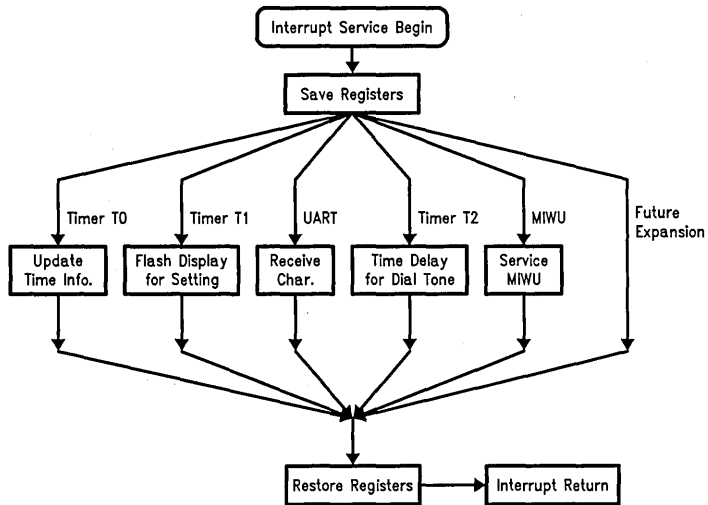

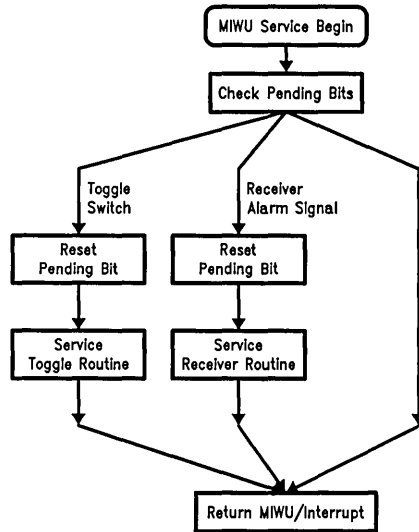

FIGURE 4. Interrupt Service Routines Flow

TL/DD/10607-4

TL/DD/10607-5

FIGURE 5. Multi-Input Wakeup/Interrupt Service Routines

Initialization Routine

The Initialization Routine loads the Data Memory locations being used in the program with default values and initializes the various control and configuration registers. It also brings up the display on the Terminal Unit and the LED Display Unit.

Time Keeping Routine

The Time Keeping Routine is the most important routine and is executed irrespective of the other modules being executed. The program uses the IDLE Timer T0 for this purpose. The IDLE Timer is a 16-bit timer and runs continuously at a fixed rate of the instruction cycle clock. The IDLE Timer counter is not memory mapped and consequently, the user cannot read or write to it. The toggling of the twelfth bit of the IDLE counter can be programmed to generate an interrupt. This interrupt is generated every 4 ms at the maximum instruction cycle clock rate of 1 MHz. The software uses this interrupt to update counters in Data Memory for time keeping. The Time Keeping routine then sets a flag to update the display which is then used by the main program.

LED Display Routine

The COP888CG uses the MICROWIRE/PLUS to interface with NSM4000 LED Display with Driver. The time and date information is displayed on the 4-digit LED display. The user is provided with a toggle switch connected to MIWU/Interrupt feature of the COP888CG to toggle the display between Hours-Minutes and Seconds-1/80th of Seconds. The toggle switch is connected to L port pin 5. Upon receipt of the MIWU/Interrupt of L port pin 5 this routine toggles the display. This routine upon receipt of the date display request through the Keypad Unit responds by switching the LED Display to show the date. The toggle switch could be used to change the display back to time. However, the display changes to time after a minute by default.

Keypad Scan Routine

This module scans the 4 x 4 matrix keyboard connected to Port D (D1-D4) as rows and to Port I (I0-I3) as columns. Thus each key in the matrix is associated with one Port D line and one Port I line. Each row in the matrix is addressed in sequence and the key closure is sensed by testing the Port I lines. The moment one key closure is detected the program jumps to load the debounce counter. The keypad scan is stopped at that particular row and the program returns to its main flow. The keypad is again scanned and when the debounce counter is decremented. When the debounce counter is zero the key pressed is accepted and decoded. The versatility of the COP888 family of instructions set allows decoding the key pressed with one instruction. The Port D (lines D1-D4) and Port I (lines I0-I3) in conjunction form an eight bit number that is unique to each key. The JID (Jump Indirect) instruction uses the contents of the accumulator to point to the indirect vector table of program address. The accumulator contents are transferred to the program counter (lower 8 bits). The data accessed from the program memory location addressed by program counter is transferred to the program counter (lower 8 bits). The JID instruction is a single-byte, three cycle instruction and provides an efficient way to decode and branch to service the appropriate routine based upon the key pressed.

The Keypad is used to set the time and data information after power up and can also be used to program the phone number to be dialed by the Auto-Dialing Unit.

Non-Volatile Data Storage Routine

The COP888CG interfaces with NM93C06A in the ASM System to store the real time data of the events monitored and also the telephone number to be dialed by the Auto-Dialer Unit. This routine is executed whenever the Receiver Unit detects a signal and the ASM System is not disarmed within 10 seconds of detection of the signal or when the

Display Terminal Unit programs the telephone number to be dialed. The Keypad can also be used to program the phone number to be dialed by the Auto-Dialer Unit. The Terminal Unit can request for the history of events, during which the COP888CG reads the NM93C06A. Please refer to the application note on MICROWIRE/PLUS for details regarding the interface between COP888CG and NMC9306.

Display Terminal Interface Routine

The Display Terminal as previously mentioned interfaces with the COP888CG through the full-duplex, double buffered UART. The terminal is used to display the history of events, real time, and sequence of operations upon detection of signal by the Receiver Unit.

The request for display of events and programming the phone number interrupts the COP888CG. However, the Time Keeping Routine updates the LED display and terminal with real time periodically, except when the COP888CG is servicing the Receiver Unit.

The operation mode of the UART may be selected in conjunction with both a prescaler and baud rate register. Character data lengths of seven, eight or nine bits are program selectable, in conjunction with a start bit, an optional parity bit, and stop bits of $\frac{7}{8}$, 1, 1 and $\frac{7}{8}$, or 2. The UART also contains a full set of error detection circuitry and a diagnostic test capability, as well as an ATTENTION mode to facilitate networking with other processors.

Please refer to the Users Manual or Microcontroller Data-book for details.

In the ASM System the COP888CG interfaces with the V550 terminal at 2400 baud, 8 data bits, 1 Stop bit, no parity. The receiver buffer full and transmit buffer empty generates an interrupt. The Port L (pins L1, L2, L3) are used for the UART interface as CKX (clock), TDX (transmit) and RDX (receive), respectively.

The display terminal is used to display time both in analog and digital form. The V550 allows interfacing both in alphanumeric and graphic modes with separate memory for each of the modes. The COP888CG is programmed to send out the ASCII ESC sequence required to generate the graphics on the screen.

Auto-Dialing Routine

This routine is responsible for dialing the number in the event of an emergency. The COP888CG interfaces with TP5088, which in turn interfaces with TP5700A. The COP888CG activates the relay that keeps the telephone line on-hook to the off-hook position. After this it times out to get the dial tone. After a fixed amount of time, the digit to be dialed is sent out on the D port, lines D1-D4, to TP5088 along with the Chip Select. The TP5088 generates the DTMF signal for the digit. The COP888CG takes care of the timing required between two digits and also the on-time of the DTMF signal for each digit. The output of the DTMF signal goes to the TP5700A which interfaces with the Tip and Ring of the telephone lines. The TP5700A receives the signal from the telephone lines and LM567 along with the associated circuitry is used to detect whether the required frequency signal was sent by the unit responding to the telephone. The output of the LM567 is connected to Port I pin 5. The Receiver Routine polls the Port I pin 5 periodically to check for response from the unit dialed by the Auto-Dialer Unit.

Receiver Routine

This is the main interrupt service routine of the ASM System. The Receiver Unit interfaces with the COP888CG

through the L port pin 4. Upon receipt of the signal from the Sensors and Transmitter Unit the Receiver Unit activates a relay which causes a MIWU/Interrupt. The interrupt service routine then waits for 10 seconds before reacting to the signal. This time is allowed to disarm the Security/Monitoring System. The Time Keeping Routine is used to calculate the delay and if the user disarms the System by toggling a switch the signal is ignored. Otherwise the Non-Volatile Storage Routine is executed to read the telephone number and this information is passed on to the Auto-Dialer Unit. The Auto-Dialer Unit dials the number and looks for a response over the telephone line. If however, there is no response, the Receiver Routine times out after a minute and tries the same number again. The number of trials can be modified in software and the time out period can also be changed. In the ASM System the number of trials is two. With slight modification the Auto-Dialer Unit can be made to dial a different number during the second attempt. The real time and date of occurrence of the event is stored in the NMC9306 along with the outcome of the telephone call. This routine keeps track of the non-volatile memory capacity and if it overflows, it prompts the user on the terminal of the same. The user is given the choice to overwrite the non-volatile memory or replace the device.

USING THE ASM SYSTEM

The ASM System upon installation and initial power-up has some preliminary steps to be performed. The time and date should be set, the phone number to be dialed by the Auto-Dialer Unit should be programmed. The toggle switch could be used to toggle the display between Hours-Minutes and Seconds-1/80th of Seconds.

Setting Time and Date

The steps involved in setting the time and date are:

1. Press key A on the keypad. The LED display flashes.
2. Set the desired time (Hours and Minutes) using the keypad.
3. The LED display and the Terminal Screen displays the time set.
4. Press key C on the keypad. The display toggles and displays the date.
5. Press key A on the keypad. The LED display begins to flash.
6. Set the date (month and day) using the keypad.
7. The LED display now shows the date set.
8. The LED display could be toggled to show the time using the toggle switch. However, the system after one minute will default to display time.

Programming the Phone Number

The phone number to be dialed could be programmed in two ways, i.e., using the terminal or the keypad. Using the terminal, the steps to be performed are:

1. Press CNTRL B on the terminal keyboard. The COP888CG sends a carriage return to terminal.
2. Press CNTRL D on the terminal keyboard. Then type the number to be dialed. At the end press CNTRL C to end programming.

Using the keypad, perform the following steps:

1. Press "*" key on the keypad.
2. Press the digits to be dialed.

3. Press “#” key on the keypad to end programming the number.

The ASM System is now ready to start monitoring. Upon receipt of the alarm signal from the Receiving Unit the ASM System will dial the number programmed. In order to display the history of events on the terminal screen press CNTRL S from the terminal keyboard.

CONCLUSIONS

The architecture, features and flexibility of the COP800 family of microcontrollers makes it cost-effective as the work-

horse of any system by eliminating external components from the circuit. This approach not only reduces the system cost and development time, but also increases the flexibility and market life of the product.

The Automated Security/Monitoring System implemented using the COP888CG illustrates a single chip system solution. The application also illustrates interfacing the COP888CG to a number of specialized peripherals using an absolute minimum number of I/O lines. The ASM System approximately uses 3k bytes of program memory (ROM) space and demonstrates an efficient method of handling multi-sourced interrupts.

Sound Effects for the COP800 Family

National Semiconductor
Application Note 663
Jerry Leventer

This application note describes the creation of sound effects using National Semiconductor's COP800 family of microcontrollers. The following applications are described in detail:

1. Whistle
2. White Noise
3. Explosion
4. Bomb
5. Laser Gun

These applications were developed on a COP820C using a 20 MHz crystal and a 1 μ s instruction cycle time. By making the appropriate changes to control registers within the routines, slower clock speeds may be used. Program flow diagrams and complete source codes are included in this document.

I. WHISTLE

The whistle routine utilizes the timer underflow interrupt and employs the TIO function on pin G3. Each timer underflow causes the TIO pin to toggle. This creates a tone whose frequency remains constant as long as the timer autoreload register value remains unchanged. In order to create a descending or ascending whistle tone, the autoreload register value is increased or decreased after every thirty-two timer interrupts (FCNTR register is used to count the interrupts). When the maximum or minimum frequency has been reached, the autoreload value must be reinitialized so that the whistle frequency does not exceed the desired range.

II. WHITE NOISE

White noise is generated by using a random number generating algorithm called a RING COUNTER. One random number is extracted periodically and placed into the MICROWIRE/PLUS™ serial shift register. These bits are shifted onto the serial output (SO) pin which is wired to a transistor amplifier that drives a speaker. The serial input (SI) and serial output (SO) pins must be tied together.

The RING COUNTER is a pseudo-random number generator which operates on the principle of a linear feedback shift register (see *Figure 1*). This shift register is not to be confused with the MICROWIRE/PLUS serial shift register. Rather it is created using two bytes of data memory (RAM), and the carry flag. Each bit is called a "stage" with the carry flag being "stage 1" and bit 0 of the two byte data register being "stage 17". Using a seventeen stage shift register results in a clean tone with little distortion.

Implementation of the ring counter shift register is accomplished by a rotate right with carry instruction (RRC A). The linear feedback function is accomplished using an "exclusive or" on stages fourteen and seventeen. This particular choice of feedback stages results in a complete cycle of bit combinations, ($2^{17} - 1$), as long as the loop does not begin with zero in the RINGVAL register.

The "exclusive or" function is not explicit in that the XOR instruction is not used. Rather, stages seventeen and fourteen are tested in software using the principle that if only one of them is set then the result is a logic one, otherwise the result is logic zero. It turns out that since the rotate occurs prior to the test, the actual bits tested are the carry flag (stage 1) and bit 2 (stage 15).

A short example using four bits can be used to demonstrate how the ring counter works (see *Figure 2*). If you perform the "exclusive or" on stages three and four, then a complete cycle results. If instead, you use stages two and four, two cycles of six and one cycle of three results depending on the bit combination you begin with.

III. EXPLOSION

The explosion sound effect is generated by manipulating the white noise algorithm to begin with a high pitch and progress to a lower pitch. This is done by altering the rate (contained in the register LUPREG) at which the random numbers are extracted from the ring counter before being placed into the MICROWIRE/PLUS serial shift register (SIOR). If for example LUPREG initially contains the value 4, the white noise will be at a high pitch. By incrementing this number after every ten timer interrupts (using the register TCNTR) the white noise pitch will be reduced. Several other registers are used to provide control of strategic portions of sound within the routine. First and last tones are controlled with FIRSTR and LASTR. The value in EXITR is used to control the overall length of the explosion and the length of each tone is controlled by the register TCNTR. To vary the white noise pitch, the register LUPCNT is used. The value in LUPCNT is incremented each time the pitch of the white noise is decreased within the timer interrupt routine. Prior to entering the ring count loop, LUPCNT is loaded into LUPREG. The serial input (SI) pin must be tied to the serial output (SO) pin.

IV. BOMB

The bomb sound effect combines the descending whistle with an explosion at the end. The TIMER I/O (TIO) and serial input (SI) pins must be tied to the serial output (SO) pin. The explosion portion of this routine was altered slightly in that the first tone control register (FIRSTR) was removed. The first initialization of TCNTR, the tone control register, provides a means to control the first tone length. Subsequent tones are controlled (at label NF2 in the timer interrupt routine) where TCNTR is reinitialized. Both versions were retained for comparison and in the event that greater control of the first tone is needed.

V. LASER GUN

The laser gun sound effect combines the output from the white noise routine and the COP800 timer I/O (TIO) pin (tie TIO to SO). The SI pin is not tied to SO in this application and the ring counter uses only nine stages instead of seventeen.

The registers used for program control are EXITR, TCNTR, and the TIMER. By adjusting the value in EXITR the duration of the laser "shot" can be shortened or lengthened. (A value larger than 03F hex may create problems.) By adjusting the TIMER values (TVALO, TVALHI) and the tone counter (TCNTR) value, interesting variations in the laser sound can be attained.

NOTE: This note applies to all routines that use both the timer interrupt and the ring counter: In order to return to the main program from which the subroutine was called, the stack pointer must be manually restored during the timer interrupt before executing the return (RET) instruction. The reason for this is that the timer interrupt is two levels below the main program. A simple return statement will only serve to return to the ring counter routine from the point at which the timer interrupt occurred. By adding two to the stack pointer (SP + 2), the return statement will force the address of the instruction following the JSR in MAIN into the program counter (PC) from which point execution will continue.

DTMF Generation with a 3.58 MHz Crystal

National Semiconductor
Application Note 666
Verne H. Wilson

AN-666

DTMF (Dual Tone Multiple Frequency) is associated with digital telephony, and provides two selected output frequencies (one high band, one low band) for a duration of 100 ms. DTMF generation consists of selecting and combining two audio tone frequencies associated with the rows (low band frequency) and columns (high band frequency) of a push-button touch tone telephone keypad.

This application note outlines two different methods of DTMF generation using a COP820C/840C microcontroller clocked with a 3.58 MHz crystal in the divide by 10 mode. This yields an instruction cycle time of 2.79 μ s. The application note also provides a low true row/column decoder for the DTMF keyboard.

The first method of DTMF generation provides two PWM (Pulse Width Modulation) outputs on pins G3 and G2 of the G port for 100 ms. These two PWM outputs represent the selected high band and low band frequencies respectively, and must be combined externally with an LM324 op amp or equivalent feed back circuit to produce the DTMF signal.

The second method of DTMF generation uses ROM lookup tables to simulate the two selected DTMF frequencies. These table lookup values for the selected high band and low band frequencies are then combined arithmetically. The high band frequencies contain a higher bias value to compensate for the DTMF requirement that the high band frequency component be 2 dB above the low band frequency component to compensate for losses in transmission. The resultant value from the arithmetic combination of sine wave values is output on L port pins L0 to L5, and must be combined externally with a six input resistor ladder network to produce the DTMF signal. This resultant value is updated every 118 μ s. The COP820C/840C timer is used to time out the 100 ms duration of the DTMF. A timer interrupt at the end of the 100 ms is used to terminate the DTMF output. The external ladder network need not contain any active components, unlike the first method of DTMF generation with the two PWM outputs into the LM324 op amp.

The associated COP820C/840C program for the DTMF generation is organized as three subroutines. The first subroutine (KBRDEC) converts the low true column/row input from the DTMF keyboard into the associated DTMF hexadecimal digit. In turn, this hex digit provides the input for the other two subroutines (DTMFGP and DTMFLP), which represent the two different methods of DTMF generation. These three subroutines contain 35, 94, and 301 bytes of COP820C/840C code respectively, including all associated ROM tables. The Program Code/ROM table breakdowns are 19/16, 78/16, and 88/213 bytes respectively.

DTMF KEYBOARD MATRIX

The matrix for selecting the high and low band frequencies associated with each key is shown in *Figure 1*. Each key is uniquely referenced by selecting one of the four low band frequencies associated with the matrix rows, coupled with selecting one of the four high band frequencies associated with the matrix columns. The low band frequencies are

697 Hz, 770 Hz, 852 Hz, and 941 Hz, while the high band frequencies are 1209 Hz, 1336 Hz, 1477 Hz, and 1633 Hz. The DTMF keyboard input decode subroutine assumes that the keyboard is encoded in a low true row/column format, where the keyboard is strobed sequentially with four low true column selects with each returning a low true row select. The low true column and row selects are encoded in the upper and lower nibbles respectively of the accumulator, which serves as the input to the DTMF keyboard input decode subroutine. The subroutine will then generate the DTMF hexadecimal digit associated with the DTMF keyboard input digit.

The DTMF keyboard decode subroutine (KBRDEC) utilizes a common ROM table lookup for each of the two nibbles representing the low true column and row encodings for the keyboard. The only legal low true nibbles for a single key input are E, D, B, and 7. All other low true nibble values represent multiple keys, no key, or no column strobe. Results from two legal nibble table lookups (from the same 16 byte ROM table) are combined to form a hex digit with the binary format of 0000RRCC, where RR represents the four row values and CC represents the four column values. The illegal nibbles are trapped, and the subroutine is exited with a RET (return) command to indicate multiple keys or no key. A pair of legal nibble table lookups result in the subroutine being exited with a RETSK (return and skip) command to indicate a single key input. This KBRDEC subroutine uses 35 bytes of code, consisting of 19 bytes of program code and 16 bytes of ROM table.

DTMF GENERATION USING PWM AND AN OP AMP

The first DTMF generation method (using the DTMFGP subroutine) generates the selected high band and low band frequencies as PWM (Pulse Width Modulation) outputs on pins G3 and G2 respectively of the G port. The COP820C/840C microcontrollers each contain only one timer, and three times must be generated to satisfy the DTMF application. These three times are the half periods of the two selected frequencies and the 100 ms duration period. Obviously the single timer can only generate one of the required times, while the program must generate the two remaining times. The solution lies in dividing the 100 ms duration time by the half periods for each of the eight DTMF frequencies, and then examining the respective high band and low band quotients and remainders. Naturally these divisions must be normalized to the instruction cycle time (t_c). 100 ms represents 35796 t_c 's. The results of these divisions are detailed in Table I.

The four high band frequencies are produced by running the COP820C/840C timer in PWM (Pulse Width Modulation) mode, while the program produces the four low band frequencies and the 100 ms duration timeout. The programmed times are achieved by using three programmed register counters R0, R2 and R3, with a backup register R1 to reload the counter R0. These three counters represent the half period, the 100 ms quotient, and the 100 ms remainder associated with each of the four low band frequencies.

FIGURE 1. DTMF Keyboard Matrix

TABLE I. Frequency Half Periods, Quotients and Remainders

	Freq. Hz	Half Period in μ s	Half Period in t_c 's	100 ms/0.5P in t_c 's	
				Quotient	Remainder
Low Band Frequencies	697	717.36	257	139	73
	770	649.35	232	154	68
	852	586.85	210	170	96
	941	531.35	190	188	76
High Band Frequencies	1209	413.56	148	241	128
	1336	374.25	134	267	18
	1477	338.53	121	295	101
	1633	306.18	110	325	46

Note: 100 ms represents 35796 t_c 's.

The DTMFGP subroutine starts by transforming the DTMF hex digit in the accumulator (with binary format 0000RRCC) into low and high frequency vectors with binary formats 0011RR11 and 0011CC00 respectively. The transformation of the hex digit 0000RRCC (where RR is the row select and CC is the column select) into the frequency vectors is shown in Table II. The conversion produces a timer vector 0011CC00 (T), and three programmed counter vectors for R1, R2, and R3. The formats for the three counter vectors are 0011RR11 (F), 0011RR10 (Q), and 0011RR01 (R). These four vectors created from the core vector are used as

inputs for a 16 byte ROM table using the LAID (Load Accumulator InDirect) instruction. One of these four vectors (the T vector) is a function of the column bits (CC), while the other three vectors (F, Q, R) are a function of the row bits (RR). This correlates to only one parameter being needed for the timer (representing the selected high band frequency), while three parameters are needed for the three counters (half period, 100 ms quotient, 100 ms remainder) associated with the low band frequency and 100 ms duration. The frequency parameter ROM translation table, accessed by the T, F, Q, and R vectors, is shown in Table III.

TABLE II. DTMF Hex Digit Translation

DTMF Hex Digit— 0000RRCC -----

Timer Vector	Timer	T	0011CC00
Half Period Vector	R1	F	0011RR11
100 ms Quotient Vector	R2	Q	0011RR10
100 ms Remainder Vector	R3	R	0011RR01

TABLE III. Frequency Parameter ROM Translation Table

T— Timer	F— Frequency	Q— Quotient	R— Remainder

0x3B	31	F	
0x3C	109	T	
0x3D	10	R	
0x3E	189	Q	
0x3F	26	F	

The theory of operation in producing the selected low band frequency starts with loading the three counters with values obtained from a ROM table. The half period for the selected frequency is counted out, after which the G2 output bit is toggled. During this half period countout, the quotient counter is decremented. This procedure is repeated until the quotient counter counts out, after which the program branches to the remainder loop. During the remainder loop, the remainder counter counts out to terminate the 100 ms. Following the remainder countout, the G2 and G3 bits are both reset, after which the DTMF subroutine is exited. Great care must be taken in time balancing the half period loop for

the selected low band frequency. Furthermore, the toggling of the G2 output bit (achieved with either a set or reset bit instruction) must also be exactly time balanced to maintain the half period time integrity. Local stall loops (consisting of a DRSZ instruction followed by a JP jump back to the DRSZ for a two byte, six instruction cycle loop) are embedded in both the half period and remainder loops. Consequently, the ROM table parameters for the half period and remainder counters are approximately only one-sixth of what otherwise might be expected. The program for the half period loop, along with the detailed time balancing of the loop for each of the low band frequencies, is shown in *Figure 2*.

	Program	Bytes/ Cycles	Conditional Cycles	Cycles	Total Cycles

	JP LUP1	1/3	3		40

Table III Frequency	Stall Loop	Total Cycles	Half Period
$[(38 - 1) \times 6]$	$\times 6$	+ 35	= 257
$[(33 - 1) \times 6]$	$\times 6$	+ 40	= 232
$[(31 - 1) \times 6]$	$\times 6$	+ 30	= 210
$[(26 - 1) \times 6]$	$\times 6$	+ 40	= 190

FIGURE 2. Time Balancing for Half Period Loop

TABLE IV. Time Balancing for Remainder Loop

Table III Remainder	Stall Loop	R Loop Overhead	Total Cycles	Table I Remainder
$[(10 - 1)]$	$\times 6]$	+ 20	= 74	73
$[(9 - 1)]$	$\times 6]$	+ 20	= 68	68
$[(14 - 1)]$	$\times 6]$	+ 20	= 98	96
$[(10 - 1)]$	$\times 6]$	+ 20	= 74	76

Note that the Q value in Table III is one greater than the quotient in Table I to compensate for the fact that the quotient count down to zero test is performed early in the half period loop. The overhead in the remainder loop is 20 instruction cycles. The detailed time balancing for the remainder loop is shown in Table IV.

The selected high band frequency is achieved by loading the half period count in t_c 's minus one (from Table III) into the timer autoreload register and running the timer in PWM output mode. The minus one is necessary since the timer toggles the G3 output bit when it underflows (counts down through zero), at which time the contents of the autoreload register are transferred into the timer.

In summary, the input digit from the keyboard (encoded in low true column/row format) is translated into a digit matrix vector XXXRRCC which is checked for 1001RRCC to indicate a single key entry. No key or multiple key entries will set a flag and terminate the DTMF subroutine. The digit matrix vector for a single key is transformed into the core vector 0000RRCC. The core vector is then translated into four other vectors (T, F, Q, R) which in turn are used to select four parameters from a 16 byte ROM table. These four parameters are used to load the timer, and the respective half period, quotient, and remainder counters. The 16 byte ROM table must be located starting at ROM location 0030 (or 0X30) in order to minimize program size, and has reference setups with the "OR A, #033" instruction for the F vector and the "OR A, #030" instruction for the T vector.

The three parameters associated with the two R bits of the core vector require a multi-level table lookup capability with the LAID instruction. This is achieved with the following section of code in the DTMF subroutine:

```

LD      B, #R1
LUP:   X      A, [B]
LD      A, [B, ]
LAID
X      A, [B+]
DEC     A
IFBNE  #4
JP      LUP

```

This program loads the F frequency vector into R1, and then decrements the vector each time around the loop. The vector is successively moved with the exchange commands from R1 to R2 to R3 as one of the same exchange commands loads the data from the ROM table into R1, R2, and R3. This successive decrementation of the F vector changes the F vector into the Q vector, and then changes the Q vector into the R vector. These vectors are used to access the ROM table with the LAID instruction. The B pointer is incremented each time around the loop after it has been used to store away the three selected ROM table parameters (one per loop). These three parameters are stored in sequential RAM locations R1, R2, and R3. The IFBNE test instruction is used to skip out of the loop once the three selected ROM table parameters have been accessed and stored away.

The timer is initialized to a count of 15 so that the first timer underflow and toggling of the G3 output bit (with timer PWM mode and G3 toggle output selected) will occur at the same time as the first toggling of the G2 output bit. The half period counts for the high band frequencies minus one are stored in the timer section of the ROM table. The selected value from this frequency ROM table is stored in the timer autoreload register. The timer is selected for PWM output mode and started with the instruction LD [B], #0B0 where the B pointer is selecting the CNTRL register at memory location 0EE.

This first DTMF generation subroutine for the COP820C/840C uses 94 bytes of code, consisting of 78 bytes of program code and 16 bytes of ROM table. A program test routine to sequentially call the DTMFGP subroutine for each of the 16 keyboard input digits is supplied with the listing for the DTMF35 program. This test routine uses a 16 byte ROM table to supply the low true encoded column/row keyboard input to the accumulator. An input from the I0 input pin of the I port is used to select which DTMF generation subroutine is to be used. The DTMFGP subroutine is selected with I0 = 0.

A TYPICAL OP AMP CONFIGURATION FOR MIXING THE TWO DTMF PWM OUTPUTS IS SHOWN IN FIGURE 3.

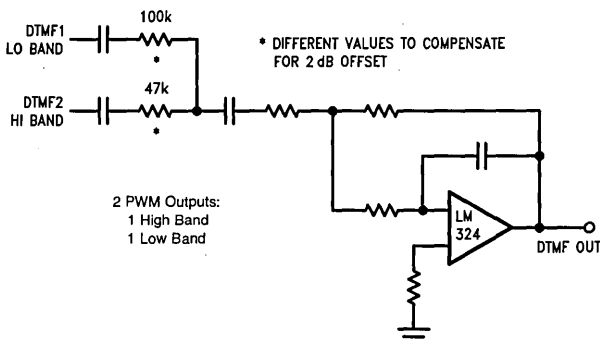

FIGURE 3. Typical Op Amp Configuration for Mixing DTMF PWM Outputs

TL/DD/10740-23

DTMF GENERATION USING A RESISTOR LADDER NETWORK

The second DTMF generation method (using the DTMFLP subroutine) generates and combines values from two table lookups simulating the two selected sine waves. The high band frequency table values have a higher base line value (16 versus 13) than the low band frequency table values. This higher bias for the high frequency values is necessary to satisfy the DTMF requirement that the high band DTMF frequencies need a value 2 dB greater than the low band DTMF frequencies to compensate for losses in transmission.

The resultant value from arithmetically combining the table lookup low band and high band frequency values is output on pins L0 to L5 of the L port in order to feed into a six input external resistor ladder network. The resultant value is updated every $117\frac{1}{3}$ μ s (one cycle of the LUP42 program loop). The LUP42 program loop contains 42 instruction cycles (t_C 's) of 2.7936511 μ s each for a total loop time of $117\frac{1}{3}$ μ s. The COP820C/840C timer is used to count out the 100 ms DTMF duration time.

An interrupt from the timer terminates the 100 ms DTMF output. Note that the Stack Pointer (SP) must be adjusted following the timer interrupt before returning from the DTMFLP subroutine.

The DTMFLP subroutine starts by quadrupling the value of the DTMF hex digit value in the accumulator, and then adding an offset value to reach the first value in the telephone key table. The telephone key ROM table contains four values associated with each of the 16 DTMF hex keys. These four values represent the low and high frequency table sizes and table starting addresses associated with the pair of frequencies (one low band, one high band) associated with each DTMF key. The FRLUP section of the program loads the four associated telephone key table values from the ROM table into the registers LFTBSZ (Low Freq Table Size), LFTADR (Low Freq Table Address), HFTBSZ (High Freq Table Size), and HFTADR (High Freq Table Address). The program then initializes the timer and autoreload register, starts the timer, and then jumps to LUP42. Note that the timer value in t_C 's is 100 ms plus one LUP42 time, since the initial DTMF output is not until the end of the LUP42 program.

Multiples of the magic number 118 μ s (approximately) are close approximations to all eight of the DTMF frequencies. The LUP42 program uses 42 instruction cycles (of 2.7936511 μ s each) to yield a LUP42 time of $117\frac{1}{3}$ μ s. The purpose of the LUP42 program is to update the six L port outputs by accessing and then combining the next set of

values from the selected low band and high band sine wave frequency tables in the ROM. The ROM table offset frequency pointers (LFPTR and HFPTR) must increment each time and then wrap around from top to bottom of the two selected ROM tables. The ROM table size parameters (LFTBSZ and HFTBSZ) for the selected frequencies are tested during each LUP42 to determine if the wrap around from ROM table top to bottom is necessary. The wrap around is implemented by clearing the frequency pointer in question. Note that the ROM tables are mapped from a reference of 0 to table size minus one, so that the table size is used in a direct comparison with the frequency offset pointer to test for the need for a wrap around. Also note that the offset pointer incremented value is used during the following LUP42 cycle, while the pre-incremented value of the pointer is used during the current cycle. However, it is the incremented value that is tested versus the table size for the need to wrap around.

After the low band and high band ROM table sine wave frequency values are accessed in each cycle of the LUP42 program, they are added together and then output to pins L0-L5 of the L port. As stated previously, the low band frequency values have a lower bias than the high band frequency values to compensate for the required 2 dB offset. Specifically, the base line and maximum values for the low frequency values are 13 and 26 respectively, while the base line and maximum values for the high frequency values are 16 and 32 respectively. Thus the combined base line value is 29, while the combined maximum value is 58. This gives a range of values on the L port output (L0-L5) from 0 to 58.

The minimum time necessary for the LUP42 update program loop is 36 instruction cycles including the jump back to the start of the loop. Consequently, two LAID instructions are inserted just prior to the jump back instruction at the end of LUP42 to supply the six extra NOP instruction cycles needed to increase the LUP42 instruction cycles from 36 to 42. A three cycle LAID instruction can always be used to simulate three single cycle NOP instructions if the accumulator data is not needed.

Table V shows the multiple LUP42 approximation to the eight DTMF frequencies, including the number of sine wave cycles and data points in the approximation. As an example, three cycles of a sine wave with a total of 19 data points across the three cycles is used to approximate the 1336 Hz DTMF frequency. The 19 cycles of LUP42 times the LUP42 time of $117\frac{1}{3}$ μ s is divided into the three cycles to yield a value of 1345.69 Hz. This gives an error of +0.73% when compared with the DTMF value of 1336 Hz. This is well within the 1.5% North American DTMF error range.

TABLE V. DTMF Frequency Approximation Table

DTMF Freq.	# of Sine Wave Cycles	# of Data Points	Calculation	Approx. Freq.	% Error
697	4	49	$4/(49 \times 117\frac{1}{3})$	= 695.73	-0.18
770	1	11	$1/(11 \times 117\frac{1}{3})$	= 774.79	+0.62
852	1	10	$1/(10 \times 117\frac{1}{3})$	= 852.27	+0.03
941	1	9	$1/(9 \times 117\frac{1}{3})$	= 946.97	+0.63
1209	1	7	$1/(7 \times 117\frac{1}{3})$	= 1217.53	+0.71
1336	3	19	$3/(19 \times 117\frac{1}{3})$	= 1345.69	+0.73
1477	4	23	$4/(23 \times 117\frac{1}{3})$	= 1482.21	+0.35
1633	4	21	$4/(21 \times 117\frac{1}{3})$	= 1623.38	-0.59

The frequency approximation is equal to the number of cycles of sine wave divided by the time in the total number of LUP42 cycles before the ROM table repeats.

The values in the DTMF sine wave ROM tables are calculated by computing the sine value at the appropriate points, scaling the sine value up to the base line value, and then adding the result to the base line value. The following example will help to clarify this calculation.

Consider the three cycles of sine wave across 19 data points for the 1336 Hz high band frequency. The first value in the table is the base line value of 16. With 2π radians per sine wave cycle, the succeeding values in the table represent the sine values of $1 \times (6\pi/19)$, $2 \times (6\pi/19)$, $3 \times (6\pi/19)$, . . . , up to $18 \times (6\pi/19)$. Consider the seventh and eighth values in the table, representing the sine values of $6 \times (6\pi/19)$ and $7 \times (6\pi/19)$ respectively. The respective calculators of $16 \times \sin[6 \times (6\pi/19)]$ and $16 \times \sin[7 \times (6\pi/19)]$ yield values of -5.20 and 9.83 . Rounding to the nearest integer gives values of -5 and 10 . When added to the base line value of 16, these values yield the results 11 and 26 for the seventh and eighth values in the 1336 Hz DTMF ROM table. Symmetry in the loop of 19 values in the DTMF table dictates that the fourteenth and thirteenth values in the table are 21 and 6, representing values of 5 and -10 from the calculations.

The area under a half cycle of sine wave relative to the area of the surrounding rectangle is $2/\pi$, where π radians represent the sine wave half cycle. This surrounding rectangle has a length of π and a height of 1, with the height representing the maximum sine value. Consequently, the area of the surrounding rectangle is π . The integral of the area under the half sine wave from 0 to π is equal to 2. The ratio of $2/\pi$ is equal to 63.66%, so that the total of the values for each half sine wave should approximate 63.66% of the sum of the max values. The maximum values (relative to the base line) are 13 and 16 respectively for the low and high band DTMF frequencies.

For the previous 1336 Hz example, the total of the absolute values for the 19 sine values from the 1336 Hz ROM

table is equal to 196. The surrounding rectangle for the three cycles of sine wave is 19 by 16 for a total area of 304. The ratio of 196/304 is 64.47% compared with the $2/\pi$ ratio of 63.66%. Thus the sine wave approximation gives an area abundance of 0.81% (equal to 64.47 - 63.66).

An application of the sine wave area criteria is shown in the generation of the DTMF 852 Hz frequency. The ten sine values calculated are 0, 7.64, 12.36, 12.36, 7.64, 0, -7.64 , -12.36 , -12.36 , and -7.64 . Rounding off to the nearest integer yields values of 0, 8, 12, 12, 8, 0, -8 , -12 , -12 and -8 . The total of these values (absolute numbers) is 80, while the area of the surrounding rectangle is 130 (10×13). The ratio of 80/130 is 61.54% compared with the $2/\pi$ ratio of 63.66%. Thus the sine wave approximation gives an area deficiency of 2.12% (equal to 63.66 - 61.54), which is overly deficient. Consequently, two of the ten sine values are augmented to yield sine values of 0, 8, 12, 13*, 8, 0, -8 , -12 , -13^* , and -8 . This gives an absolute total of 82 and a ratio of 82/130, which equals 63.08% and serves as a much better approximation to the $2/\pi$ ratio of 63.66%.

The sine wave area criteria is also used to modify two values in the DTMF 941 Hz frequency. The nine sine values calculated are 0, 8.36, 12.80, 11.26, 4.45, -4.45 , -11.26 , -12.80 , and -8.36 . Rounding off to the nearest integer yields values of 0, 8, 13, 11, 4, -4 , -11 , -13 , and -8 . The total of these values (absolute numbers) is 72, while the area of the surrounding rectangle is 117 (9×13). The ratio of 72/117 is 61.54% compared to the $2/\pi$ ratio of 63.66%. Thus the sine wave approximation gives an area deficiency of 2.12% (equal to 63.66 - 61.54), which is overly deficient. Rounding up the two values of 4.45 and -4.45 to 5 and -5 , rather than down to 4 and -4 , yields values of 0, 8, 13, 11, 5, -5 , -11 , -13 and -8 . This gives an absolute total of 74 and a ratio of 74/117, which equals 63.25% and serves as a much better approximation to the $2/\pi$ ratio of 63.66%.

With these modified values for the 852 and 941 DTMF frequencies, the area criteria ratio of $2/\pi$ = 63.66% for the sine wave compared to the surrounding rectangle has the following values:

DTMF Freq.	Sum of Values	Rectangle Area	Percentage	Diff.
697 Hz	406	$49 \times 13 = 637$	63.74%	+0.08%
770 Hz	92	$11 \times 13 = 143$	64.34%	+0.68%
852 Hz	82	$10 \times 13 = 130$	63.08%	-0.58%
941 Hz	74	$9 \times 13 = 117$	63.25%	-0.41%
1209 Hz	72	$7 \times 16 = 112$	64.29%	+0.63%
1336 Hz	196	$19 \times 16 = 304$	64.47%	+0.81%
1477 Hz	232	$23 \times 16 = 368$	63.04%	-0.62%
1633 Hz	216	$21 \times 16 = 336$	64.29%	+0.63%

The LUP42 program loop is interrupted by the COP820C/840C timer after 100 ms of DTMF output. As stated previously, the Stack Pointer (SP) must be adjusted (incremented by 2) following the timer interrupt before returning from the DTMFLP subroutine.

This second DTMF generation subroutine for the COP820C/840C uses 301 bytes of code, consisting of 88 bytes of program code and 213 bytes of ROM table. The following is a summary of the DTMFLP subroutine code allocation.

DTMFLP Code Allocation	# of Bytes
1. Subroutine Header Code	42
2. Interrupt Code	16
3. LUP42 Code	30
4. Telephone Key Table	64
5. Sine Value Tables	149
Total	301

A program test routine to sequentially call the DTMFLP subroutine for each of the 16 DTMF keyboard input digits is supplied with the listing for the DTMF35 program. This test routine uses a 16 byte ROM table to supply the low true encoded column/row keyboard input to the accumulator. An input from the I0 pin of the I port is used to select which DTMF generation subroutine is to be used. The DTMFLP subroutine is selected with I0 = 1.

A TYPICAL RESISTOR LADDER NETWORK IS SHOWN IN FIGURE 4.

SUMMARY

In summary, the DTMF35 program assumes a COP820C/840C clocked with a 3.58 MHz crystal in divide by 10 mode. The DTMF35 program contains three subroutines, KBRDEC, DTMFGP, and DTMFLP. The KBRDEC subroutine is a low true DTMF keyboard decoder, while the DTMFGP and DTMFLP subroutines represent the alternative methods of DTMF generation.

The KBRDEC subroutine provides a low true decoding of the DTMF keyboard input and assumes that the keyboard input has been encoded in a low true column/row format, with the columns of the keyboard being sequentially strobed.

The DTMFGP subroutine produces two PWM (Pulse Width Modulation) outputs (representing the selected high and low band DTMF frequencies) for combination with an external op amp network (LM324 or equivalent).

The DTMFLP subroutine produces six bits of combined high band and low band DTMF frequency output for combination in an external resistor ladder network. This output represents a combined sine wave simulation of the two selected DTMF frequencies by combining values from two selected ROM tables, and updating these values every 118 μ s.

The three DTMF35 subroutines contain the following number of bytes of program and ROM table memory:

Subroutine	# of Bytes of Program	# of Bytes of ROM Table	Total # of Bytes
KBRDEC	19	16	35
DTMFGP	78	16	94
DTMFLP	88	213	301

471          .FORM
472          ;
473          ; THE FREQUENCY APPROXIMATION IS EQUAL TO THE NUMBER OF
474          ; CYCLES OF SINE WAVE DIVIDED BY THE TIME IN THE TOTAL
475          ; NUMBER OF LUP42 CYCLES BEFORE THE REPETITION OF THE
476          ; ROM TABLE. AS AN EXAMPLE, CONSIDER THE THREE CYCLES
477          ; OF SINE WAVE AND 19 VALUES IN THE ASSOCIATED 1336 HZ
478          ; ROM TABLE. THE 19 CYCLES OF LUP42 TIMES THE LUP42
479          ; TIME OF 117 1/3 USEC IS DIVIDED INTO THE THREE CYCLES
480          ; OF SINE WAVE TO YIELD A VALUE OF 1345.69 HZ AS THE
481          ; 1336 HZ APPROXIMATION.
482          ;
483          ; THE VALUES IN THE ROM TABLES FOR THE DTMF SINE WAVES
484          ; SHOULD WRAP AROUND END TO END IN EITHER DIRECTION TO
485          ; FORM A SYMETRICAL LOOP. THE FIRST VALUE IN THE ROM
486          ; TABLE REPRESENTS THE BASE LINE FOR THAT FREQUENCY.
487          ;
488          ; THE HIGH BAND DTMF FREQUENCIES HAVE A BASE LINE VALUE
489          ; OF 16 AND A MAXIMUM VALUE OF 32. THE LOW BAND DTMF
490          ; FREQUENCIES HAVE A BASE LINE VALUE OF 13 AND A
491          ; MAXIMUM VALUE OF 26. THIS DIFFERENCE IN BASE LINE
492          ; VALUES IS NECESSARY TO SATISFY THE REQUIREMENT OF THE
493          ; HIGH BAND FREQUENCIES NEEDING A LEVEL 2 DB ABOVE THE
494          ; LEVEL OF THE LOW BAND FREQUENCIES TO COMPENSATE FOR
495          ; LOSSES IN TRANSMISSION. THE SUM OF THE TWO BASE LINE
496          ; VALUES YIELDS A BASE LINE VALUE OF 29, WHILE THE SUM
497          ; OF THE TWO MAXIMUM VALUES YIELDS A MAXIMUM VALUE OF
498          ; 58. THUS THE SIX BIT DTMF OUTPUT FROM THE L PORT TO
499          ; THE LADDER NETWORK RANGES FROM 0 TO 58, WITH A BASE
500          ; LINE VALUE OF 29.
501          ;
502          ; THE VALUES IN THE DTMF SINE WAVE TABLES ARE
503          ; CALCULATED BY COMPUTING THE SINE VALUE AT THE
504          ; APPROPRIATE POINTS, SCALING THE SINE VALUE UP TO THE
505          ; BASE LINE VALUE, AND THEN ADDING THE RESULT TO THE
506          ; BASE LINE VALUE. THE FOLLOWING EXAMPLE WILL HELP TO
507          ; CLARIFY THIS CALCULATION.
508          ;
509          ; CONSIDER THE THREE CYCLES OF SINE WAVE ACROSS 19
510          ; DATA POINTS FOR THE 1336 HZ DTMF HIGH BAND FREQUENCY.
511          ; THE FIRST VALUE IN THE TABLE IS THE BASE LINE VALUE
512          ; OF 16. WITH 2 PI RADIANS PER SINE WAVE CYCLE,
513          ; THE SUCCEEDING VALUES IN THE TABLE REPRESENT THE
514          ; SINE VALUES OF 1 X (6 PI / 19), 2 X (6 PI / 19),
515          ; 3 X (6 PI / 19), . . . . , UP TO 18 X (6 PI / 19).
516          ; LET US NOW CONSIDER THE SEVENTH AND EIGHTH VALUES
517          ; IN THE TABLE, REPRESENTING THE SINE VALUES OF
518          ; 6 X (6 PI / 19) AND 7 X (6 PI / 19) RESPECTIVELY.
519          ; THE CALCULATIONS OF 16 X SIN [6 X (6 PI / 19)] AND
520          ; 16 X SIN [7 X (6 PI / 19)] YIELD VALUES OF - 5.20 AND
521          ; 9.83 RESPECTIVELY. ROUNDED TO THE NEAREST INTEGER

```

TL/DD/10740-12

```

522 ; GIVES VALUES OF - 5 AND 10. WHEN ADDED TO THE BASE
523 ; LINE VALUE OF 16, THESE VALUES YIELD THE RESULTS
524 ; 11 AND 26 FOR THE SEVENTH AND EIGHTH VALUES IN THE
525 ; 1336 HZ DTMF TABLE. SYMMETRY IN THE LOOP OF 19 VALUES
526 ; IN THE DTMF TABLE DICTATES THAT THE FOURTEENTH AND
527 ; THIRTEENTH VALUES IN THE TABLE ARE 21 AND 6,
528 ; REPRESENTING VALUES OF 5 AND - 10 FROM THE
529 ; CALCULATIONS.
530 ;
531 ; THE AREA UNDER A HALF CYCLE OF SINE WAVE RELATIVE TO
532 ; THE AREA OF THE SURROUNDING RECTANGLE IS 2/PI, WHERE
533 ; PI RADIANS REPRESENT THE SINE WAVE HALF CYCLE. THIS
534 ; SURROUNDING RECTANGLE HAS A LENGTH OF PI AND A HEIGHT
535 ; OF 1, WITH THE HEIGHT REPRESENTING THE MAXIMUM SINE
536 ; VALUE. CONSEQUENTLY, THE AREA OF THIS SURROUNDING
537 ; RECTANGLE IS PI. THE INTEGRAL OF THE AREA UNDER THE
538 ; HALF SINE WAVE FROM 0 TO PI IS EQUAL TO 2. THE RATIO
539 ; OF 2/PI IS EQUAL TO 63.66 % , SO THAT THE TOTAL OF
540 ; THE VALUES FOR EACH HALF SINE WAVE SHOULD APPROXIMATE
541 ; 63.66 % OF THE SUM OF THE MAX VALUES. THE MAXIMUM
542 ; VALUES (RELATIVE TO THE BASE LINE) ARE 13 AND 16
543 ; RESPECTIVELY, FOR THE LOW AND HIGH BAND FREQUENCIES.

2-Way Multiplexed LCD Drive and Low Cost A/D Converter Using V/F Techniques with COP8 Microcontrollers

National Semiconductor
Application Note 673
Volker Soffel

ABSTRACT

This application note is intended to show a general solution for implementing a low cost A/D and a 2-way multiplexed LCD drive using National Semiconductor's COP840C 8-bit microcontroller. The implementation is demonstrated by means of a digital personal scale. Details and function of the weight sensor itself are not covered in this note. Also the algorithms used to calculate the weight from the measured frequency are not included, as they are too specific and depend on the kind of sensor used.

Typical Applications

- Weighing scales
- Sensors with voltage output
- Capacitive or resistive sensors
- All kinds of measuring equipment
- Automotive test and control systems

Features

- 2-way multiplexed LCD drive capability up to 30 segments (4 digit and 2 dot points)
- Precision frequency measurement
- Low current consumption
- Current saving HALT mode
- Additional computing power for application specific tasks

INTRODUCTION

Today's most popular digital scales all have the following characteristics:

They are battery powered and use a LCD to display the weight. Instead of using a discrete A/D-converter, in many cases a V/F converter is used, which converts an output voltage change of the weight sensor to a frequency change. This frequency is measured by a microcontroller and is used to calculate the weight. The advantages of a V/F over an A/D converter are multifold. Only one line from the V/F to the microcontroller is needed, whereas a parallel A/D needs at least 8 lines or even more (National also offers A/Ds with serial output). A V/F can be constructed very simply using National Semiconductor's low cost, precision voltage to frequency converters LM331 or LM331A. Other possibilities are using Op-amps or a 555-timer in astable mode.

V/F-CONVERSION

Hardware

The basic configuration of the scale described in this application note is shown in *Figure 1*.

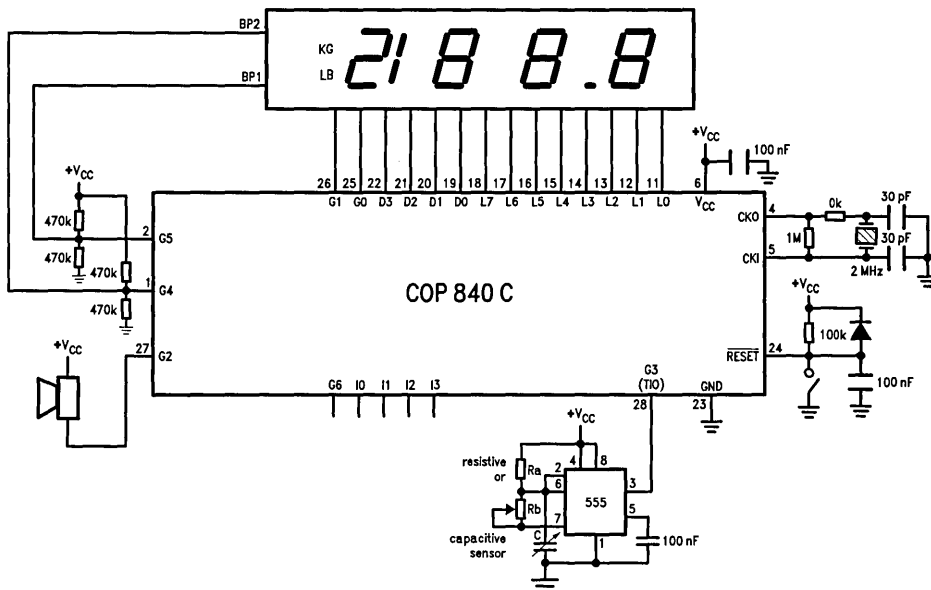

FIGURE 1. System Diagram

TL/DD/10788-1

A capacitive or resistive sensor's weight related capacitance or resistance change is transformed by a 555 timer (in astable mode) to a change of frequency. The output frequency f is determined by the formula:

$$f = 1.44 / ((Ra + 2Rb) * C)$$

The output high time is given by:

$$t1 = 0.693 * (Ra + Rb) * C$$

The output low time is given by:

$$t2 = 0.693 * Rb * C$$

This frequency is measured using the COP800 16-bit timer in the "input capture" mode. After calculation, the weight is displayed on a 2-way multiplexed LCD. Using this configuration a complete scale can be built using only two ICs and a few external passive components.

For more information on V/F converters generally used with voltage output sensors, refer to the literature listed in the reference section.

Frequency Measurement

The COP 16-bit timer is ideally suited for precise frequency measurements with minimum software overhead. This timer has three programmable operating modes, of which the "input capture" mode is used for the frequency measurement. Allocated with the timer is a 16-bit "autoload/capture register". The G3-I/O-pin serves as the timer capture input (TIO). In the "input capture" mode the timer is decremented with the instruction cycle frequency (t_c). Each positive going edge at TIO (also neg. edge programmable) causes the timer value to be copied automatically to the autoload/capture register without stopping the timer or destroying its

contents. The "timer pending" flag (TPND) in the PSW-register is set to indicate a capture has occurred, and if the timer-interrupt is enabled, an interrupt is generated. The frequency measurement routine listed below executes the following operations (refer to the RAM/register definition file listed at the beginning for symbolic names used in the routines):

The timer is preset with FFFF Hex and is started by setting the TRUN bit, after which the software checks the TPND-flag in a loop (timer interrupt is disabled). When the TPND flag is set the first time, the contents of the capture register is saved in RAM locations STALO and STAHI (start value). The TPND pending flag now must be reset by the software. Then, another 255 positive going edges are counted (equal to 255 pulses) before the capture register is saved in RAM locations ENDLO, ENDHI (end value). The shortest time period that can be measured depends on the number of instruction cycles needed to save the capture register, because with the next positive going edge on TIO the contents of the capture register is overwritten (worst case is 18 instruction cycles, which equals a max. frequency of 55.5 kHz at $t_c = 1 \mu s$).

The end-value is subtracted from the start-value and the result is restored in RAM locations STALO, STAHI. This value can then be used to calculate the time period of the frequency applied to TIO (G3) by multiplying it with the t_c -time and dividing the result by the number of pulses measured ($N = 255$).

$$T = (\text{startvalue} - \text{endvalue}) * t_c / N$$

TL/DD/10788-6

2-WAY MULTIPLEXED LCD DRIVE

Today a wide variety of LCDs, ranging from static to multiplex rates of 1:64 are available on the market. The multiplex rate of a LCD can be determined by the number of its backplanes (segment-common plate). The higher the multiplex rate the more individual segments can be controlled using only one line. e.g. a static LCD only has one backplane; only one segment can be controlled with one line. A two-way multiplexed LCD has two backplanes and two segments can be controlled with one line, etc.

Common to all LCDs is the fact that the drive voltage applied to the backplane(s) and segments has to be alternating. DC-components higher than 100 mV can cause electrochemical reactions (refer to manufacturer's spec), which reduce reliability and lifetime of the display.

If the multiplex ratio of the LCD is N and the amount of available outputs is M, the number of segments that can be driven is:

$$S = (M - N) * N$$

So the maximum number of a 2-way mux LCD's segments that can be driven with a COP800 in 28-pin package (if all outputs can be used to drive the LCD) is:

$$S = (18 - 2) * 2 = 32$$

During one LCD refresh cycle tx (typical values for 1/tx = fx are in the range 30 Hz . . . 60 Hz), three different voltages levels: Vop, 0.5*Vop and 0V have to be generated. The "off" voltage across a segment is not 0V as with static LCDs and also the "on" voltage is not Vop, but only a fraction of it. The ratio of "on" to "off" r.m.s.-voltage (discrimination) is determined by the multiplex ratio and the number of voltage levels involved. The most desirable discrimination ratio is one that maximizes the ratio of VON to VOFF, allowing the maximum voltage difference between activated and non-activated states. In general the maximum achievable ratio for any particular value of N is given by:

$$(V_{ON}/V_{OFF})_{max} = \text{SQR}((\text{SQR}(N) + 1)/(\text{SQR}(N) - 1))$$

$$\text{SQR} = \text{square root}$$

Using this formula the maximum achievable discrimination ratio for a 2-way multiplex LCD is 2.41, however, it is also possible to order a customized display with a smaller ratio. For ease of operation, most LCD drivers use equal voltage steps (0V, 0.5 *Vop, Vop). Thus a discrimination ratio of 2.24 is achieved. When using the COP800 to drive a 2-way multiplexed LCD the only external hardware required to achieve the three voltage steps are 4 equal resistors that form two voltage dividers—one for each backplane

(Figure 1). The procedure is to set G4 and G5 to "0" for 0V, to HI-Z (TRI-STATE®) for 0.5*Vop and to "1" in order to establish Vop at the backplane electrodes.

With the COP800 each I/O pin can be set individually to TRI-STATE, "1" or "0", so this procedure can be implemented very easily.

The current consumption of typical LCDs is in the range of 3 µA to 4 µA (at Vop = 4.5V, refresh rate 60 Hz) per square centimeter of activated area. Thus the backplane and segment terminals can be treated as HI-Z loads. At high refresh rates the LCD's current consumption increases dramatically, which is the reason why many LCD manufacturers recommend not using a refresh frequency higher than 60 Hz.

Timing Considerations

As shown in Figures 2 and 3, one LCD refresh cycle tx is subdivided into four equally distant time sections ta, tb, tc and td during which the backplane and segment terminals have to be updated in order to switch a specific segment on or off. Considering a refresh frequency of 50 Hz (tx = 20 ms) ta, tb, tc and td are equal to 5 ms; a COP800 running from an external clock of 2 MHz has an internal instruction cycle time of 5 µs and a typical current consumption of less than 350 µA (at VCC = 3V and room temperature), thus meeting both the requirements of low current consumption and additional computing power between LCD refreshes.

The timing is done using the COP800's 16-bit timer in the PWM autoloader mode. The timer and the assigned 16-bit autoloader register are preset with proper values. By setting the TRUN-flag in the CNTRL-register the timer is decremented each instruction cycle. A flag (TPND) is set at underflow and the timer is automatically reloaded with the value stored in the autoloader-register. Timer underflow can also be programmed to generate an interrupt.

Segment Control

Figure 2 shows the voltage-waveforms applied to the two backplane-electrodes (a) and the waveform at a segment-electrode (b), which is needed to switch segment A on and segment B off. The resulting voltage over the segments (c and d) is achieved by subtracting waveform (b) from BP1 (segment A) and waveform (b) from BP2 (segment B).

Figure 3 shows the four different waveforms which must be generated to meet all possible combinations of two segments connected to the same driving terminal (off-off, on-off, off-on, on-on).

Figure 4 shows the internal segment and backplane connections for a typical 2-way mux LCD.

LCD Drive Subroutine

The LCD drive subroutine DISPL converts a 16-bit binary value to a 24-bit BCD-value for easier display data fetch. The drive subroutine itself is built up of a main routine doing the backplane refresh and 7 subroutines (SEG0, SEG1, SEG2, SEG3, SEGOUT, TTPND, DISPD). The subroutines SEG0 to SEG4 are used to get the LCD segment data from a look-up table in ROM for time phases ta, tb, tc and td respectively. Subroutine SEGOUT writes the segment data for each time phase to the corresponding output ports. One time phase takes 5 ms, giving a total refresh cycle time of 20 ms (50 Hz). The exact timing is done by using the COP800 16-bit timer in the PWM autoload mode. In that mode the timer is reloaded with the value stored in the autoload register on every timer underflow. At the same time the timer pending flag is set. The subroutine TTPND checks this flag in a loop. If the timer pending flag is set, this subroutine resets it and returns to the calling program. Thus a 5 ms time delay is created before the segment and backplane data for the next time phase is written to the output ports. Finally the subroutine DISPD switches off the LCD by setting the backplane and segment connections to "0". In this digital scale application a frequency measurement is made while the LCD is off. Then the weight is calculated from this frequency and is displayed for 10s. After this 10s the LCD is switched off again and the COP800 is programmed to enter the current saving HALT mode ($I_{DD} < 10 \mu A$). A new weight cycle on the digital scale is initiated by pressing a push button, which causes a reset of the microcontroller.

CONCLUSIONS

National Semiconductor's COP800 Microcontroller family is ideally suited for use with V/F converters and 2-way multiplexed LCDs, as they offer features, which are essential for these types of applications. The high resolution, 3-mode programmable 16-bit timer allows precise frequency measurement in the input capture mode with minimum software overhead. The timer's PWM autoreload mode offers an easy way to implement a precise timebase for the LCD refresh. The COP800's programmable I/O ports provide flexibility in driving 2-way multiplexed LCDs directly. The COP800 family, fabricated using M2CMOS technology, offers both low voltage (min V_{CC} of 2.5V) and low current drain.

PC[®] MOUSE Implementation Using COP800

National Semiconductor
Application Note 681
Alvin Chan

ABSTRACT

The mouse is a very convenient and popular device used in data entry in desktop computers and workstations. For desktop publishing, CAD, paint or drawing programs, using the mouse is inevitable. This application note will describe how to use the COP822C microcontroller to implement a mouse controller.

INTRODUCTION

Mouse Systems was the first company to introduce a mouse for PCs. Together with Microsoft and Logitech, they are the most popular vendors in the PC mouse market. Most mainstream PC programs that use pointing devices are able to support the communication protocols laid down by Mouse Systems and Microsoft.

A typical mouse consists of a microcontroller and its associated circuitry, which are a few capacitors, resistors and transistors. Accompanying the electronics are the mechanical parts, consisting of buttons, roller ball and two disks with slots. Together they perform several major functions: motion detection, host communication, power supply, and button status detection.

MOTION DETECTION

Motion detection with a mouse consists of four commonly known mechanisms. They are the mechanical mouse, the opto-mechanical mouse, the optical mouse and the wheel mouse.

The optical mouse differs from the rest as it requires no mechanical parts. It uses a special pad with a reflective surface and grid lines. Light emitted from the LEDs at the bottom of the mouse is reflected by the surface and movement is detected with photo-transistors.

The mechanical and the opto-mechanical mouse use a roller ball. The ball presses against two rollers which are connected to two disks for the encoding of horizontal and vertical motion. The mechanical mouse has contact points on the disks. As the disks move they touch the contact bars,

which in turn generates signals to the microcontroller. The opto-mechanical mouse uses disks that contain evenly spaced slots. Each disk has a pair of LEDs on one side and a pair of photo-transistors on the other side.

The wheel mouse has the same operation as the mechanical mouse except that the ball is eliminated and the rollers are rotated against the outside surface on which the mouse is placed.

HOST COMMUNICATION

Besides having different operating mechanisms, the mouse also has different modes of communication with the host. It can be done through the system bus, the serial port or a special connector. The bus mouse takes up an expansion slot in the PC. The serial mouse uses one of the COM ports.

Although the rest of this report will be based on the opto-mechanical mouse using the serial port connection, the same principle applies to the mechanical and the wheel mouse.

MOTION DETECTION FOR THE OPTO-MECHANICAL MOUSE

The mechanical parts of the opto-mechanical mouse actually consist of one roller ball, two rollers connected to the disks and two pieces of plastic with two slots on each one for LED light to pass through. The two slots are cut so that they form a 90 degree phase difference. The LEDs and the photo-transistors are separated by the disks and the plastic. As the disks move, light pulses are received by the photo-transistors. The microcontroller can then use these quadrature signals to decode the movement of the mouse.

Figure 1a shows the arrangement of the LEDs, disks, plastic and photo-transistors. The shaft connecting the disk and the ball is shown separately on *Figure 1b*. *Figure 2* shows the signals obtained from the photo-transistors when the mouse moves. The signals will not be exactly square waves because of unstable hand movements.

FIGURE 2

RESOLUTION, TRACKING SPEED AND BAUD RATE

The resolution of the mouse is defined as the number of movement counts the mouse can provide for each fixed distance travelled. It is dependent on the physical dimension of the ball and the rollers. It can be calculated by measuring the sizes of the mechanical parts.

An example for the calculation can be shown by making the following assumptions:

- The disks have 40 slots and 40 spokes
- Each spoke has two data counts
(This will be explained in the section "An Algorithm for Detecting Movements")
- Each slot also has two data counts
- The roller has a diameter of 5mm

For each revolution of the roller, there will be $40 \times 2 \times 2 = 160$ counts of data movement. At the same time, the mouse would have travelled a distance of $\pi \times 5 = 15.7\text{mm}$. Therefore the resolution of the mouse is $15.7/160 = 0.098\text{mm}$ per count. This is equivalent to 259 counts or dots per inch (dpi).

The tracking speed is defined as the fastest speed that the mouse can move without the microcontroller losing track of the movement. This depends on how fast the microcontroller can sample the pulses from the photo-transistors. The effect of a slow tracking speed will contribute to jerking movements of the cursor on the screen.

The baud rate is fixed by the software and the protocol of the mouse type that is being emulated. For mouse systems and microsoft mouse, they are both 1200. Baud rate will affect both the resolution and the tracking speed. The internal movement counter may overflow while the mouse is still sending the last report with a slow baud rate. With a fast baud rate, more reports can be sent for a certain distance moved and the cursor should appear to be smoother.

POWER SUPPLY FOR THE SERIAL MOUSE

Since the serial port of the PC has no power supply lines, the RTS, CTS, DTR and DSR RS232 interface lines are

utilized. Therefore the microcontroller and the mouse hardware should have very little power consumption. National Semiconductor's COP822C fits into this category perfectly. The voltage level in the RS232 lines can be either positive or negative. When they are positive, the power supply can be obtained by clamping down with diodes. When they are negative, a 555 timer is used as an oscillator to transform the voltage level to positive. The 1988 National Semiconductor Linear 3 Databook has an example of how to generate a variable duty cycle oscillator using the LMC555 in page 5-282.

While the RTS and DTR lines are used to provide the voltage for the mouse hardware, the TXD line of the host is utilized as the source for the communication signals. When idle, the TXD line is in the mark state, which is the most negative voltage. A prp transistor can be used to drive the voltage of the RXD pin to a voltage level that is compatible with the RS232 interface standard.

AN ALGORITHM FOR DETECTING MOVEMENTS

The input signal of the photo-transistors is similar to that shown in *Figure 2*. Track 1 leads track 0 by 90 degrees. Movement is recorded as either of the tracks changes state. State tables can be generated for clockwise and counter-clockwise motions.

With the two tracks being 90 degrees out of phase, there could be a total of four possible track states. It can be observed that the binary values formed by combining the present and previous states are unique for clockwise and counter-clockwise motion. A sixteen entry jump table can be formed to increment or decrement the position of the cursor. If the value obtained does not correspond to either the clockwise or counter-clockwise movement, it could be treated as noise. In that case either there is noise on the microcontroller input pins or the microcontroller is tracking motions faster than the movement of the mouse. A possible algorithm can be generated as follows. The number of instruction cycles for some instructions are shown on the left.

(TRK1, TRK0) _t (TRK1, TRK0) _{t-1} Binary Value				(TRK1, TRK0) _t (TRK1, TRK0) _{t-1} Binary Value					
CCW				CW					
0	1	0	0	4	1	0	0	0	8
1	1	0	1	D	0	0	0	1	1
1	0	1	1	B	0	1	1	1	7
0	0	1	0	2	1	1	1	0	E

```

Going through the longest route in the sensor routine takes 75 instruction cycles. So at 5 MHz the microcontroller can track movement changes within 150 μ s by using this algorithm.

MOUSE PROTOCOLS

Since most programs in the PC support the mouse systems and microsoft mouse, these two protocols will be discussed here. The protocols are byte-oriented and each byte is framed by one start-bit and two stop-bits. The most commonly used reporting mode is that a report will be sent if there is any change in the status of the position or of the buttons.

MICROSOFT COMPATIBLE DATA FORMAT

	Bit							
	6	5	4	3	2	1	0	Number
1	L	R	Y7	Y6	X7	X6	X5	Byte 1
0	X5	X4	X3	X2	X1	X0	Y0	Byte 2
0	Y5	Y4	Y3	Y2	Y1	Y0		Byte 3

L, R = Key data (Left, Right key) 1 = key depressed

X0-X7 = X distance 8-bit two's complement value -128 to +127

Y0-Y7 = Y distance 8-bit two's complement value -128 to +127

Positive = South

In the Microsoft Compatible Format, data is transferred in the form of seven-bit bytes. Y movement is positive to the south and negative to the north.

FIVE BYTE PACKED BINARY FORMAT (MOUSE SYSTEMS CORP)

	Bit								
	7	6	5	4	3	2	1	0	Number
1	0	0	0	0	L*	M*	R*		Byte 1
X7	X6	X5	X4	X3	X2	X1	X0		Byte 2
Y7	Y6	Y5	Y4	Y3	Y2	Y1	Y0		Byte 3
X7	X6	X5	X4	X3	X2	X1	X0		Byte 4
Y7	Y6	Y5	Y4	Y3	Y2	Y1	Y0		Byte 5

L*, M*, R* = Key data (Left, Middle, Right key), 0 = key depressed

X0-X7 = X distance 8-bit two's complement value -127 to +127

Y0-Y7 = Y distance 8-bit two's complement value -127 to +127

In the Five Byte Packed Binary Format data is transferred in the form of eight-bit bytes (eight data bits without parity). Bytes 4 and 5 are the movement of the mouse during the transmission of the first report.

THE COP822C MICROCONTROLLER

The COP822C is an 8-bit microcontroller with 20 pins, of which 16 are I/O pins. The I/O pins are separated into two ports, port L and port G. Port G has built-in Schmitt-triggered inputs. There is 1k of ROM and 64 bytes of RAM. In the mouse application, the COP822C's features used can be summarized below. Port G is used for the photo-transistor's input. Pin G0 is used as the external interrupt input to monitor the RTS signal for the microsoft compatible protocol. The internal timer can be used for baud rate timing and interrupt generation. The COP822C draws only 4 mA at a crystal frequency of 5 MHz. The instruction cycle time when operating at this frequency is 2 μ s.

A MOUSE EXAMPLE

The I/O pins for the COP822C are assigned as follows:

Pin	Function
G0	Interrupt Input (Monitoring RTS Toggle)
G1	Reserved for Input Data (TXD of Host)
G2	Output Data (RXD of Host)
G3-G6	LED Sensor Input
L0-L2	Button Input
L3	Jumper Input (for Default Mouse Mode)

The timer is assigned for baud rate generation. It is configured in the PWM auto-reload mode (with no G3 toggle output) with a value of 1A0 hex in both the timer and the auto-reload register. When operating at 5 MHz, it is equivalent to 833 μ s or 1200 baud. When the timer counts down, an interrupt is generated and the service routine will indicate in a timer status byte that it is time for the next bit. The subroutine that handles the transmission will look at this status byte to send the data.

The other interrupt comes from the G0 pin. This is implemented to satisfy the microsoft mouse requirement. As the RTS line toggles, it causes the microcontroller to be interrupted. The response to the toggling is the transmission of the character "M" to indicate the presence of the mouse.

The main program starts by doing some initializations. Then it loops through four subroutines that send the report, sense the movement, sense the buttons, and set up the report format.

Subroutine "SDATA" uses a state table to determine what is to be transmitted. There are 11 or 12 states because microsoft has only 7 data bits and mouse systems has 8. The state table is shown below:

SENDST	State
0	IDLE
1	START BIT
2-8	DATA (FOR MICROSOFT)
2-9	DATA (FOR MOUSE SYSTEMS)
9-10	STOP BIT (FOR MICROSOFT)
10-11	STOP BIT (FOR MOUSE SYSTEMS)
11	NEXT WORD (FOR MICROSOFT)
12	NEXT WORD (FOR MOUSE SYSTEMS)

The G2 pin is set to the level according to the state and the data bit that is transmitted.

Subroutine "SENSOR" checks the input pins connected to the LEDs. The horizontal direction is checked first followed by the vertical direction. Two jump tables are needed to decode the binary value formed by combining the present and previous status of the wheels. The movements are recorded in two counters.

Subroutines "BUTUS" and "BUTMS" are used for polling the button input. They compare the button input with the value polled last time and set up a flag if the value changes. Two subroutines are used for the ease of setting up reports for different mice. The same applies for subroutines "SRPTMS" and "SRPTUS" which set up the report format for transmission. The status change flag is checked and the report is formatted according to the mouse protocol. The

movement counters are then cleared. Since the sign of the vertical movement of mouse systems and microsoft is reversed, the counter value in subroutine "SRPTMS" is complemented to form the right value.

There is an extra subroutine "SY2RPT" which sets up the last two bytes in the mouse systems' report. It is called after the first three bytes of the report are sent.

The efficiency of the mouse depends solely on the effectiveness of the software to loop through sensing and transmission subroutines. For the COP822C, one of the most effective addressing modes is the B register indirect mode.

It uses only one byte and one instruction cycle. With autoincrement or autodecrement, it uses one byte and two instruction cycles. In order to utilize this addressing mode more often, the organization of the RAM data has to be carefully thought out. In the mouse example, it can be seen that by placing related variables next to each other, the saving of code and execution time is significant. Also, if the RAM data can fit in the first 16 bytes, the load B immediate instruction is also more efficient. The subroutine "SRPTMS" is shown below and it can be seen that more than half the instructions are B register indirect which are efficient and compact.

CONCLUSION

The COP822C has been used as a mouse controller. The code presented is a minimum requirement for implementing a mouse systems and microsoft compatible mouse. About 550 bytes of ROM code has been used. The remaining ROM area can be used for internal diagnostics and for communicating with the host's mouse driver program. The unused I/O pins can be used to turn the LED's on only when necessary to save extra power. This report demonstrated the use of the efficient instruction set of the COP800 family. It can be seen that the architecture of the COP822C is most suitable for implementing a mouse controller. The table below summarizes the advantages of the COP822C.

Feature	Advantage
Port G	Schmitt Triggered Input for Photo-Transistors
G0	External Interrupt for RTS Toggling
Timer	For Baud Rate Generation
Low Power	4 mA at 5 MHz
Small Size	20-Pin DIP

Using COP800 Devices to Control DC Stepper Motors

National Semiconductor
Application Note 714
Michelle Giles

INTRODUCTION

COP800 devices can be used to control DC stepper motors with limited effort. This application note describes the use of a COP820 to control the speed, direction and rotation angle of a stepper motor. In addition to the COP820, this application requires a quad high current peripheral driver (DS3658) to meet the high current needs of the stepper motor.

DC STEPPER MOTOR

A DC stepper motor translates current pulses into rotor movement. A typical motor contains four winding coils labeled red, yellow/white, red/white, and yellow. Applying current to these windings forces the motor to step. For normal operation, two windings are activated (pulsed) concurrently. The motor moves clockwise one step per change in windings activated with the following activation sequence: red and yellow, yellow and red/white, red/white and yellow/white, yellow/white and red, repeat. Half-steps may be generated by altering the sequence to: red and yellow, yellow, yellow and red/white, red/white, red/white and yellow/white, yellow/white, yellow/white and red, red, repeat. The motor runs in a counterclockwise direction if either sequence is applied in reverse order. The speed of rotation (number of steps/second) is controlled by the frequency of the pulses.

COP820 CONTROL OF STEPPER MOTOR

The COP820 controls the stepper motor by sending pulse sequences to the motor windings in response to control commands. Commands executed by the code in this application include: single step the motor in a clockwise or counterclockwise direction (i.e. rotate the rotor through a certain number of degrees), run the motor continuously at one of four speeds in a clockwise or counterclockwise direction, and stop the motor.

Note: Half-stepping is not implemented in this example.

During continuous mode operation, the 16-bit timer of the COP820 is used to control the speed of the stepper motor. The timer is set up with a value that causes an underflow once every x seconds or at a frequency of $1/x$. Each underflow of the timer interrupts the microcontroller. In response to the timer interrupt, the microcontroller generates a new pulse and causes a single step of the motor. Thus the motor steps at the frequency of the timer underflows. This application sets up the timer to generate interrupts at four different frequencies. These frequencies produce the following motor speeds: 25 steps/second, 100 steps/second, 200 steps/second, and 400 steps/second.

The determination of which windings to activate and deactivate to step the motor is performed by a single subroutine in this example. A block of memory is allocated to store a step pointer and the four possible stepper drive values are shown in Table I (9,C,6,3). Consecutive memory locations are used to store the stepper drive values so that applying the value from location X and then location $X+1$ (or $X-1$) causes the motor to step once. The motor drive subroutine increments or decrements the pointer to the current drive value based on the selection of a clockwise or counterclockwise direction. Writing the value from the newly selected location to the motor causes a single step of the motor in the appropriate direction.

During single step operation, the microcontroller steps the motor the exact number of times requested in the control command. Each step corresponds to 1.8 degrees of rotor movement. Therefore, a request to perform 200 steps will rotate the rotor through one complete revolution (360 degrees) at a fixed speed.

A block diagram of the application is shown in *Figure 1*. A flowchart of the code used to control the motor is given in *Figure 2*. The complete code is given at the end.

TABLE I. Stepper Motor Drive Sequence

Step	Yellow	Red/White	Yellow/White	Red	Hex Value
0	ON	OFF	OFF	ON	9
1	ON	ON	OFF	OFF	C
2	OFF	ON	ON	OFF	6
3	OFF	OFF	ON	ON	3
4	ON	OFF	OFF	ON	9

MF2 Compatible Keyboard with COP8 Microcontrollers

National Semiconductor
Application Note 734
Volker Soffel

ABSTRACT

This application note describes the implementation of an IBM MF2 compatible keyboard with National Semiconductor's COP888CL or COP943C/COP880CL microcontrollers. Two different solutions have been developed. One solution, suitable for laptop/notebook keyboards is based on the COP888CL with special power saving techniques. The other for most price competitive standard desktop keyboards is based on the COP943C/COP880C microcontrollers. The same principles can be applied to all types of keyboards or data input devices.

FEATURES

- Single chip solution
- Low cost R/C or ceramic oscillator optional
- LED direct drive capability
- I/Os with software programmable on chip pull-ups
- Current saving M2CMOS technology
- Multi-input wakeup and HALT mode for further power consumption reduction (COP888CL only)
- Software key rollover
- Schmitt triggers on keyboard data and clock lines

INTRODUCTION

The expression MF2 keyboard stands for multi-functional keyboard version 2. This type of keyboard was first developed and defined by IBM for use with all types of PC (XT,

AT, PS/2). In the meantime it has become an industry standard and today nearly all PCs have an MF2 compatible keyboard. As the name suggests, this keyboard features all operation modes which are necessary to stay compatible with the older XT and AT type keyboards. In the following chapters the features and functions of an MF2 keyboard as well as their implementation with a COP8 microcontroller are described.

MF2 KEYBOARD KEY-LAYOUT

Figure 1 shows the key layout of the U.S. version of an MF2 keyboard. Its outer appearance is characterized by 101 keys (102 for some countries), a separate cursor and numeric key pad, and 12 function keys in the upper row. The keyboard sends a "make" code if a key is depressed and a "break" code if the key is released. These make and break codes are independent of any country-specific keyboard layouts, which means they are independent of the symbols printed on the keys. These codes are solely determined by the physical position of a key on the keyboard. The physical position of a key on an MF2 keyboard is defined by its assigned key number, which is shown in Figure 1.

HARDWARE

Laptop/Notebook Keyboard With COP888CL

Figure 2 shows the schematics of an MF2 keyboard with a COP888CL microcontroller. The G, C and L ports of the COP888CL are software programmable I/Os and can be programmed either as TRI-STATE® inputs, inputs with weak pull-up, push-pull output low, or push-pull output high.

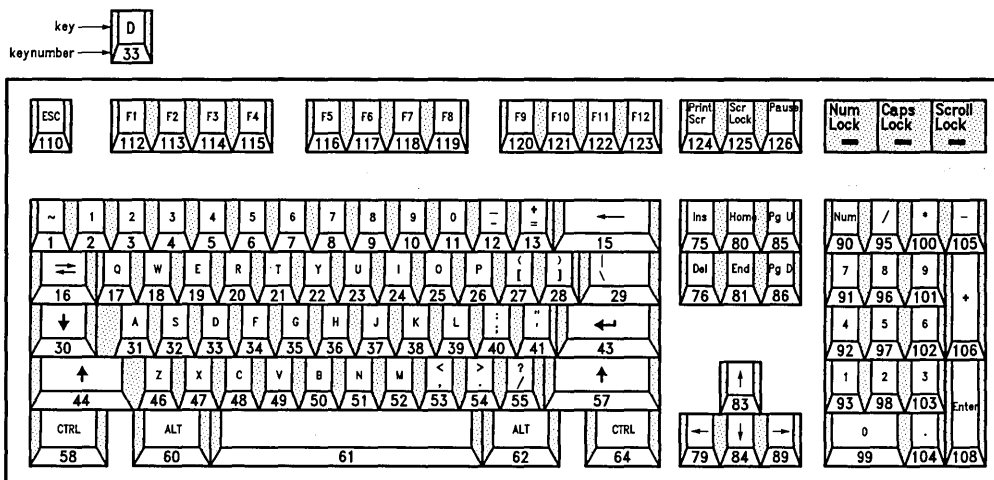

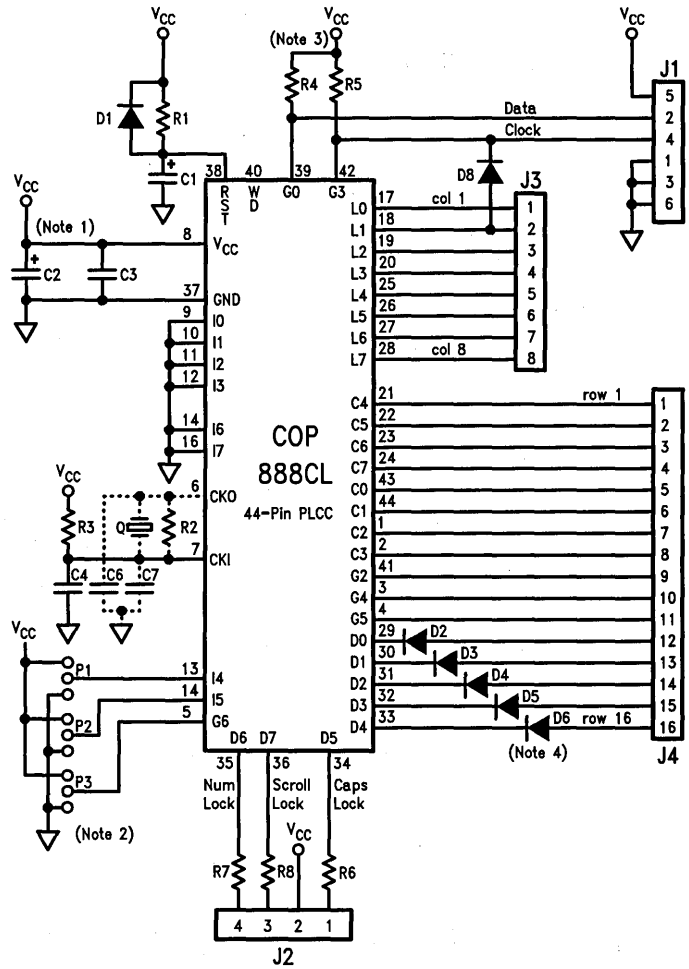

FIGURE 1. MF2 Keyboard U.S. Layout

TL/DD/11091-10

Note 1: C2 (47 μ F level off capacitor) can be removed when the power supply ripple < $\pm 10\%$, 0.5 V/ms.

Note 2: Jumper P1: Mode select: 0 = XT-mode, 1 = AT-mode. Jumper P2, P3: not used.

Note 3: Care must be taken if there are pullups in the computer system that clock/data line current < 3 mA.

Note 4: Diodes D2-D6 should be removed if keyboard has hardware keyrollover (diodes in matrix).

FIGURE 2. MF-2 Keyboard Schematics with a 44-Pin COP888CL

TL/DD/11091-11

The keyboard is organized as an 8 input by 16 output matrix. The COP888CL's L port is configured as a weak pull-up input port, thus allowing the use of the multi-input wakeup feature. Most of the time the chip is in the current saving HALT mode ($I_{dd} \leq 10 \mu A$). Any keystroke or a data transmission from the computer will create a high to low transition on one of the L lines, which wakes up the μC from HALT mode. After returning from the HALT mode, the keyboard is scanned in order to detect which key is pressed and the appropriate key code is sent to the computer. This event-driven keyboard scanning results in lowest possible current consumption as HALT mode is even entered between successive single keystrokes. The diodes in the D-lines of the key matrix prevent a high current from being drawn. When two keys in the same column are pressed, two outputs could be potentially connected together: one of the D output lines, which is high and the polled line, which is pulled low. In this case, excessive current would be drawn without the protection diodes. These diodes can be omitted if the keyboard already has decoupling diodes in its matrix (hardware key rollover). All other matrix lines source current in the μA range and there is no need for current limiting diodes.

The G0 and G3 pins are used for the keyboard data and clock lines. The pull-ups on these lines ensure a defined logic "1" level. The keyboard interface on the computer side uses open collector drivers and the G0, G3 pins of the COP888CL are configured as TRI-STATE (Hi-Z) inputs when a "1" is written to the data or clock line. To output a logic "0" the μC pulls the data or clock line low (push-pull low output). A maximum current of 3 mA can be sunk into the data and clock pins. Schmitt triggers on the data and clock line inputs reduce the risk of errors in the data received by the keyboard.

The microcontroller provides the option of using a low cost R/C oscillator with frequency variation tight enough to fulfill the requirements for a keyboard, in addition to the option of using a crystal or a ceramic clock.

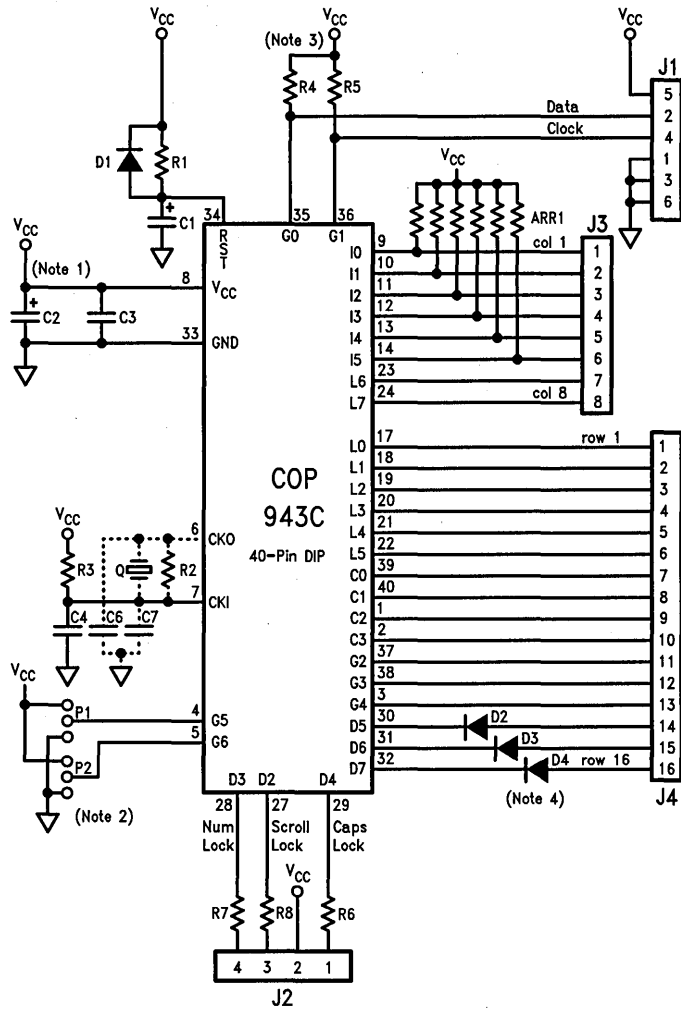

The XT or AT/PS-2 operation mode can be selected via a hardware switch. Additional inputs for customer specific settings are available.

The three LEDs of an MF2 keyboard are driven directly by three of the COP888CL's high sink D-lines (max. 15 mA for each pin), thus eliminating the need for additional LED drivers or transistors.

The keyboard logic generates a Power-On Reset (POR) signal when the power is first applied to the keyboard. After POR the keyboard performs the Basic Assurance Test (BAT). The BAT consists of a keyboard controller self-test. During the BAT, any activity on the data and clock lines is ignored. The 3 keyboard LEDs are turned on at the beginning and turned off at the end of the BAT. Upon satisfactory completion of the BAT, the keyboard sends the BAT completion code (hex AA) to the computer and keyboard scanning begins. Any code other than hex AA is interpreted by the computer as a BAT error.

Desktop Keyboard with COP943C or COP880C

Figure 3 shows the schematic for an MF2 keyboard with the COP943C/COP880C. The only difference compared to COP888CL solution is that the COP943C/COP880C microcontrollers do not have the multi-input wakeup feature, which allows an event driven keyboard scanning. The key matrix is therefore continuously scanned in a loop. With the COP943C/COP880C solution a part of the I port is used as the key matrix input. The I port is a TRI-STATE (Hi-Z) input port (requires external pull-ups).

Note 1: C2 (47 μ F level off capacitor) can be removed when the power supply ripple < $\pm 10\%$, 0.5 V/ms.

Note 2: Jumper P1: Mode select; 0 = XT-mode, 1 = AT-mode. Jumper P2: P3: not used.

Note 3: Care must be taken if there are pullups in the computer system that clock/data line current < 3 mA.

Note 4: Diodes D2-D4 should be removed if keyboard has hardware keyrollover (diodes in matrix).

FIGURE 3. MF-2 Keyboard Schematic with a 40-Pin COP943C/COP880C

TL/DD/11091-12

Key Matrix Organization

Figure 4 shows an example of what an MF2 keyswitch matrix could look like. Each key position in the matrix is marked with its key number.

For example: Key number "58" is located at the key matrix position number "2" and has the AT-set make code "14

Hex". Looking at Figure 1, one can see that key number "58" belongs to the left "CNTRL" key. Note that the "SHIFT", "CNTRL" and "ALT" keys are located in their own matrix lines, separate from all other keys. The reasons for that will be explained in the chapter "Software Key Roll-over".

FIGURE 4. Keyboard Matrix COP888CL AT Code Set

TL/DD/11091-13

Code Sets

The MF2 keyboard supports 3 different sets of make and break codes. Code set 1 is used for XT/PC and PS/2-30 compatible computers. Code set 2 is used for AT and all other PS/2 models compatible computers and code set 3 is used for workstations and terminal emulations on the PC. The country specific keyboard driver on the PC side converts the "key position" codes from the keyboard into the ASCII codes that correspond to the characters printed on the keycaps (as long as the right driver is installed on the PC). Appendix 1 gives a complete overview of the key numbers and their make and break codes for all 3 code sets. The symbols of the U.S. keyboard layout are only listed for reference and are different for other country layouts. The break code for code set 1 is equal to the make code with the most significant bit set. The make codes preceded with a "F0 Hex" code give the break codes of code sets 2 and 3.

KEYBOARD SOFTWARE

The software of the keyboard microcontroller can be subdivided into the following five main tasks:

- key detection
- software key rollover
- key decoding and encoding
- keycode transmission
- keyboard command set

Key Detection

Key detection is done by scanning the keyboard matrix in the following way. Sequentially each of the 16 matrix output lines are pulled low, while all the others are high. The 8

matrix input lines are read and the 8-bit input value is compared with the result of the previous scanning of the same matrix output line (a history of the previous scan is kept in the μ C's RAM). Thus the keyboard microcontroller's key detection routine detects any key change in that matrix output line (key pressed or released) since the previous scan. It is important to recognize released keys, as the MF2 keyboard not only sends a key's "make" code when the key is pressed, but also a key's "break" code when the key is released. Key debouncing is performed by software by making sure that the time between two scans is bigger than the key bounce time (typically 8 ms).

Software Key Rollover

Software key rollover means that no decoupling diodes are used in the key switch matrix. However, the keyboard action is still N key rollover in nature. That is, if N keys are depressed in some sequence and held down, the make code of these keys is transmitted in that sequence. However, if three keys from three corners of a rectangle in the key switching matrix are depressed, a "ghost" key (a key which is not really pressed) would be created (see *Figure 5*). To prevent this, a special algorithm, which checks for such special key combinations, has been implemented into the keyboard software. If a "ghost" key has been detected the keyboard outputs the "key detection error code" and the N key rollover reverts to a 2 key rollover. To ensure that all 3-key combinations used on a PC (e.g., CNTRL+ALT+DEL) are still possible, keyboard manufacturers using this method organize the key switch matrix accordingly (an example is given in *Figure 4*).

Key Decoding and Encoding

After detection of a key change (pressing or releasing a key), the software first has to determine the physical location of the key in the key matrix. This decoding process is done by calculating an internal key number out of the key matrix column and row position of the changed key. At the same time, it is determined if the key has been pressed or released. A pressed or released key is then signaled by setting or resetting a "key down" flag in RAM. The internal key number and the "key down" status flag are the input parameters to the key encoding procedure. The internal key number is used to get the "make" code for the key out of a ROM look-up table, which has been matched to the physical matrix organization of the keyboard. If the "key down" flag is reset (key is released) the software calculates the key "break" code out of the previously fetched key "make" code. In this way, each pressed or released key is encoded with its appropriate "make" or "break" code, which is then written to the keyboard controllers 16 byte output buffer (FIFO) until the computer interface is ready to receive it. Before writing to the FIFO the software checks whether there is still enough capacity to store the key code.

Key Repetition

All keys are typematic (repetitive) by default. That means when a key is pressed and held down, the μ C continues to send the "make" code for that key until it is released. When two or more keys are held down, only the code for the last key pressed is repeated. Typematic operation will stop

when this key is released, even if other keys are still held down.

The default values for typematic operation are:

delay time = 500 ms
 repetition rate = 10 characters/second,

where the delay time is the time which is inserted before a character is repeated for the first time.

Operating Protocol

There are two different transmission protocols for an MF2 keyboard: the AT transmission protocol and the XT transmission protocol. Data transmission to and from the keyboard is synchronous serial, the data format for the XT mode is:

9 bits in length
 1 start bit (high)
 8 data bits (LSB first)

The data format for AT and PS/2 modes is:

11 bits in length
 1 start bit (low)
 8 data bits (LSB first)
 1 parity bit (odd)
 1 stop bit (high)

If no data is transmitted, both data and clock lines are in the high state. The clock signal is always provided by the keyboard. *Figure 6* shows the XT and the AT protocol timings.

FIGURE 6. XT and AT Protocol Timings

Keyboard Data Transmission in XT Format

At the falling edge of the clock, the start bit (high) is shifted out, followed by the 8 data bits (least significant bit first). Data is valid on the rising edge of the clock and changes after the falling edge of the clock.

Keyboard Data Transmission in AT Format

Before sending data, the keyboard monitors the clock and data lines. If the clock line is low, then the keyboard is disabled by the computer and no data is transmitted. The microcontroller continues to scan the keyboard and stores key data in its output buffer. If the data line is low, while the clock line is high, the computer requests to send and the

keyboard goes into receive mode. The keyboard is only allowed to transmit data when both data and clock lines are high.

The keyboard pulls the data line low (start bit) and starts the clock. The 8 data bits (least significant bit first) are shifted out, followed by the parity (odd) and stop bit (high). Data is valid after the falling edge of the clock and changes after the rising edge of the clock. If no data is transmitted both data and clock lines are high. If the computer pulls the clock line low for at least 60 μ s before the 10th bit is transmitted, the keyboard stops transmission and stores the aborted data in its output buffer.

Keyboard Receives Data

The keyboard can only receive data from the computer in AT-PS/2 mode. The computer pulls the data line low (start bit) after which the keyboard starts to shift out 11 clock pulses within 15 ms. Transmission has to be completed within 2 ms. Data from the computer changes after the falling edge of the clock and is valid before the rising edge of

the clock. After the start bit, 8 data bits (least significant bit first), followed by the parity bit (odd) and the stop bit (high) are shifted out by the computer with the clock signal provided by the keyboard. The keyboard pulls the stop bit low in order to acknowledge the receipt of the data. If a transmission error occurred (parity error or similar) the keyboard issues the "RESEND" command to the PC.

Commands from the Computer

The following table shows the commands and their hexadecimal values the computer may send to the keyboard. Only AT-PS/2 compatible computers can send commands to the keyboard and the keyboard can only receive the commands when operated in the AT-mode.

The commands can be sent to the keyboard at any time. The keyboard responds within 20 ms to any valid transmission with ACK (FA Hex), except for the ECHO command where the keyboard responds with EE Hex, the RESEND command and the reserved commands.

Command	Hex Value
Set/Reset Mode Indicators	ED
Echo	EE
Reserved	EF
Select Alternate Code Set	F0
Reserved	F1
Read Keyboard ID	F2
Set Typematic Rate/Delay	F3
Enable	F4
Default Disable	F5
Set Default	F6
Set All Keys	
Typematic/No Break	F7
Make/Break/No Typematic	F8
Make/No Typematic	F9
Typem./Make/Br.	FA
Set Key Type	
Typematic/No Break	FB
Make/Break/No Typematic	FC
Make/No Typematic	FD
Resend	FE
Reset	FF

In the XT mode the keyboard only accepts the RESET command, which is assumed when the computer pulls the clock line low for at least 10 ms.

Commands to the Computer

The following table shows the commands and their hexadecimal values the keyboard may send to the system.

Command	Hex Value
Key Detection Error/ Buffer Overrun	00 (Code Sets 2 and 3)
Keyboard ID	83AB
BAT Completion Code	AA
BAT Failure Code	FC
Echo	EE
Acknowledge	FA
Resend	FE
Key Detection Error/ Buffer Overrun	FF (Code Set 1)

SUMMARY

When using National Semiconductor's microcontroller to implement the functions of an MF2 keyboard, very few external components are necessary. *Figure 2* shows the complete schematic of an MF2 keyboard based on the COP888CL. The implementation of software key rollover eliminates the need for decoupling diodes in the 16 by 8 key matrix. LED direct drive capability of the COP8 and a RC oscillator with tolerances tight enough to meet the requirements for a keyboard further reduce component count and price. Schmitt triggers on the ports used for the keyboards data and clock lines add additional security against transmission errors. Where low power consumption is the most important design factor (e.g., laptop or notebook computers) the COP8's M2CMOS technology and the multi-input wakeup feature offer a remarkable improvement over the NMOS controllers used in most of today's existing solutions.

National Semiconductor offers three chips tailored for the needs of a keyboard designer. Starting with the most price competitive 2.5k ROM device COP943C, an upgrade path is provided with the COP880C to 4k ROM. Both devices are intended for the use in standard MF2 desktop keyboards. The COP888CL is ideally suited for notebook or lap-

top keyboards, as it has special power saving features. The complete software for an MF2 keyboard as well as complete demo keyboards and keyboard evaluation boards for the COP888CL and COP943C/COP880C microcontrollers are available. Contact National Semiconductor's μ C marketing or applications for further information.

RS-232C Interface with COP800

National Semiconductor
Application Note 739
Michelle Giles

INTRODUCTION

This application note describes an implementation of the RS-232C interface with a COP888CG. The COP888CG 8-bit microcontroller features three 16-bit timer/counters, MICROWIRE/PLUSTM Serial I/O, multi-source vectored interrupt capability, two comparators, a full duplex UART, and two power saving modes (HALT and IDLE). The COP888CG feature set allows for efficient handling of RS-232C hardware handshaking and serial data transmission/reception.

SYSTEM OVERVIEW

In this application, a COP888CG is connected to a terminal using the standard RS-232C interface. The serial port of the terminal is attached to the COP888CG interface hardware using a standard ribbon cable with DB-25 connectors on either end. The terminal keyboard transmits ASCII characters via the cable to the COP888CG interface. All characters received by the COP888CG are echoed back to the terminal screen. If the COP888CG detects a parity or framing error, it transmits an error message back to the terminal screen.

HARDWARE DESCRIPTION

The COP888CG features used in this application include the user programmable UART, the 8-bit configurable L PORT, and vectored interrupts. In addition to the COP888CG, the RS-232C interface requires a DS14C88 driver and a DS14C89A receiver. The DS14C88 converts TTL/CMOS level signals to RS-232C defined levels and the DS14C89A does the opposite. *Figure 1* contains a diagram of the COP888CG interface hardware.

The COP888CG is configured as data communications equipment (DCE) and the terminal is assumed to be data terminal equipment (DTE). The following RS-232C signals are used to communicate between the COP888CG (DCE) and the terminal (DTE):

RS-232C Signal Name	Signal Origin
TxD (Transmit Data)	DTE
RxD (Receive Data)	DCE
CTS (Clear To Send)	DCE
RTS (Request To Send)	DTE
DSR (Data Set Ready)	DCE
DTR (Data Terminal Ready)	DTE
DCD (Data Carrier Detect)	DCE

Five general purpose I/O pins on the COP888CG L PORT are used for the control signals CTS, DSR, DCD, RTS and DTR. Two additional L PORT pins are used for TxD and RxD. These two general purpose pins are configured for their alternate functions, UART transmit (TDX) and UART receive (RDX). According to the RS-232C interface standard, DCE transmits data to DTE on RxD and receives data from DTE on TxD. Therefore, the UART transmit data pin (TDX) is used for the RS-232C receive data signal (RxD) and the UART receive data pin (RDX) is used for the RS-232C transmit data signal (TxD). In this example, all handshaking between DCE and DTE is performed in hardware.

The terminal is setup to interface with the COP888CG by selecting the 9600 baud, 7 bits/character, odd parity and one stop bit options. The local echo back of characters is disabled to allow the COP888CG to perform the echo back function. The terminal is also configured to use the hardware control signals (CTS, DSR, RTS, DTR) for handshaking.

SOFTWARE DESCRIPTION

The software for this application consists of an initialization routine, several interrupt routines, and a disable routine. These routines handle RS-232C handshaking, transmitting and receiving of characters, error checking, and echoing back of received characters. *Figures 2* thru *5* contain flowcharts of the routines. The complete code is given at the end of this application note.

The initialization routine configures the UART, initializes the transmit/receive data buffer, and enables the 8-bit L PORT handling of RS-232C control signals. In this particular example, the UART is configured to operate at 9600 BAUD in full duplex, asynchronous mode. The framing format is chosen to be: 7 bits/character, odd parity, and one stop bit. Different baud rates, modes of operation, and framing formats may be selected by setting the ENUCMD, ENUICMD, BAUDVAL and PSRVAL constants located at the beginning of the code to alternative values. (Refer to the COP888CG data sheet or COP888 Family User's Manual for details on configuring the UART.) Each RS-232C control signal is assigned to an L PORT pin. Pins L0, L2, L5 and L6 are configured as outputs for the DCD, TxD, CTS and DSR signals, respectively. Pins L3, L4 and L7 are configured as inputs for TxD, RTS and DTR, respectively. The transmit/receive data buffer is a circular buffer whose location and size is selected by setting the START and END constants located at the beginning of the program. The initialization routine sets up the buffer based on these constants.

The interrupt routines respond to transmit buffer empty, receive buffer full, and L PORT interrupts. A generic context switching routine is used for entering and exiting all interrupts. This routine saves the contents of the accumulator, the PSW register and the B pointer before vectoring to the appropriate interrupt routine. It also restores the contents of saved registers before a return from interrupt is executed.

The UART transmitter interrupt is called when the transmit buffer empty flag (TBMT) is set. This routine checks for active RTS and DTR control signals. If both signals are active and there is data to be transmitted, a byte of data is loaded into the UART transmit buffer. Otherwise, the UART transmitter is disabled.

The L PORT interrupts are used to indicate an active-low transition of RTS and/or DTR. When both signals are active (the remote receiver is ready to accept data), this routine enables the UART transmitter.

The UART receiver interrupt routine is called when the receive buffer full flag (RBFL) is set. This routine reads the

UART receive buffer and checks for errors. If no errors are detected, the incoming data is placed in the data buffer for echoing. If errors are detected, an error message is queued for transmission.

The receiver interrupt disables the remote transmitter by deactivating CTS whenever the transmit/receive data buffer is almost full. This action prevents the data buffer from overflowing. Note that CTS is turned off before the buffer is completely full to insure buffer space will exist for storing characters which are in the process of being sent when CTS is deactivated.

The disable routine clears the UART control registers, disables the L PORT interrupts, and de-activates the RS-232C control signals.

CONCLUSION

The user configurable UART, multiple external interrupt capabilities, and vectored interrupt scheme of the COP888CG microcontroller allow for an efficient implementation of the RS-232C interface standard. This application note shows how the COP888CG may be configured for connection to a terminal using these features. However, the code for this application can be easily adapted to other applications requiring different baud rates or framing formats, connection to a modem (DCE), separate transmit and receive buffers, incoming command decoding and/or handling of character strings. The versatility of the RS-232C standard and the COP888CG provides a means to develop practical solutions for many applications.

```

1      ;The following set of routines uses the COP888CG UART and several I/O pins
2      ;to simulate an RS232 port interface. The code handles hardware control
3      ;signals, echo back of received characters, and error checking. A single
4      ;routine called INIT initializes the UART and hardware control signals.
5      ;The transmitting and receiving of characters is handled in several
6      ;interrupt routines. The UART is disabled by calling the DISABLE routine.
7      ;The user must select values for several constants before compiling
8      ;this code.
9      ;
10     ;NOTES:
11     ; * The COP transmitter is enabled only when the transmit/receive
12     ;   buffer is not empty and the appropriate RS232 control signals
13     ;   from the remote receiver are present.
14     ; * The COP receiver is always enabled. the remote transmitter
15     ; * The remote transmitter is disabled whenever the transmit/
16     ;   receive data buffer is full.

Quadrature Signal Interface to a COP400 Microcontroller

National Semiconductor
Application Note 749
Walter Bacharowski

AN-749

INTRODUCTION

Switches have always been a popular way of getting information into a microcontroller. Two-bit quadrature output devices, also known as two-bit gray code output, use two switches that are mechanically coupled together thru a shaft so that as the shaft is rotated the switches generate two square waves that are 90 degrees out of phase with each other. This is also known as being in quadrature, see *Figure 1*. The reason for doing this is that within the two signals there is the information to detect the direction of rotation, i.e., clockwise (CW) or counterclockwise (CCW). This type of device allows an input variable to be increased or decreased by CW or CCW rotation of the shaft. Additionally, these devices allow continuous rotation in either direction, which lets the span and resolution of the input variable to be a function of the software.

FIGURE 1

OPERATION

Figure 2 shows a hardware connection of a quadrature output device to the COP400 microcontroller. Although in this example the G0 and G1 I/O pins are used, any pin that can be used as an input could be used with the appropriate changes in the software.

In this example the output of device QD1 is processed to detect a state change in the quadrature signal and which direction the change was in. A 3-digit BCD variable, which is stored in RAM, is then incremented or decremented. The variable is defined to have a range of 200 to 350 units. The routine allows the variable to saturate at its upper and lower limits when reached.

Figure 3 displays the two waveforms that are generated by QD1 as its shaft is rotated from an arbitrary starting position. Each edge represents a change of state. By keeping track of the state that was moved from and the state that currently exists, it can be determined which direction the rotation was in.

Referring to *Figure 3*, there are 4 possible states for a starting position, (00, 01, 11, 10), and they will be referred to as the previous state. There are also 4 possible states to move to, (00, 01, 11, 10), and they will be referred to as the current state. *Figure 4* lists the 8 possible combinations of bits that can be formed by starting from each previous state and rotating CW or CCW to the current state. If the two bits of the previous state and current state are concatenated into one 4-bit value, each value will be unique. The routine

FIGURE 3. Quadrature Signal Output (Gray Code)

used in this example assigns the two bits of the current state to the low 2 bits of a 4-bit value, and the 2 bits of the previous state to the high 2 bits of a 4-bit value. This 4-bit value (see the column under the PS/CS heading in Figure 4) is then used as a pointer into a jump table which branches to the add or subtract part of the routine. This method takes advantage of the "jump indirect" instruction which implements a multiway branch based on the value of a pointer. The routine to input data from the quadrature device reads the value of G0 and G1 and compares it to the value stored from the previous read operation. If the two values are equal there is no input to process. If the two values are not equal there is an input and the data is processed to determine if one is to be added to or subtracted from the variable.

The flow chart details the operation of the subroutine "QUAD".

In Figure 4, only 8 of the possible 16 combinations are used. To account for potential spurious operation if one of the 8 undefined combinations occur, they are ignored by this routine by branching to a return instruction which bypasses any additional processing.

The source listing for this example subroutine, which is named "QUAD", is provided. An initialization routine that is required to set up the starting parameters is also included.

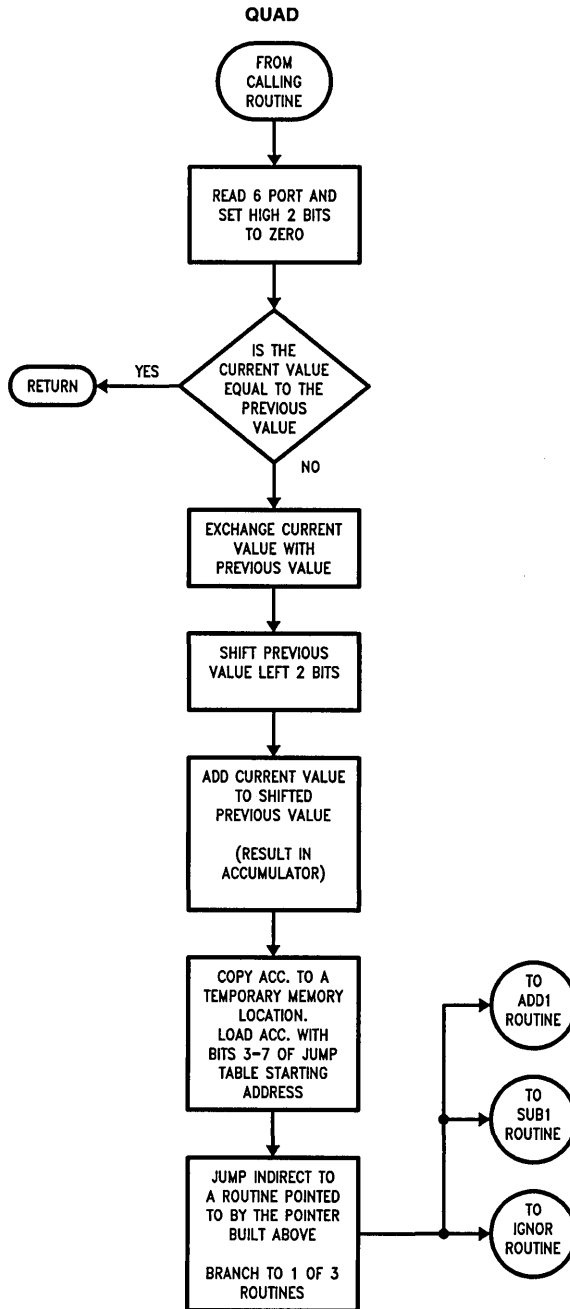

CONCLUSION

This application note demonstrates the relative ease of interfacing a quadrature device to a COP400 microcontroller. The combination of a low cost microcontroller and input device can provide the basis for a cost effective instrument or appliance design.

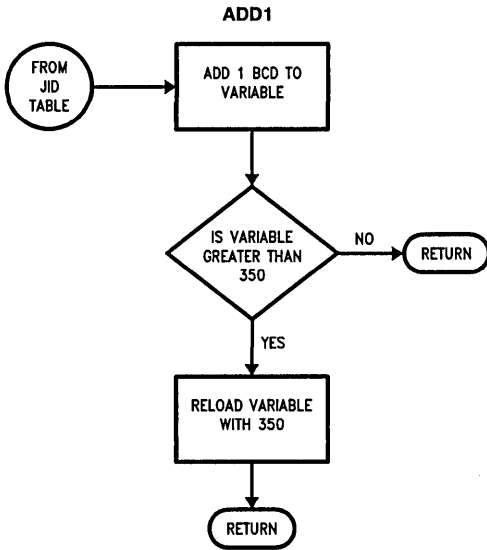

Direction	PS/CS	Hex Value	Operation
CW	00 10	2	Add 1
CCW	00 01	1	Subtract 1
CW	01 00	4	Add 1
CCW	01 11	7	Subtract 1
CW	11 01	D	Add 1
CCW	11 10	E	Subtract 1
CW	10 11	B	Add 1
CCW	10 00	8	Subtract 1

PS = Previous State
CS = Current State

The 16-Bit HPC™ Family: Optimized for Performance

Key Features

- World's first 16-bit CMOS microcontroller
- World's fastest CMOS microcontroller
- 100 ns for fastest instruction at 40 MHz
- Full 16-bit architecture and implementation
- 64 kbyte address space
- High code efficiency with single-byte, multiple-function instructions
- 16 x 16-bit multiply, 32 x 16-bit divide
- Eight vectored interrupt sources
- Watchdog logic monitors
- 16-bit timer/counters
- Up to 52 general-purpose high-speed I/O lines
- On-chip ROM to 16 kbytes
- On-chip RAM to 1 kbyte
- On-chip peripherals
 - DMA
 - HDLC
 - Timers
 - Input-capture registers
 - UART
 - User-programmable memory
 - High speed SRAM
 - High speed timers
 - A/D
 - DSP
- M²CMOS fabrication
- MICROWIRE/PLUSTM serial interface
- ROMless versions available
- Wide operating voltage range:
+ 4.5V to +5.5V
- Military temp range available
(-55°C to +125°C)
- MIL-STD-883C versions available
- 68-pin PGA, PLCC, LDCC packages and 80-pin PQFP

National's High Performance Controller (HPC) family is not only the world's first 16-bit CMOS microcontroller family, but also the world's fastest.

Currently operating at a clock rate of 40 MHz, the HPC fabricated in scalable M²CMOSTM, allowing die-shrinks ultimately, to submicron levels. Meaning the HPC will be operating at much higher frequencies in the future.

The HPC is designed for high-performance applications. With its 16 x 16-bit multiply and 32 x 16-bit divide, the HPC is appropriate for compute-intensive environments that used to be the sole domain of the microprocessor.

The HPC is ideal, for example, for signal conditioning applications. The HPC's high throughput helps eliminate external components from typical signal processing/control circuits, and allows key parts of the application to be implemented in software rather than hardware.

This not only reduces system cost and development time, but also increases the flexibility and market life of the product.

At the same time, because the HPC has a control-oriented architecture, important functions are still implemented in hardware, providing critical performance advantages unavailable in a pure-software solution, such as a general microprocessor-based design.

It is this powerful performance capability that, when combined with the wide range of peripheral functions that are available (such as UARTs and HDLC), make the HPC a true systems solution on a chip.

The Powerful HPC Core

The HPC is an "application-specific" microcontroller.

Based on a common, high-performance CPU "core", each HPC family member is "customized" to meet the exact needs of a particular application.

The core, based on a microprocessor-like von Neumann architecture, contains seven key functional elements:

1. Arithmetic Logic Unit (ALU)
2. 6 working registers
3. 8 interrupts
4. 3 timers
5. Control logic
6. Watchdog circuitry
7. MICROWIRE/PLUS interface

The internal data paths, registers, timers, and ALU are all 16 bits wide.

So the HPC can directly address up to 64 kbytes of "external" memory.

The external data bus, however, is configurable as 8 or 16 bits, allowing it to efficiently interface with a variety of peripheral devices.

Flexible Peripheral Support

The HPC core can support a full range of peripheral functions:

- High-level Data Link Control (HDLC) for ISO-standard data communications
- Universal Asynchronous Receiver/Transmitters (UARTs) for full-duplex, 300/1200/2400/9600-baud serial communications
- High-Speed Outputs and Pulse-Width Modulated (PWM) timers for efficient external interfaces
- User-programmable memory
- Analog-to-Digital (A/D) converters for interfacing "real-world" inputs
- Multiply/Accumulate Unit for fast signed multiply or multiply-accumulate
Plus:
- Up to 64 kbytes of direct-addressable memory
- Up to 52 I/O ports on a 68-pin package
- Chip select output logic with programmable control

Efficient Instruction Set

The HPC family achieves much of its performance through its unique, highly optimized instruction set. Unlike the instruction set of a typical microprocessor, the HPC instruction set is designed for maximum code efficiency. Because ROM-space is necessarily limited on a single-chip solution, programs must be compact and economical.

The HPC instruction set supports nine addressing modes, like a high-performance 16-bit microprocessor. And each instruction in the set is designed to execute a number of individual functions, so the same operations can be executed with tighter code.

As a result, the typical HPC instruction cycle is only 50 ns at 40 MHz. And the typical HPC 16-bit multiply or divide takes less than 4 μ s.

To achieve the same level of performance in other 16-bit and high-end 8-bit microcontrollers, as indicated by recent benchmark studies, would require up to *two times the memory space* as the HPC.

Low Power Operation

The HPC uses power as efficiently as it uses memory space.

The HPC draws only 47 mA of current at 20 MHz. And its even less at lower clock rates.

In addition, the HPC has two software-selectable power-down modes:

1. IDLE, which stops all operations except for the oscillator and one timer, thereby maintaining all RAM, registers, and I/O in a static state.
2. HALT, which stops all operations including the oscillator and timers, but holds RAM, registers, and I/O stable.

Key Applications

- Signal conditioning/processing/control
- Automotive systems
- Data processing
- Telecommunications
- Hard disk drives
- Military
- Embedded controllers
- Medical
- Factory automation
- Industrial control
- Compute-intensive environments
- High-end control
- Tape and disk drives
- Security systems
- Laser printers
- SCSI control

High Level Language Support

A C compiler and C-source level debugger is available for software development on standard platforms: the IBM PC running DOS Sun system running UNIX.

With powerful tools such as these, the HPC can be quickly and efficiently programmed for any high-performance application.

For further information, see Section 7 on Microcontroller Development Support.

HPC Family

COMMON FEATURES

- M²C MOS Process Technology
- Instruction Cycle Time:
 - 100 ns @ 20 MHz
 - 67 ns @ 30 MHz
 - 50 ns @ 40 MHz for HPC46100
- Idle and Halt Modes

- WATCHDOG
- 64k Address Space
- MICROWIRE/PLUS Serial Interface
- UART
- Minimum of four 16-Bit Timer/Counters with Synchronous Outputs

PRELIMINARY

HPC16083/HPC26083/HPC36083/HPC46083/ HPC16003/HPC26003/HPC36003/HPC46003 High-Performance microControllers

General Description

The HPC16083 and HPC16003 are members of the HPC™ family of High Performance microControllers. Each member of the family has the same core CPU with a unique memory and I/O configuration to suit specific applications. The HPC16083 has 8k bytes of on-chip ROM. The HPC16003 has no on-chip ROM and is intended for use with external direct memory. Each part is fabricated in National's advanced microCMOS technology. This process combined with an advanced architecture provides fast, flexible I/O control, efficient data manipulation, and high speed computation.

The HPC devices are complete microcomputers on a single chip. All system timing, internal logic, ROM, RAM, and I/O are provided on the chip to produce a cost effective solution for high performance applications. On-chip functions such as UART, up to eight 16-bit timers with 4 input capture registers, vectored interrupts, WATCHDOG™ logic and MICROWIRE/PLUSTM provide a high level of system integration. The ability to address up to 64k bytes of external memory enables the HPC to be used in powerful applications typically performed by microprocessors and expensive peripheral chips. The term "HPC16083" is used throughout this data-sheet to refer to the HPC16083 and HPC16003 devices unless otherwise specified.

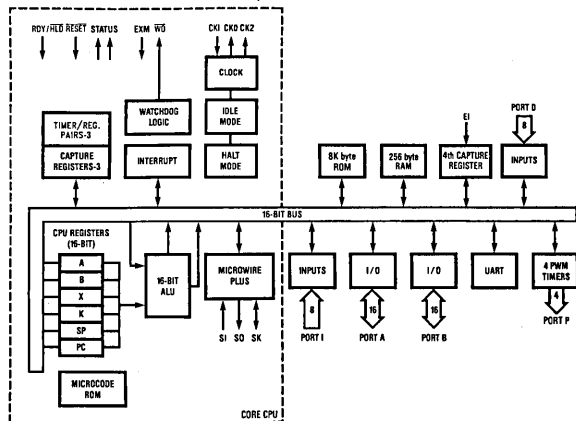

The microCMOS process results in very low current drain and enables the user to select the optimum speed/power product for his system. The IDLE and HALT modes provide further current savings. The HPC is available in 68-pin PLCC, LDCC, PGA and 80-Pin PQFP packages.

Features

- HPC family—core features:
 - 16-bit architecture, both byte and word
 - 16-bit data bus, ALU, and registers
 - 64k bytes of external direct memory addressing
 - FAST—200 ns for fastest instruction when using 20.0 MHz clock, 134 ns at 30 MHz
 - High code efficiency—most instructions are single byte
 - 16 x 16 multiply and 32 x 16 divide
 - Eight vectored interrupt sources
 - Four 16-bit timer/counters with 4 synchronous outputs and WATCHDOG logic
 - MICROWIRE/PLUS serial I/O interface
 - CMOS—very low power with two power save modes: IDLE and HALT
- UART—full duplex, programmable baud rate
- Four additional 16-bit timer/counters with pulse width modulated outputs
- Four input capture registers
- 52 general purpose I/O lines (memory mapped)
- 8k bytes of ROM, 256 bytes of RAM on chip
- ROMless version available (HPC16003)
- Commercial (0°C to +70°C), industrial (-40°C to +85°C), automotive (-40°C to +105°C) and military (-55°C to +125°C) temperature ranges

For applications requiring more RAM and ROM see HPC16064 data sheet.

Block Diagram (HPC16083 with 8k ROM shown)

TL/DD/8801-1

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Total Allowable Source or Sink Current	100 mA
Storage Temperature Range	-65°C to +150°C
Lead Temperature (Soldering, 10 sec)	300°C

V_{CC} with Respect to GND -0.5V to 7.0V
All Other Pins ($V_{CC} + 0.5$)V to (GND - 0.5)V

Note: Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.

DC Electrical Characteristics $V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 0^\circ\text{C}$ to $+70^\circ\text{C}$ for HPC46083/HPC46003, -40°C to $+85^\circ\text{C}$ for HPC36083/HPC36003, -40°C to $+105^\circ\text{C}$ for HPC26083/HPC26003, -55°C to $+125^\circ\text{C}$ for HPC16083/HPC16003

Symbol	Parameter	Test Conditions	Min	Max	Units
I_{CC1}	Supply Current	$V_{CC} = 5.5V, f_{in} = 30\text{ MHz}$ (Note 1)		65	mA
		$V_{CC} = 5.5V, f_{in} = 20\text{ MHz}$ (Note 1)		47	mA
		$V_{CC} = 5.5V, f_{in} = 2.0\text{ MHz}$ (Note 1)		10	mA
I_{CC2}	IDLE Mode Current	$V_{CC} = 5.5V, f_{in} = 30\text{ MHz}$ (Note 1)		5.0	mA
		$V_{CC} = 5.5V, f_{in} = 20\text{ MHz}$, (Note 1)		3.0	mA
		$V_{CC} = 5.5V, f_{in} = 2.0\text{ MHz}$, (Note 1)		1	mA
I_{CC3}	HALT Mode Current	$V_{CC} = 5.5V, f_{in} = 0\text{ kHz}$, (Note 1)		200	μA
		$V_{CC} = 2.5V, f_{in} = 0\text{ kHz}$, (Note 1)		50	μA

INPUT VOLTAGE LEVELS FOR SCHMITT TRIGGERED INPUTS $\overline{\text{RESET}}$, NMI AND $\overline{\text{WO}}$; AND ALSO CKI

V_{IH1}	Logic High		$0.9 V_{CC}$		V
V_{IL1}	Logic Low			$0.1 V_{CC}$	V

ALL OTHER INPUTS

V_{IH2}	Logic High		$0.7 V_{CC}$		V
V_{IL2}	Logic Low			$0.2 V_{CC}$	V
I_{LI1}	Input Leakage Current	$V_{IN} = 0$ and $V_{IN} = V_{CC}$		± 2	μA
I_{LI2}	Input Leakage Current RDY/HLD, EXUI	$V_{IN} = 0$	-3	-50	μA
I_{LI3}	Input Leakage Current B12	$\overline{\text{RESET}} = 0, V_{IN} = V_{CC}$	0.5	7	mA

Ready Input	$t_{DAR} = \frac{1}{4}t_C + WS - 50$	Falling Edge of ALE to Falling Edge of RDY		75	ns	
	$t_{RWP} = t_C$	RDY Pulse Width	100		ns	

Note: $C_L = 40$ pF.

Note 1: These AC characteristics are guaranteed with external clock drive on CK1 having 50% duty cycle and with less than 15 pF load on CKO with rise and fall times (t_{CK1R} and t_{CK1F}) on CK1 input less than 2.5 ns.

Note 2: Do not design with these parameters unless CK1 is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CK1 or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{HLD} falling edge occurring at the latest time it can be accepted during the present CPU cycle being executed. If \overline{HLD} falling edge occurs later, t_{HAE} as long as $(3t_C + 4WS + 72t_C + 100)$ may occur depending on the following CPU instruction cycles, its wait state and ready input.

Note 4: WS (t_{WAIT}) x (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $t_C = 20$ MHz, with one wait programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

Note 6: This is guaranteed by design and not tested.

30 MHz

AC Electrical Characteristics (Continued)

(See Notes 1 and 4 and Figure 1 thru Figure 5) $V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 0^\circ C$ to $+70^\circ C$ for HPC46083/HPC46003, $-40^\circ C$ to $+85^\circ C$ for HPC36083/HPC36003, $-40^\circ C$ to $+105^\circ C$ for HPC26083/HPC26003, $-55^\circ C$ to $+125^\circ C$ for HPC16083/HPC16003

	Symbol and Formula	Parameter	Min	Max	Units	Note
Clocks	f_C	CKI Operating Frequency	2	30	MHz	
	$t_{C1} = 1/f_C$	CKI Clock Period	33	500	ns	
	t_{CKIH}	CKI High Time	15		ns	
	t_{CKIL}	CKI Low Time	16.6		ns	
	$t_C = 2/f_C$	CPU Timing Cycle	66		ns	
	$t_{WAIT} = t_C$	CPU Wait State Period	66		ns	
	t_{DC1C2R}	Delay of CK2 Rising Edge after CK1 Falling Edge	0	55	ns	(Note 1)
	t_{DC1C2F}	Delay of CK2 Falling Edge after CK1 Falling Edge	0	55	ns	(Note 1)
	$f_U = f_C/8$	External UART Clock Input Frequency		3.75**	MHz	
	f_{MW}	External MICROWIRE/PLUS Clock Input Frequency		1.875	MHz	
Timers	$f_{XIN} = f_C/22$	External Timer Input Frequency		1.364	MHz	
	$t_{XIN} = t_C$	Pulse Width for Timer Inputs	66		ns	
MICROWIRE/ PLUS	t_{UWS}	MICROWIRE Setup Time—Master —Slave	100 20		ns	
	t_{UWH}	MICROWIRE Hold Time—Master —Slave	20 50		ns	
	t_{UWV}	MICROWIRE Output Valid Time—Master —Slave		50 150	ns	
External Hold	$t_{SALE} = 3/4 t_C + 40$	HLD Falling Edge before ALE Rising Edge	90		ns	
	$t_{HWP} = t_C + 10$	HLD Pulse Width	76		ns	
	$t_{HAE} = t_C + 85$	HLDA Falling Edge after HLD Falling Edge		151	ns	(Note 3)
	$t_{HAD} = 3/4 t_C + 85$	HLDA Rising Edge after HLD Rising Edge		135	ns	
	$t_{BF} = 1/2 t_C + 66$	Bus Float after HLDA Falling Edge		99	ns	(Note 5)
	$t_{BE} = 1/2 t_C + 66$	Bus Enable after HLDA Rising Edge	99		ns	(Note 5)
UPI Timing	t_{UAS}	Address Setup Time to Falling Edge of \overline{URD}	10		ns	
	t_{UAH}	Address Hold Time from Rising Edge of \overline{URD}	10		ns	
	t_{RPW}	\overline{URD} Pulse Width	100		ns	
	t_{OE}	\overline{URD} Falling Edge to Output Data Valid	0	60	ns	
	t_{OD}	Rising Edge of \overline{URD} to Output Data Invalid	5	35	ns	(Note 3)
	t_{DRDY}	RDRDY Delay from Rising Edge of \overline{URD}		70	ns	
	t_{WDW}	\overline{UWR} Pulse Width	40		ns	
	t_{UDS}	Input Data Valid before Rising Edge of \overline{UWR}	10		ns	
	t_{UDH}	Input Data Hold after Rising Edge of \overline{UWR}	15		ns	
	t_A	WRRDY Delay from Rising Edge of \overline{UWR}		70	ns	

**This maximum frequency is attainable provided that this external baud clock has a duty cycle such that the high period includes two (2) falling edges of the CK2 clock.

30 MHz

AC Electrical Characteristics

(See Notes 1 and 4 and Figure 1 thru Figure 5) $V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 0^\circ C$ to $+70^\circ C$ for HPC46083/HPC46003, $-40^\circ C$ to $+85^\circ C$ for HPC36083/HPC36003, $-40^\circ C$ to $+105^\circ C$ for HPC26083/HPC26003, $-55^\circ C$ to $+125^\circ C$ for HPC16083/HPC16003 (Continued)

	Symbol and Formula	Parameter	Min	Max	Units	Notes
Address Cycles	$t_{DC1ALER}$	Delay from CKI Rising Edge to ALE Rising Edge	0	35	ns	(Notes 1, 2)
	$t_{DC1ALEF}$	Delay from CKI Rising Edge to ALE Falling Edge	0	35	ns	(Notes 1, 2)
	$t_{DC2ALER} = \frac{1}{4} t_C + 20$	Delay from CK2 Rising Edge to ALE Rising Edge		37	ns	(Note 2)
	$t_{DC2ALEF} = \frac{1}{4} t_C + 20$	Delay from CK2 Falling Edge to ALE Falling Edge		37	ns	(Note 2)
	$t_{LL} = \frac{1}{2} t_C - 9$	ALE Pulse Width	24		ns	
	$t_{ST} = \frac{1}{4} t_C - 7$	Setup of Address Valid before ALE Falling Edge	9		ns	
Read Cycles	$t_{VP} = \frac{1}{4} t_C - 5$	Hold of Address Valid after ALE Falling Edge	11		ns	
	$t_{ARR} = \frac{1}{4} t_C - 5$	ALE Falling Edge to \overline{RD} Falling Edge	12		ns	
	$t_{ACC} = t_C + WS - 32$	Data Input Valid after Address Output Valid		100	ns	(Note 2)
	$t_{RD} = \frac{1}{2} t_C + WS - 39$	Data Input Valid after \overline{RD} Falling Edge		60	ns	
	$t_{RW} = \frac{1}{2} t_C + WS - 14$	\overline{RD} Pulse Width	85		ns	
	$t_{DR} = \frac{3}{4} t_C - 15$	Hold of Data Input Valid after \overline{RD} Rising Edge	0	35	ns	
Write Cycles	$t_{RDA} = t_C - 15$	Bus Enable after \overline{RD} Rising Edge	51		ns	
	$t_{ARW} = \frac{1}{2} t_C - 5$	ALE Falling Edge to \overline{WR} Falling Edge	28		ns	
	$t_{WW} = \frac{3}{4} t_C + WS - 15$	\overline{WR} Pulse Width	101		ns	
	$t_V = \frac{1}{2} t_C + WS - 5$	Data Output Valid before \overline{WR} Rising Edge	94		ns	
Ready Input	$t_{HW} = \frac{1}{4} t_C - 10$	Hold of Data Valid after \overline{WR} Rising Edge	7		ns	
	$t_{DAR} = \frac{1}{4} t_C + WS - 50$	Falling Edge of ALE to Falling Edge of RDY		33	ns	
	$t_{RWP} = t_C$	RDY Pulse Width	66		ns	

Note: $C_L = 40$ pF.

Note 1: These AC characteristics are guaranteed with external clock drive on CKI having 50% duty cycle and with less than 15 pF load on CKO with rise and fall times (t_{CKIR} and t_{CKIL}) on CKI input less than 2.5 ns.

Note 2: Do not design with these parameters unless CKI is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CKI or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{HLD} falling edge occurring at the latest time it can be accepted during the present CPU cycle being executed. If \overline{HLD} falling edge occurs later, t_{HAE} as long as $(3t_C + 4WS + 72t_C + 100)$ may occur depending on the following CPU instruction cycles, its wait states and ready input.

Note 4: $WS \times t_{WAIT}$ (number of pre-programmed wait states). Minimum and maximum values are calculated from maximum operating frequency, $t_C = 30$ MHz, with one wait state programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

Note 6: This is guaranteed by design and not tested.

I_{CC2}	Idle Mode Current	$F_{IN} = 20$ MHz, External Clock		3.5		3.5		3.5	mA	
I_{CC}	Halt Mode Current	$NMI = V_{CC}$		2		2		2	mA	
CI/O	Input/Output Capacitance	$f_{test} = 1.0$ MHz, I/O Pin to Ground		20					pF	(Note 4)
CI	Input Capacitance	$f_{test} = 1.0$ MHz, Input Pin to Ground	SBGRP4							
				10						pF

Note 1: Electrical end point testing (when required) for Groups C & D shall consist only of subgroups 1, 2, 9 and 10.

Note 2: Port A V_{IH} test limit includes 700 mV offset caused by output loads being on during Data Drive Time.

Note 3: Port A V_{IL} test limit includes 400 mV offset caused by output loads being on during Data Drive Time.

Note 4: Verified at initial qual only.

Note 7: Future revisions of this device will not have pullups on pins I_0, I_7 which will be tested to I_{L1} conditions.

AC Electrical Specifications Test Conditions $V_{CC} = 4.5V$ and $5.5V$ (Unless Otherwise Specified) (Note 1)

Note 1: Electrical end point testing (when required) for groups C & D shall consist only of subgroups 1, 2, 9 and 10.

Note 5: Tested in functional patterns. Not directly measured.

Note 6: $C_L = 70$ pF. Input and output levels are per DC characteristics.

Pin Descriptions

The HPC16083 is available in 68-pin PLCC, LDCC, PGA, and 80-pin PQFP packages.

I/O PORTS

Port A is a 16-bit bidirectional I/O port with a data direction register to enable each separate pin to be individually defined as an input or output. When accessing external memory, port A is used as the multiplexed address/data bus.

Port B is a 16-bit port with 12 bits of bidirectional I/O similar in structure to Port A. Pins B10, B11, B12 and B15 are general purpose outputs only in this mode. Port B may also be configured via a 16-bit function register BFUN to individually allow each pin to have an alternate function.

B0:	TDX	UART Data Output
B1:		
B2:	CKX	UART Clock (Input or Output)
B3:	T2IO	Timer2 I/O Pin
B4:	T3IO	Timer3 I/O Pin
B5:	SO	MICROWIRE/PLUS Output
B6:	SK	MICROWIRE/PLUS Clock (Input or Output)
B7:	\overline{HLDA}	Hold Acknowledge Output
B8:	TS0	Timer Synchronous Output
B9:	TS1	Timer Synchronous Output
B10:	UA0	Address 0 Input for UPI Mode
B11:	\overline{WRRDY}	Write Ready Output for UPI Mode
B12:		
B13:	TS2	Timer Synchronous Output

Pin Descriptions (Continued)

- B14: TS3 Timer Synchronous Output
 B15: $\overline{RD\overline{RDY}}$ Read Ready Output for UPI Mode

When accessing external memory, four bits of port B are used as follows:

- B10: ALE Address Latch Enable Output
 B11: \overline{WR} Write Output
 B12: \overline{HBE} High Byte Enable Output/Input (sampled at reset)
 B15: \overline{RD} Read Output

Port I is an 8-bit input port that can be read as general purpose inputs and is also used for the following functions:

- I0:
 I1: NMI Nonmaskable Interrupt Input
 I2: INT2 Maskable Interrupt/Input Capture/ \overline{URD}
 I3: INT3 Maskable Interrupt/Input Capture/ \overline{UWR}
 I4: INT4 Maskable Interrupt/Input Capture
 I5: SI MICROWIRE/PLUS Data Input
 I6: RDX UART Data Input
 I7:

Port D is an 8-bit input port that can be used as general purpose digital inputs.

Port P is a 4-bit output port that can be used as general purpose data, or selected to be controlled by timers 4 through 7 in order to generate frequency, duty cycle and pulse width modulated outputs.

POWER SUPPLY PINS

- V_{CC1} and V_{CC2} Positive Power Supply
 GND Ground for On-Chip Logic
 DGND Ground for Output Buffers

Note: There are two electrically connected V_{CC} pins on the chip, GND and DGND are electrically isolated. Both V_{CC} pins and both ground pins must be used.

CLOCK PINS

- CKI The Chip System Clock Input
 CKO The Chip System Clock Output (inversion of CKI)
 Pins CKI and CKO are usually connected across an external crystal.

- CK2 Clock Output (CKI divided by 2)

OTHER PINS

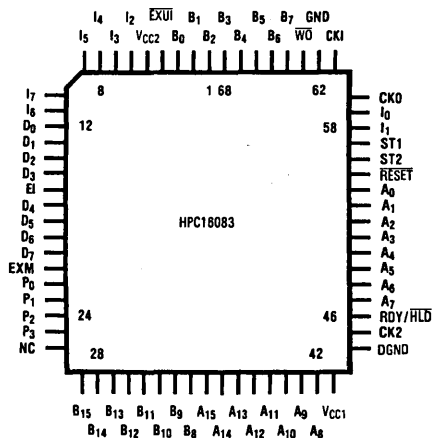

- \overline{WO} This is an active low open drain output that signals an illegal situation has been detected by the Watch Dog logic.
 ST1 Bus Cycle Status Output: indicates first opcode fetch.
 ST2 Bus Cycle Status Output: indicates machine states (skip, interrupt and first instruction cycle).
 \overline{RESET} is an active low input that forces the chip to start and sets the ports in a TRI-STATE mode.

$\overline{RDY}/\overline{HLD}$ has two uses, selected by a software bit. It's either a READY input to extend the bus cycle for slower memories, or a HOLD request input to put the bus in a high impedance state for DMA purposes.

- NC (no connection) do not connect anything to this pin.
 EXM External memory enable (active high) disables internal ROM and maps it to external memory.
 EI External interrupt with vector address FFF1:FFF0. (Rising/falling edge or high/low level sensitive). Alternately can be configured as 4th input capture.
 \overline{EXUI} External interrupt which is internally OR'ed with the UART interrupt with vector address FFF3:FFF2 (Active Low).

Ports A & B

The highly flexible A and B ports are similarly structured. The Port A (see *Figure 11*), consists of a data register and a direction register. Port B (see *Figures 12, 13, 14*) has an alternate function register in addition to the data and direction registers. All the control registers are read/write registers.

The associated direction registers allow the port pins to be individually programmed as inputs or outputs. Port pins selected as inputs, are placed in a TRI-STATE mode by resetting corresponding bits in the direction register.

A write operation to a port pin configured as an input causes the value to be written into the data register, a read operation returns the value of the pin. Writing to port pins configured as outputs causes the pins to have the same value, reading the pins returns the value of the data register.

Primary and secondary functions are multiplexed onto Port B through the alternate function register (BFUN). The secondary functions are enabled by setting the corresponding bits in the BFUN register.

Operating Modes

To offer the user a variety of I/O and expanded memory options, the HPC16083 has four operating modes. The ROMless HPC16003 has one mode of operation. The various modes of operation are determined by the state of both the EXM pin and the EA bit in the PSW register. The state of the EXM pin determines whether on-chip ROM will be accessed or external memory will be accessed within the address range of the on-chip ROM. The on-chip ROM range of the HPC16083 is E000 to FFFF (8k bytes). The HPC16003 has no on-chip ROM and is intended for use with external memory for program storage. A logic "0" state on the EXM pin will cause the HPC device to address on-chip ROM when the Program Counter (PC) contains addresses within the on-chip ROM address range. A logic "1" state on the EXM pin will cause the HPC device to address memory that is external to the HPC when the PC contains on-chip ROM addresses. The EXM pin should always be pulled high (logic "1") on the HPC16003 because no on-chip ROM is available. The function of the EA bit is to determine the legal addressing range of the HPC device. A logic "0" state in the EA bit of the PSW register does two things—addresses are limited to the on-chip ROM range and on-chip RAM and Register range, and the "illegal address detection" feature of the WATCHDOG logic is engaged. A logic "1" in the EA bit enables accesses to be made anywhere within the 64k byte address range and the "illegal address detection" feature of the WATCHDOG logic is disabled. The EA bit should be set to "1" by software when using the HPC16003 to disable the "illegal address detection" feature of WATCHDOG.

All HPC devices can be used with external memory. External memory may be any combination of RAM and ROM. Both 8-bit and 16-bit external data bus modes are available. Upon entering an operating mode in which external memory is used, port A becomes the Address/Data bus. Four pins of port B become the control lines ALE, \overline{RD} , \overline{WR} and HBE. The High Byte Enable pin (\overline{HBE}) is used in 16-bit mode to select high order memory bytes. The \overline{RD} and \overline{WR} signals are only generated if the selected address is off-chip. The 8-bit mode is selected by pulling \overline{HBE} high at reset. If \overline{HBE} is left floating or connected to a memory device chip select at reset, the 16-bit mode is entered. The following sections describe the operating modes of the HPC16083 and HPC16003.

Note: The HPC devices use 16-bit words for stack memory. Therefore, when using the 8-bit mode, User's Stack must be in internal RAM.

HPC16083 Operating Modes

SINGLE CHIP NORMAL MODE

In this mode, the HPC16083 functions as a self-contained microcomputer (see *Figure 15*) with all memory (RAM and

ROM) on-chip. It can address internal memory only, consisting of 8k bytes of ROM (E000 to FFFF) and 256 bytes of on-chip RAM and registers (0000 to 01FF). The "illegal address detection" feature of the WATCHDOG is enabled in the Single-Chip Normal mode and a WATCHDOG Output (\overline{WO}) will occur if an attempt is made to access addresses that are outside of the on-chip ROM and RAM range of the device. Ports A and B are used for I/O functions and not for addressing external memory. The EXM pin and the EA bit of the PSW register must both be logic "0" to enter the Single-Chip Normal mode.

EXPANDED NORMAL MODE

The Expanded Normal mode of operation enables the HPC16083 to address external memory in addition to the on-chip ROM and RAM (see Table II). WATCHDOG illegal address detection is disabled and memory accesses may be made anywhere in the 64k byte address range without triggering an illegal address condition. The Expanded Normal mode is entered with the EXM pin pulled low (logic "0") and setting the EA bit in the PSW register to "1".

SINGLE-CHIP ROMLESS MODE

In this mode, the on-chip mask programmed ROM of the HPC16083 is not used. The address space corresponding to the on-chip ROM is mapped into external memory so 8k bytes of external memory may be used with the HPC16083 (see Table II). The WATCHDOG circuitry detects illegal addresses (addresses not within the on-chip ROM and RAM range). The Single-Chip ROMless mode is entered when the EXM pin is pulled high (logic "1") and the EA bit is logic "0".

EXPANDED ROMLESS MODE

This mode of operation is similar to Single-Chip ROMless mode in that no on-chip ROM is used, however, a full 64k bytes of external memory may be used. The "illegal address detection" feature of WATCHDOG is disabled. The EXM pin must be pulled high (logic "1") and the EA bit in the PSW register set to "1" to enter this mode.

TABLE II. HPC16083 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Single-Chip Normal	0	0	E000:FFFF on-chip
Expanded Normal	0	1	E000:FFFF on-chip 0200:DFFF off-chip
Single-Chip ROMless	1	0	E000:FFFF off-chip
Expanded ROMless	1	1	0200:FFFF off-chip

Note: In all operating modes, the on-chip RAM and Registers (0000:01FF) may be accessed.

HPC16003 Operating Modes

EXPANDED ROMLESS MODE (HPC16003)

Because the HPC16003 has no on-chip ROM, it has only one mode of operation, the Expanded ROMless Mode. The EXM pin must be pulled high (logic "1") on power up, the EA bit in the PSW register should be set to a "1". The HPC16003 is a ROMless device and is intended for use with external memory. The external memory may be any combination of ROM and RAM. Up to 64k bytes of external memory may be accessed. It is necessary to vector on reset to an address between F000 and FFFF, therefore the user should have external memory at these addresses. The EA bit in the PSW register must immediately be set to "1" at the beginning of the user's program to disable illegal address detection in the WATCHDOG logic.

TABLE III. HPC16003 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Expanded ROMless	1	1	0200:FFFF off-chip

Note: The on-chip RAM and Registers (0000:01FF) of the HPC16003 may be accessed at all times.

HPC16003 Operating Modes (Continued)

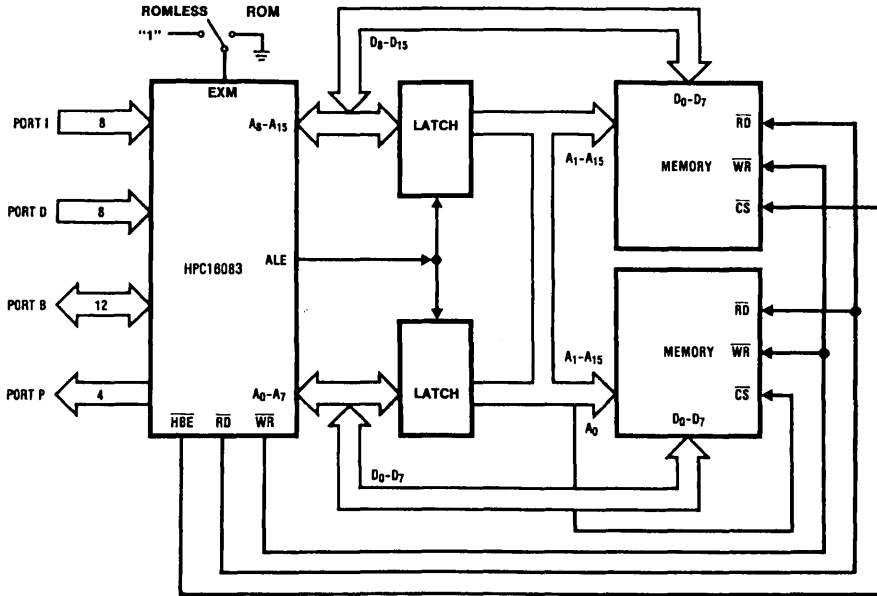

FIGURE 17. 16-Bit External Memory

TL/DD/8801-19

Wait States

The internal ROM can be accessed at the maximum operating frequency with one wait state. With 0 wait states, internal ROM accesses are limited to $\frac{2}{3} f_C$ max.

The HPC16083 provides four software selectable Wait States that allow access to slower memories. The Wait States are selected by the state of two bits in the PSW register. Additionally, the RDY input may be used to extend the instruction cycle, allowing the user to interface with slow memories and peripherals.

Power Save Modes

Two power saving modes are available on the HPC16083: HALT and IDLE. In the HALT mode, all processor activities are stopped. In the IDLE mode, the on-board oscillator and timer T0 are active but all other processor activities are stopped. In either mode, all on-board RAM, registers and I/O are unaffected.

HALT MODE

The HPC16083 is placed in the HALT mode under software control by setting bits in the PSW. All processor activities, including the clock and timers, are stopped. In the HALT mode, power requirements for the HPC16083 are minimal and the applied voltage (V_{CC}) may be decreased without altering the state of the machine. There are two ways of exiting the HALT mode: via the RESET or the NMI. The RESET input reinitializes the processor. Use of the NMI input will generate a vectored interrupt and resume operation from that point with no initialization. The HALT mode can be enabled or disabled by means of a control register HALT enable. To prevent accidental use of the HALT mode the HALT enable register can be modified only once.

IDLE MODE

The HPC16083 is placed in the IDLE mode through the PSW. In this mode, all processor activity, except the on-board oscillator and Timer T0, is stopped. As with the HALT mode, the processor is returned to full operation by the RESET or NMI inputs, but without waiting for oscillator stabilization. A timer T0 overflow will also cause the HPC16083 to resume normal operation.

HPC16083 Interrupts

Complex interrupt handling is easily accomplished by the HPC16083's vectored interrupt scheme. There are eight possible interrupt sources as shown in Table IV.

TABLE IV. Interrupts

Vector Address	Interrupt Source	Arbitration Ranking
FFFF:FFFE	RESET	0
FFFD:FFFC	Nonmaskable external on rising edge of I1 pin	1
FFFB:FFFA	External interrupt on I2 pin	2
FFF9:FFF8	External interrupt on I3 pin	3
FFF7:FFF6	External interrupt on I4 pin	4
FFF5:FFF4	Overflow on internal timers	5
FFF3:FFF2	Internal on the UART transmit/receive complete or external on EXUI	6
FFF1:FFF0	External interrupt on EI pin	7

Interrupt Arbitration

The HPC16083 contains arbitration logic to determine which interrupt will be serviced first if two or more interrupts occur simultaneously. The arbitration ranking is given in Table IV. The interrupt on $\overline{\text{RESET}}$ has the highest rank and is serviced first.

Interrupt Processing

Interrupts are serviced after the current instruction is completed except for the $\overline{\text{RESET}}$, which is serviced immediately. $\overline{\text{RESET}}$ and $\overline{\text{EXUI}}$ are level-LOW-sensitive interrupts and EI is programmable for edge-(RISING or FALLING) or level-(HIGH or LOW) sensitivity. All other interrupts are edge-sensitive. NMI is positive-edge sensitive. The external interrupts on I2, I3 and I4 can be software selected to be rising or falling edge. External interrupt ($\overline{\text{EXUI}}$) is shared with the UART interrupt. This interrupt is level-low sensitive. To select this interrupt disable the ERI and ETI UART interrupt bits in the ENUI register. To select the UART interrupt leave this pin floating or tie it high.

Interrupt Control Registers

The HPC16083 allows the various interrupt sources and conditions to be programmed. This is done through the various control registers. A brief description of the different control registers is given below.

INTERRUPT ENABLE REGISTER (ENIR)

$\overline{\text{RESET}}$ and the External Interrupt on I1 are non-maskable interrupts. The other interrupts can be individually enabled or disabled. Additionally, a Global Interrupt Enable Bit in the ENIR Register allows the Maskable interrupts to be collectively enabled or disabled. Thus, in order for a particular interrupt to request service both the individual enable bit and the Global Interrupt bit (GIE) have to be set.

INTERRUPT PENDING REGISTER (IRPD)

The IRPD register contains a bit allocated for each interrupt vector. The occurrence of specified interrupt trigger conditions causes the appropriate bit to be set. There is no indication of the order in which the interrupts have been received. The bits are set independently of the fact that the

interrupts may be disabled. IRPD is a Read/Write register. The bits corresponding to the maskable, external interrupts are normally cleared by the HPC16083 after servicing the interrupts.

For the interrupts from the on-board peripherals, the user has the responsibility of resetting the interrupt pending flags through software.

The NMI bit is read only and I2, I3, and I4 are designed as to only allow a zero to be written to the pending bit (writing a one has no affect). A LOAD IMMEDIATE instruction is to be the only instruction used to clear a bit or bits in the IRPD register. This allows a mask to be used, thus ensuring that the other pending bits are not affected.

INTERRUPT CONDITION REGISTER (IRCD)

Three bits of the register select the input polarity of the external interrupt on I2, I3, and I4.

Servicing the Interrupts

The Interrupt, once acknowledged, pushes the program counter (PC) onto the stack thus incrementing the stack pointer (SP) twice. The Global Interrupt Enable bit (GIE) is copied into the CGIE bit of the PSW register; it is then reset, thus disabling further interrupts. The program counter is loaded with the contents of the memory at the vector address and the processor resumes operation at this point. At the end of the interrupt service routine, the user does a RETI instruction to pop the stack and re-enable interrupts if the CGIE bit is set, or RET to just pop the stack if the CGIE bit is clear, and then returns to the main program. The GIE bit can be set in the interrupt service routine to nest interrupts if desired. *Figure 18* shows the Interrupt Enable Logic.

RESET

The $\overline{\text{RESET}}$ input initializes the processor and sets ports A and B in the TRI-STATE condition and port P in the LOW state. $\overline{\text{RESET}}$ is an active-low Schmitt trigger input. The processor vectors to FFFF:FFFE and resumes operation at the address contained at that memory location (which must correspond to an on board location). The Reset vector address must be between E000 and FFFF when using the HPC16003.

FIGURE 18. Block Diagram of Interrupt Logic

Timer Overview

The HPC16083 contains a powerful set of flexible timers enabling the HPC16083 to perform extensive timer functions; not usually associated with microcontrollers.

The HPC16083 contains nine 16-bit timers. Timer T0 is a free-running timer, counting up at a fixed CKI/16 (Clock Input/16) rate. It is used for WATCHDOG logic, high speed event capture, and to exit from the IDLE mode. Consequently, it cannot be stopped or written to under software control. Timer T0 permits precise measurements by means of the capture registers I2CR, I3CR, and I4CR. A control bit in the register TMMODE configures timer T1 and its associated register R1 as capture registers I3CR and I2CR. The capture registers I2CR, I3CR, and I4CR respectively, record the value of timer T0 when specific events occur on the interrupt pins I2, I3, and I4. The control register IRCD programs the capture registers to trigger on either a rising edge or a falling edge of its respective input. The specified edge can also be programmed to generate an interrupt (see Figure 19).

The HPC16083 provides an additional 16-bit free running timer, T8, with associated input capture register EICR (External Interrupt Capture Register) and Configuration Register, EICON. EICON is used to select the mode and edge of the EI pin. EICR is a 16-bit capture register which records the value of T8 (which is identical to T0) when a specific event occurs on the EI pin.

The timers T2 and T3 have selectable clock rates. The clock input to these two timers may be selected from the following two sources: an external pin, or derived internally by dividing the clock input. Timer T2 has additional capability of being clocked by the timer T3 underflow. This allows the user to cascade timers T3 and T2 into a 32-bit timer/counter. The control register DIVBY programs the clock input to timers T2 and T3 (see Figure 20).

The timers T1 through T7 in conjunction with their registers form Timer-Register pairs. The registers hold the pulse duration values. All the Timer-Register pairs can be read from or written to. Each timer can be started or stopped under

software control. Once enabled, the timers count down, and upon underflow, the contents of its associated register are automatically loaded into the timer.

FIGURE 19. Timers T0, T1 and T8 with Four Input Capture Registers

SYNCHRONOUS OUTPUTS

The flexible timer structure of the HPC16083 simplifies pulse generation and measurement. There are four synchronous timer outputs (TS0 through TS3) that work in conjunction with the timer T2. The synchronous timer outputs can be used either as regular outputs or individually programmed to toggle on timer T2 underflows (see Figure 20). Timer/register pairs 4-7 form four identical units which can generate synchronous outputs on port P (see Figure 21).

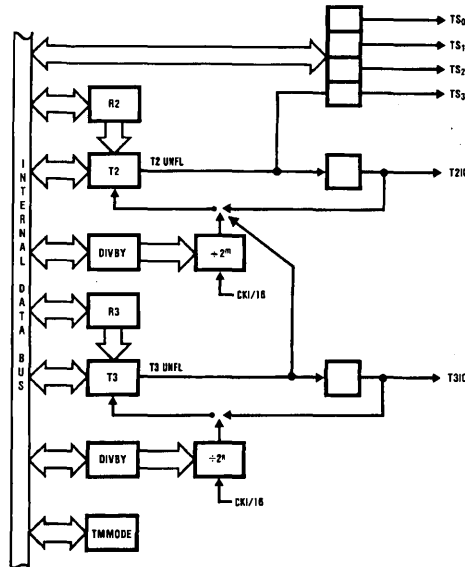

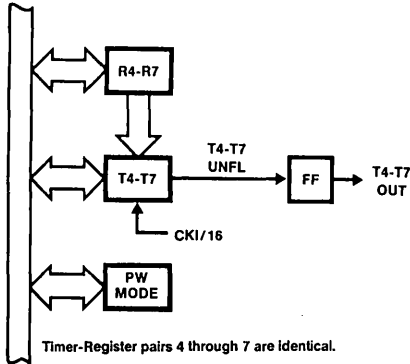

FIGURE 20. Timers T2-T3 Block

Timer Overview (Continued)

Timer-Register pairs 4 through 7 are identical.

TL/DD/8801-23

FIGURE 21. Timers T4-T7 Block

Maximum output frequency for any timer output can be obtained by setting timer/register pair to zero. This then will produce an output frequency equal to 1/2 the frequency of the source used for clocking the timer.

Timer Registers

There are four control registers that program the timers. The divide by (DIVBY) register programs the clock input to timers T2 and T3. The timer mode register (TMMODE) contains control bits to start and stop timers T1 through T3. It also contains bits to latch, acknowledge and enable interrupts from timers T0 through T3. The control register PWMODE similarly programs the pulse width timers T4 through T7 by allowing them to be started, stopped, and to latch and enable interrupts on underflows. The PORTP register contains bits to preset the outputs and enable the synchronous timer output functions.

Timer Applications

The use of Pulse Width Timers for the generation of various waveforms is easily accomplished by the HPC16083.

Frequencies can be generated by using the timer/register pairs. A square wave is generated when the register value is a constant. The duty cycle can be controlled simply by changing the register value.

TL/DD/8801-24

FIGURE 22. Square Wave Frequency Generation

Synchronous outputs based on Timer T2 can be generated on the 4 outputs TS0-TS3. Each output can be individually programmed to toggle on T2 underflow. Register R2 contains the time delay between events. Figure 23 is an example of synchronous pulse train generation.

WATCHDOG Logic

The WATCHDOG Logic monitors the operations taking place and signals upon the occurrence of any illegal activity. The illegal conditions that trigger the WATCHDOG logic are potentially infinite loops and illegal addresses. Should the

TL/DD/8801-25

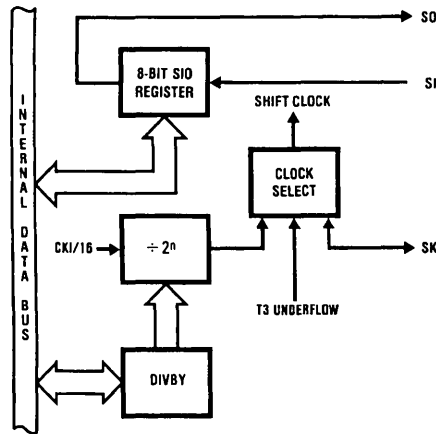

FIGURE 23. Synchronous Pulse Generation

WATCHDOG register not be written to before Timer T0 overflows twice, or more often than once every 4096 counts, an infinite loop condition is assumed to have occurred. An illegal condition also occurs when the processor generates an illegal address when in the Single-Chip modes.* Any illegal condition forces the WATCHDOG Output (WO) pin low. The WO pin is an open drain output and can be connected to the RESET or NMI inputs or to the users external logic.

*Note: See Operating Modes for details.

MICROWIRE/PLUS

MICROWIRE/PLUS is used for synchronous serial data communications (see Figure 24). MICROWIRE/PLUS has an 8-bit parallel-loaded, serial shift register using SI as the input and SO as the output. SK is the clock for the serial shift register (SIO). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. A DONE flag indicates when the data shift is completed.

TL/DD/8801-26

FIGURE 24. MICROWIRE/PLUS

The MICROWIRE/PLUS capability enables it to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., A/D converters, display drivers, EEPROMs).

MICROWIRE/PLUS Operation

The HPC16083 can enter the MICROWIRE/PLUS mode as the master or a slave. A control bit in the IRCD register determines whether the HPC16083 is the master or slave. The shift clock is generated when the HPC16083 is configured as a master. An externally generated shift clock on the SK pin is used when the HPC16083 is configured as a slave. When the HPC16083 is a master, the DIVBY register programs the frequency of the SK clock. The DIVBY register allows the SK clock frequency to be programmed in 15 selectable steps from 64 Hz to 1 MHz with CKI at 16.0 MHz. The contents of the SIO register may be accessed through any of the memory access instructions. Data waiting to be transmitted in the SIO register is clocked out on the falling edge of the SK clock. Serial data on the SI pin is clocked in on the rising edge of the SK clock.

MICROWIRE/PLUS Application

Figure 25 illustrates a MICROWIRE/PLUS arrangement for an automotive application. The microcontroller-based sys-

tem could be used to interface to an instrument cluster and various parts of the automobile. The diagram shows two HPC16083 microcontrollers interconnected to other MICROWIRE peripherals. HPC16083 #1 is set up as the master and initiates all data transfers. HPC16083 #2 is set up as a slave answering to the master.

The master microcontroller interfaces the operator with the system and could also manage the instrument cluster in an automotive application. Information is visually presented to the operator by means of a LCD display controlled by the COP472 display driver. The data to be displayed is sent serially to the COP472 over the MICROWIRE/PLUS link. Data such as accumulated mileage could be stored and retrieved from the EEPROM COP494. The slave HPC16083 could be used as a fuel injection processor and generate timing signals required to operate the fuel valves. The master processor could be used to periodically send updated values to the slave via the MICROWIRE/PLUS link. To speed up the response, chip select logic is implemented by connecting an output from the master to the external interrupt input on the slave.

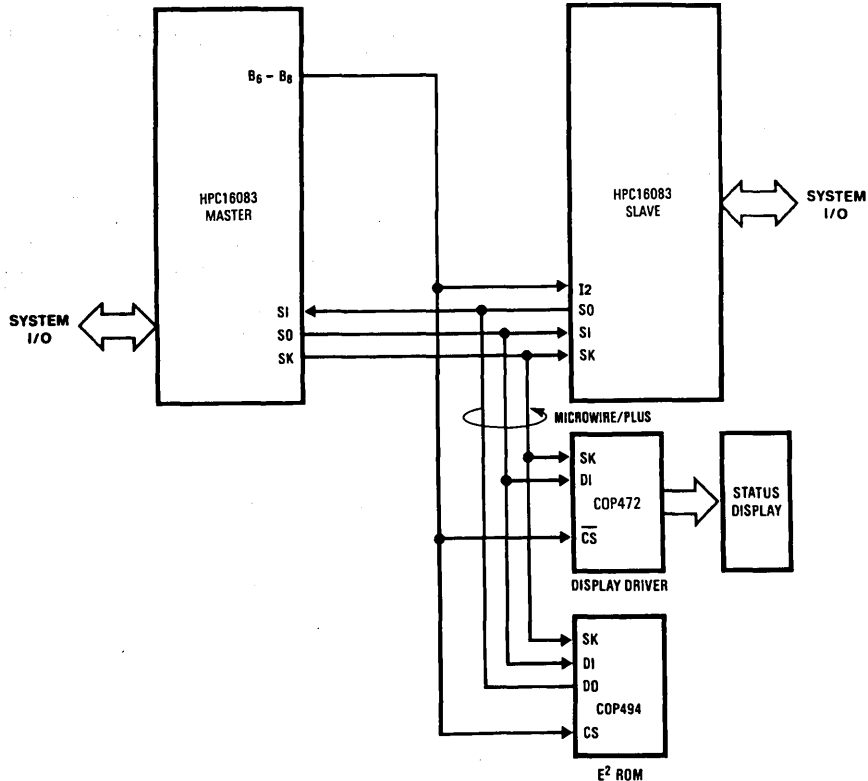

FIGURE 25. MICROWIRE/PLUS Application

TL/DD/8801-27

HPC16083 UART

The HPC16083 contains a software programmable UART. The UART (see Figure 26) consists of a transmit shift register, a receiver shift register and five addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR) and a UART interrupt and clock source register (ENUI). The ENUI register contains flags for transmit and receive functions; this register also determines the length of the data frame (8 or 9 bits) and the value of the ninth bit in transmission. The ENUR register flags framing and data overrun errors while the UART is receiving. Other functions of the ENUR register include saving the ninth bit received in the data frame and enabling or disabling the UART's Wake-up Mode of operation. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts.

The baud rate clock for the Receiver and Transmitter can be selected for either an internal or external source using two bits in the ENUI register. The internal baud rate is programmed by the DIVBY register. The baud rate may be selected from a range of 8 Hz to 128 kHz in binary steps or T3 underflow. By selecting a 9.83 MHz crystal, all standard baud rates from 75 baud to 38.4 kBaud can be generated. The external baud clock source comes from the CKX pin. The Transmitter and Receiver can be run at different rates by selecting one to operate from the internal clock and the other from an external source.

The HPC16083 UART supports two data formats. The first format for data transmission consists of one start bit, eight data bits and one or two stop bits. The second data format for transmission consists of one start bit, nine data bits, and one or two stop bits. Receiving formats differ from transmission only in that the Receiver always requires only one stop bit in a data frame.

UART Wake-up Mode

The HPC16083 UART features a Wake-up Mode of operation. This mode of operation enables the HPC16083 to be networked with other processors. Typically in such environments, the messages consist of addresses and actual data. Addresses are specified by having the ninth bit in the data frame set to 1. Data in the message is specified by having the ninth bit in the data frame reset to 0.

The UART monitors the communication stream looking for addresses. When the data word with the ninth bit set is received, the UART signals the HPC16083 with an interrupt. The processor then examines the content of the receiver buffer to decide whether it has been addressed and whether to accept subsequent data.

FIGURE 26. UART Block Diagram

TL/DD/8801-28

Universal Peripheral Interface

The Universal Peripheral Interface (UPI) allows the HPC16083 to be used as an intelligent peripheral to another processor. The UPI could thus be used to tightly link two HPC16083's and set up systems with very high data exchange rates. Another area of application could be where a HPC16083 is programmed as an intelligent peripheral to a host system such as the Series 32000[®] microprocessor. *Figure 27* illustrates how a HPC16083 could be used as an intelligent peripheral for a Series 32000-based application.

The interface consists of a Data Bus (port A), a Read Strobe (\overline{URD}), a Write Strobe (\overline{UWR}), a Read Ready Line (\overline{RDRDY}), a Write Ready Line (\overline{WRRDY}) and one Address Input (UA0). The data bus can be either eight or sixteen bits wide.

The \overline{URD} and \overline{UWR} inputs may be used to interrupt the HPC16083. The \overline{RDRDY} and \overline{WRRDY} outputs may be used to interrupt the host processor.

The UPI contains an Input Buffer (IBUF), an Output Buffer (OBUF) and a Control Register (UPIC). In the UPI mode, port A on the HPC16083 is the data bus. UPI can only be used if the HPC16083 is in the Single-Chip mode.

Shared Memory Support

Shared memory access provides a rapid technique to exchange data. It is effective when data is moved from a peripheral to memory or when data is moved between blocks of memory. A related area where shared memory access proves effective is in multiprocessing applications where two CPUs share a common memory block. The HPC16083 supports shared memory access with two pins. The pins are the $\overline{RDY}/\overline{HLD}$ input pin and the \overline{HLDA} output pin. The user can software select either the Hold or Ready function by the state of a control bit. The \overline{HLDA} output is multiplexed onto port B.

The host uses DMA to interface with the HPC16083. The host initiates a data transfer by activating the \overline{HLD} input of the HPC16083. In response, the HPC16083 places its system bus in a TRI-STATE Mode, freeing it for use by the host. The host waits for the acknowledge signal (\overline{HLDA}) from the HPC16083 indicating that the system bus is free. On receiving the acknowledge, the host can rapidly transfer data into, or out of, the shared memory by using a conventional DMA controller. Upon completion of the message transfer, the host removes the HOLD request and the HPC16083 resumes normal operations.

Figure 28 illustrates an application of the shared memory interface between the HPC16083 and a Series 32000 system. To insure proper operation, the interface logic shown is recommended as the means for enabling and disabling the user's bus.

Memory

The HPC16083 has been designed to offer flexibility in memory usage. A total address space of 64 kbytes can be addressed with 8 kbytes of ROM and 256 bytes of RAM available on the chip itself. The ROM may contain program instructions, constants or data. The ROM and RAM share the same address space allowing instructions to be executed out of RAM.

Program memory addressing is accomplished by the 16-bit program counter on a byte basis. Memory can be addressed directly by instructions or indirectly through the B, X and SP registers. Memory can be addressed as words or bytes. Words are always addressed on even-byte boundaries. The HPC16083 uses memory-mapped organization to support registers, I/O and on-chip peripheral functions.

The HPC16083 memory address space extends to 64 kbytes and registers and I/O are mapped as shown in Table V.

Design Considerations

Designs using the HPC family of 16-bit high speed CMOS microcontrollers need to follow some general guidelines on usage and board layout.

Floating inputs are a frequently overlooked problem. CMOS inputs have extremely high impedance and, if left open, can float to any voltage. You should thus tie unused inputs to V_{CC} or ground, either through a resistor or directly. Unlike the inputs, unused outputs should be left floating to allow the output to switch without drawing any DC current.

To reduce voltage transients, keep the supply line's parasitic inductances as low as possible by reducing trace lengths, using wide traces, ground planes, and by decoupling the supply with bypass capacitors. In order to prevent additional voltage spiking, this local bypass capacitor must exhibit low inductive reactance. You should therefore use high frequency ceramic capacitors and place them very near the IC to minimize wiring inductance.

- Keep V_{CC} bus routing short. When using double sided or multilayer circuit boards, use ground plane techniques.
- Keep ground lines short, and on PC boards make them as wide as possible, even if trace width varies. Use separate ground traces to supply high current devices such as relay and transmission line drivers.
- In systems mixing linear and logic functions and where supply noise is critical to the analog components' performance, provide separate supply buses or even separate supplies.
- If you use local regulators, bypass their inputs with a tantalum capacitor of at least $1 \mu F$ and bypass their outputs with a $10 \mu F$ to $50 \mu F$ tantalum or aluminum electrolytic capacitor.
- If the system uses a centralized regulated power supply, use a $10 \mu F$ to $20 \mu F$ tantalum electrolytic capacitor or a $50 \mu F$ to $100 \mu F$ aluminum electrolytic capacitor to decouple the V_{CC} bus connected to the circuit board.
- Provide localized decoupling. For random logic, a rule of thumb dictates approximately 10 nF (spaced within 12 cm) per every two to five packages, and 100 nF for every 10 packages. You can group these capacitances, but it's more effective to distribute them among the ICs. If the design has a fair amount of synchronous logic with outputs that tend to switch simultaneously, additional decoupling might be advisable. Octal flip flop and buffers in bus-oriented circuits might also require more decoupling. Note that wire-wrapped circuits can require more decoupling than ground plane or multilayer PC boards.

TL/DD/8801-40

FIGURE 29. Recommended Crystal Circuit

A recommended crystal oscillator circuit to be used with the HPC is shown below. See table for recommended component values. The recommended values given in the table below have yielded consistent results and are made to match a crystal with a 18 pF load capacitance, with some small allowance for layout capacitance.

A recommended layout for the oscillator network should be as close to the processor as physically possible, entirely within $1''$ distance. This is to reduce lead inductance from long PC traces, as well as interference from other components, and reduce trace capacitance. The layout contains a large ground plane either on the top or bottom surface of the board to provide signal shielding, and a convenient location to ground both the HPC, and the case of the crystal.

It is very critical to have an extremely clean power supply for the HPC crystal oscillator. Ideally one would like a V_{CC} and ground plane that provide low inductance power lines to the chip. The power planes in the PC board should be decoupled with three decoupling capacitors as close to the chip as possible. A $1.0 \mu F$, a $0.1 \mu F$, and a $0.001 \mu F$ dipped mica or ceramic cap mounted as close to the HPC as is physically possible on the board, using the shortest leads, or surface mount components. This should provide a stable power supply, and noiseless ground plane which will vastly improve the performance of the crystal oscillator network.

HPC Oscillator Table

XTAL Frequency (MHz)	$R_1 (\Omega)$
≤ 2	1500
4	1200
6	910
8	750
10	600

22	150
24	120
26	100
28	75
30	62

$R_F = 3.3 \text{ M}\Omega$

$C_1 = 27 \text{ pF}$

$C_2 = 33 \text{ pF}$

XTAL Specifications: The crystal used was an M-TRON Industries MP-1 Series XTAL. "AT" cut parallel resonant

$C_L = 18 \text{ pF}$

Series Resistance is:

$25 \Omega @ 25 \text{ MHz}$

$40 \Omega @ 10 \text{ MHz}$

$600 \Omega @ 2 \text{ MHz}$

HPC16083 CPU

The HPC16083 CPU has a 16-bit ALU and six 16-bit registers

Arithmetic Logic Unit (ALU)

The ALU is 16 bits wide and can do 16-bit add, subtract and shift or logic AND, OR and exclusive OR in one timing cycle. The ALU can also output the carry bit to a 1-bit C register.

Accumulator (A) Register

The 16-bit A register is the source and destination register for most I/O, arithmetic, logic and data memory access operations.

Address (B and X) Registers

The 16-bit B and X registers can be used for indirect addressing. They can automatically count up or down to sequence through data memory.

Boundary (K) Register

The 16-bit K register is used to set limits in repetitive loops of code as register B sequences through data memory.

Stack Pointer (SP) Register

The 16-bit SP register is the pointer that addresses the stack. The SP register is incremented by two for each push or call and decremented by two for each pop or return. The stack can be placed anywhere in user memory and be as deep as the available memory permits.

Program (PC) Register

The 16-bit PC register addresses program memory.

Addressing Modes

ADDRESSING MODES—ACCUMULATOR AS DESTINATION

Register Indirect

This is the "normal" mode of addressing for the HPC16083 (instructions are single-byte). The operand is the memory addressed by the B register (or X register for some instructions).

Direct

The instruction contains an 8-bit or 16-bit address field that directly points to the memory for the operand.

Indirect

The instruction contains an 8-bit address field. The contents of the WORD addressed points to the memory for the operand.

Indexed

The instruction contains an 8-bit address field and an 8- or 16-bit displacement field. The contents of the WORD addressed is added to the displacement to get the address of the operand.

Immediate

The instruction contains an 8-bit or 16-bit immediate field that is used as the operand.

Register Indirect (Auto Increment and Decrement)

The operand is the memory addressed by the X register. This mode automatically increments or decrements the X register (by 1 for bytes and by 2 for words).

Register Indirect (Auto Increment and Decrement) with Conditional Skip

The operand is the memory addressed by the B register. This mode automatically increments or decrements the B register (by 1 for bytes and by 2 for words). The B register is then compared with the K register. A skip condition is generated if B goes past K.

ADDRESSING MODES—DIRECT MEMORY AS DESTINATION

Direct Memory to Direct Memory

The instruction contains two 8- or 16-bit address fields. One field directly points to the source operand and the other field directly points to the destination operand.

Immediate to Direct Memory

The instruction contains an 8- or 16-bit address field and an 8- or 16-bit immediate field. The immediate field is the operand and the direct field is the destination.

Double Register Indirect Using the B and X Registers

Used only with Reset, Set and IF bit instructions; a specific bit within the 64 kbyte address range is addressed using the B and X registers. The address of a byte of memory is formed by adding the contents of the B register to the most significant 13 bits of the X register. The specific bit to be modified or tested within the byte of memory is selected using the least significant 3 bits of register X.

HPC Instruction Set Description

Mnemonic	Description	Action
ARITHMETIC INSTRUCTIONS		
ADD	Add	$MA + Meml \rightarrow MA$ carry $\rightarrow C$
ADC	Add with carry	$MA + Meml + C \rightarrow MA$ carry $\rightarrow C$
ADDS	Add short imm8	$MA + imm8 \rightarrow MA$ carry $\rightarrow C$
DADC	Decimal add with carry	$MA + Meml + C \rightarrow MA$ (Decimal) carry $\rightarrow C$
SUBC	Subtract with carry	$MA - Meml + C \rightarrow MA$ carry $\rightarrow C$
DSUBC	Decimal subtract w/carry	$MA - Meml + C \rightarrow MA$ (Decimal) carry $\rightarrow C$
MULT	Multiply (unsigned)	$MA * Meml \rightarrow MA \& X, 0 \rightarrow K, 0 \rightarrow C$
DIV	Divide (unsigned)	$MA / Meml \rightarrow MA, rem. \rightarrow X, 0 \rightarrow K, 0 \rightarrow C$
DIVD	Divide Double Word (unsigned)	$(X \& MA) / Meml \rightarrow MA, rem \rightarrow X, 0 \rightarrow K, carry \rightarrow C$
IFEQ	If equal	Compare MA & Meml, Do next if equal
IFGT	If greater than	Compare MA & Meml, Do next if MA > Meml
AND	Logical and	$MA \text{ and } Meml \rightarrow MA$
OR	Logical or	$MA \text{ or } Meml \rightarrow MA$
XOR	Logical exclusive-or	$MA \text{ xor } Meml \rightarrow MA$
MEMORY MODIFY INSTRUCTIONS		
INC	Increment	$Mem + 1 \rightarrow Mem$
DECSZ	Decrement, skip if 0	$Mem - 1 \rightarrow Mem$, Skip next if Mem = 0

HPC Instruction Set Description (Continued)

Mnemonic	Description	Action
BIT INSTRUCTIONS		
SBIT	Set bit	1 → Mem.bit
RBIT	Reset bit	0 → Mem.bit
IFBIT	If bit	If Mem.bit is true, do next instr.
MEMORY TRANSFER INSTRUCTIONS		
LD	Load	Mem1 → MA
ST	Load, incr/decr X	Mem(X) → A, X ± 1 (or 2) → X
X	Store to Memory	A → Mem
	Exchange	A ↔ Mem
	Exchange, incr/decr X	A ↔ Mem(X), X ± 1 (or 2) → X
PUSH	Push Memory to Stack	W → W(SP), SP + 2 → SP
POP	Pop Stack to Memory	SP - 2 → SP, W(SP) → W
LDS	Load A, incr/decr B, Skip on condition	Mem(B) → A, B ± 1 (or 2) → B, Skip next if B greater/less than K
XS	Exchange, incr/decr B, Skip on condition	Mem(B) ↔ A, B ± 1 (or 2) → B, Skip next if B greater/less than K
REGISTER LOAD IMMEDIATE INSTRUCTIONS		
LD B	Load B immediate	imm → B
LD K	Load K immediate	imm → K
LD X	Load X immediate	imm → X
LD BK	Load B and K immediate	imm → B, imm → K
ACCUMULATOR AND C INSTRUCTIONS		
CLR A	Clear A	0 → A
INC A	Increment A	A + 1 → A
DEC A	Decrement A	A - 1 → A
COMP A	Complement A	1's complement of A → A
SWAP A	Swap nibbles of A	A15:12 ← A11:8 ← A7:4 ↔ A3:0
RRC A	Rotate A right thru C	C → A15 → ... → A0 → C
RLC A	Rotate A left thru C	C ← A15 ← ... ← A0 ← C
SHR A	Shift A right	0 → A15 → ... → A0 → C
SHL A	Shift A left	C ← A15 ← ... ← A0 ← 0
SC	Set C	1 → C
RC	Reset C	0 → C
IFC	IF C	Do next if C = 1
IFNC	IF not C	Do next if C = 0
TRANSFER OF CONTROL INSTRUCTIONS		
JSRP	Jump subroutine from table	PC → [SP], SP + 2 → SP W(table#) → PC
JSR	Jump subroutine relative	PC → [SP], SP + 2 → SP, PC + # → PC (# is +1025 to -1023)
JSRL	Jump subroutine long	PC → [SP], SP + 2 → SP, PC + # → PC
JP	Jump relative short	PC + # → PC (# is +32 to -31)
JMP	Jump relative	PC + # → PC (# is +257 to -255)
JMPL	Jump relative long	PC + # → PC
JID	Jump indirect at PC + A	PC + A + 1 → PC then Mem(PC) + PC → PC
JIDW		
NOP	No Operation	PC + 1 → PC
RET	Return	SP - 2 → SP, [SP] → PC
RETSK	Return then skip next	SP - 2 → SP, [SP] → PC, & skip
RETI	Return from interrupt	SP - 2 → SP, [SP] → PC, interrupt re-enabled

Note: W is 16-bit word of memory

MA is Accumulator A or direct memory (8 or 16-bit)

Mem is 8-bit byte or 16-bit word of memory

Mem1 is 8- or 16-bit memory or 8 or 16-bit immediate data

imm is 8-bit or 16-bit immediate data

imm8 is 8-bit immediate data only

Memory Usage

Code Efficiency

One of the most important criteria of a single chip microcontroller is code efficiency. The more efficient the code, the more features that can be put on a chip. The memory size on a chip is fixed so if code is not efficient, features may have to be sacrificed or the programmer may have to buy a larger, more expensive version of the chip.

The HPC16083 has been designed to be extremely code-efficient. The HPC16083 looks very good in all the standard coding benchmarks; however, it is not realistic to rely only on benchmarks. Many large jobs have been programmed onto the HPC16083, and the code savings over other popular microcontrollers has been considerable.

Reasons for this saving of code include the following:

SINGLE BYTE INSTRUCTIONS

The majority of instructions on the HPC16083 are single-byte. There are two especially code-saving instructions:

JP is a 1-byte jump. True, it can only jump within a range of plus or minus 32, but many loops and decisions are often within a small range of program memory. Most other micros need 2-byte instructions for any short jumps.

JSRP is a 1-byte call subroutine. The user makes a table of the 16 most frequently called subroutines and these calls will only take one byte. Most other micros require two and even three bytes to call a subroutine. The user does not have to decide which subroutine addresses to put into the table; the assembler can give this information.

EFFICIENT SUBROUTINE CALLS

The 2-byte JSR instructions can call any subroutine within plus or minus 1k of program memory.

MULTIFUNCTION INSTRUCTIONS FOR DATA MOVEMENT AND PROGRAM LOOPING

The HPC16083 has single-byte instructions that perform multiple tasks. For example, the XS instruction will do the following:

1. Exchange A and memory pointed to by the B register
2. Increment or decrement the B register
3. Compare the B register to the K register
4. Generate a conditional skip if B has passed K

The value of this multipurpose instruction becomes evident when looping through sequential areas of memory and exiting when the loop is finished.

BIT MANIPULATION INSTRUCTIONS

Any bit of memory, I/O or registers can be set, reset or tested by the single byte bit instructions. The bits can be addressed directly or indirectly. Since all registers and I/O are mapped into the memory, it is very easy to manipulate specific bits to do efficient control.

DECIMAL ADD AND SUBTRACT

This instruction is needed to interface with the decimal user world.

It can handle both 16-bit words and 8-bit bytes.

The 16-bit capability saves code since many variables can be stored as one piece of data and the programmer does not have to break his data into two bytes. Many applications store most data in 4-digit variables. The HPC16083 supplies 8-bit byte capability for 2-digit variables and literal variables.

MULTIPLY AND DIVIDE INSTRUCTIONS

The HPC16083 has 16-bit multiply, 16-bit by 16-bit divide, and 32-bit by 16-bit divide instructions. This saves both code and time. Multiply and divide can use immediate data or data from memory. The ability to multiply and divide by immediate data saves code since this function is often needed for scaling, base conversion, computing indexes of arrays, etc.

Development Support

HPC MICROCONTROLLER DEVELOPMENT SYSTEM

The HPC microcontroller development system is an in-system emulator (ISE) designed to support the entire family of HPC Microcontrollers. The complete package of hardware and software tools combined with a host system provides a powerful system for design, development and debug of HPC based designs. Software tools are available for IBM® PC/AT® (MS-DOS, PC-DOS) and for UNIX® based multi-user Sun® SPARCstation (SunOSTM).

The stand alone units comes complete with a power supply and external emulation POD. This unit can be connected to various host systems through an RS-232 link. The software package includes an ANSI compatible C-Compiler, Linker, Assembler and librarian package. Source symbolic debug capability is provided through a user friendly MS-windows 3.0 interface for IBM PC/AT environments and through a line debugger under Sunview for Sun SPARCstations.

The ISE provides fully transparent in-system emulation at speeds up to 20 MHz 1 waitstate. A 2k word (48-bit wide) trace buffer gives trace trigger and non intrusive monitoring of the system. External triggering is also available through an external logic interface socket on the POD. Direct EPROM programming can be done through the use of externally mounted EPROM socket. Form-Fit-Function emulator programming is supported by a programming board included with the system. Comprehensive on-line help and diagnostics features reduce user's design and debug time. 8 hardware breakpoints (Address/range), 64k bytes of user memory, and break on external events are some of the other features offered.

Hewlett Packard model HP64775 Emulator/Analyzer providing in-system emulation for up to 30 MHz 1 waitstate is also available. Contact your local sales office for technical details and support.

Development Support (Continued)

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. Dial-A-Helper is an Electronic Bulletin Board Information system and additionally, provides the capability of remotely accessing the development system at a customer site.

INFORMATION SYSTEM

The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communications to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities can be found. The minimum require-

ment for accessing Dial-A-Helper is a Hayes compatible modem.

If the user has a PC with a communications package then files from the FILE SECTION can be down loaded to disk for later use.

Order P/N: MDS-DIAL-A-HLP

Information system package contains:
 DIAL-A-HELPER Users Manual
 Public Domain Communications Software

FACTORY APPLICATIONS SUPPORT

Dial-A-Helper also provides immediate factory applications support. If a user is having difficulty in operating a MDS, he can leave messages on our electronic bulletin board, which we will respond to.

Part Selection

The HPC family includes devices with many different options and configurations to meet various application needs. The number HPC16083 has been generically used throughout this datasheet to represent the whole family of parts. The following chart explains how to order various options available when ordering HPC family members.

Note: All options may not currently be available.

TL/DD/8801-31

FIGURE 30. HPC Family Part Numbering Scheme

Examples

- HPC46003V20 — ROMless, Commercial temp. (0°C to 70°C), PLCC
- HPC16083XXX/U20 — 8k masked ROM, Military temp. (-55°C to +125°C), PGA
- HPC26083XXX/V20 — 8k masked ROM, Automotive temp. (-40°C to +105°C), PLCC

HPC36164/46164, HPC36104/46104

High-Performance microController with A/D

General Description

The HPC46164 and HPC46104 are members of the HPC™ family of High Performance microControllers. Each member of the family has the same core CPU with a unique memory and I/O configuration to suit specific applications. The HPC46164 has 16k bytes of on-chip ROM. The HPC46104 has no on-chip ROM and is intended for use with external memory. Each part is fabricated in National's advanced microCMOS technology. This process combined with an advanced architecture provides fast, flexible I/O control, efficient data manipulation, and high speed computation.

The HPC devices are complete microcomputers on a single chip. All system timing, internal logic, ROM, RAM, and I/O are provided on the chip to produce a cost effective solution for high performance applications. On-chip functions such as UART, up to eight 16-bit timers with 4 input capture registers, vectored interrupts, WATCHDOG™ logic and MICRO-WIRE/PLUS™ provide a high level of system integration. The ability to address up to 64k bytes of external memory enables the HPC to be used in powerful applications typically performed by microprocessors and expensive peripheral chips. The term "HPC46164" is used throughout this data-sheet to refer to the HPC46164 and HPC46104 devices unless otherwise specified.

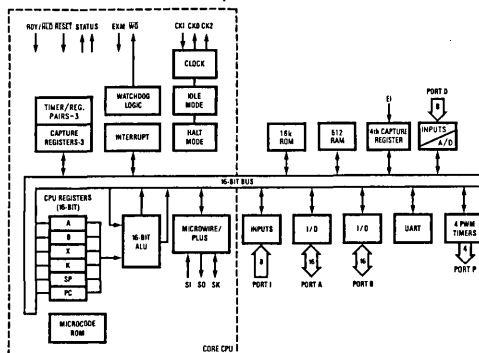

The HPC46164 and HPC46104 have, as an on-board peripheral, an 8-channel 8-bit Analog-to-Digital Converter. This A/D converter can operate in a single-ended mode where the analog input voltage is applied across one of the eight input channels (D0–D7) and AGND. The A/D converter can also operate in differential mode where the analog input voltage is applied across two adjacent input channels. The A/D converter will convert up to eight channels in single-ended mode and up to four channel pairs in differential mode.

The microCMOS process results in very low current drain and enables the user to select the optimum speed/power product for his system. The IDLE and HALT modes provide further current savings. The HPC is available only in an 80-pin PQFP package.

Features

- HPC family—core features:
 - 16-bit architecture, both byte and word
 - 16-bit data bus, ALU, and registers
 - 64k bytes of external direct memory addressing
 - FAST—200 ns for fastest instruction when using 20.0 MHz clock, 134 ns at 30.0 MHz
 - High code efficiency—most instructions are single byte
 - 16 x 16 multiply and 32 x 16 divide
 - Eight vectored interrupt sources
 - Four 16-bit timer/counters with 4 synchronous outputs and WATCHDOG logic
 - MICROWIRE/PLUS serial I/O interface
 - CMOS—very low power with two power save modes: IDLE and HALT
- A/D—8-channel 8-bit analog-to-digital converter with conversion time
- Minimum 7.5 μ s for single conversion
- A/D—supports conversions in "quiet mode"
- UART—full duplex, programmable baud rate
- Four additional 16-bit timer/counters with pulse width modulated outputs
- Four input capture registers
- 52 general purpose I/O lines (memory mapped)
- 16k bytes of ROM, 512 bytes of RAM on-chip
- ROMless version available (HPC46104)
- Commercial (0°C to +70°C) and industrial (-40°C to +85°C) temperature ranges

Block Diagram (HPC46164 with 16k ROM shown)

TL/DD/9682-1

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Total Allowable Source or Sink Current	100 mA
Storage Temperature Range	-65°C to +150°C
Lead Temperature (Soldering, 10 sec.)	300°C

V_{CC} with Respect to GND -0.5V to 7.0V
All Other Pins ($V_{CC} + 0.5$)V to (GND - 0.5)V

Note: Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.

DC Electrical Characteristics

$V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 0^\circ C$ to $+70^\circ C$ for HPC46164/HPC46104, $-40^\circ C$ to $+85^\circ C$ for HPC36164/HPC36104

Symbol	Parameter	Test Conditions	Min	Max	Units
I _{CC1}	Supply Current	$V_{CC} = 5.5V, f_{in} = 30$ MHz (Note 1)		65	mA
		$V_{CC} = 5.5V, f_{in} = 20$ MHz (Note 1)		47	mA
		$V_{CC} = 5.5V, f_{in} = 2.0$ MHz (Note 1)		15	mA
I _{CC2}	IDLE Mode Current	$V_{CC} = 5.5V, f_{in} = 30$ MHz (Note 1)		5	mA
		$V_{CC} = 5.5V, f_{in} = 20$ MHz (Note 1)		3	mA
		$V_{CC} = 5.5V, f_{in} = 2.0$ MHz (Note 1)		1	mA
I _{CC3}	HALT Mode Current	$V_{CC} = 5.5V, f_{in} = 0$ kHz (Note 1)		300	μA
		$V_{CC} = 2.5V, f_{in} = 0$ kHz (Note 1)		100	μA

INPUT VOLTAGE LEVELS FOR SCHMITT TRIGGERED INPUTS RESET, NMI, \overline{WO} ; AND ALSO CKI

	$t_{HAD} = \frac{3}{4} t_C + 85$	$\overline{HLD\bar{A}}$ Rising Edge after \overline{HLD} Rising Edge		160	ns	
	$t_{BF} = \frac{1}{2} t_C + 66$	Bus Float after $\overline{HLD\bar{A}}$ Falling Edge		116	ns	(Note 5)
	$t_{BE} = \frac{1}{2} t_C + 66$	Bus Enable after $\overline{HLD\bar{A}}$ Rising Edge	116		ns	(Note 5)
UPI Timing	t_{UAS}	Address Setup Time to Falling Edge of \overline{URD}	10		ns	
	t_{UAH}	Address Hold Time from Rising Edge of \overline{URD}	10		ns	
	t_{RPW}	\overline{URD} Pulse Width	100		ns	
	t_{OE}	\overline{URD} Falling Edge to Output Data Valid	0	60	ns	
	t_{OD}	Rising Edge of \overline{URD} to Output Data Invalid	5	35	ns	(Note 6)
	t_{DRDY}	\overline{RDRDY} Delay from Rising Edge of \overline{URD}		70	ns	
	t_{WDW}	\overline{UWR} Pulse Width	40		ns	
	t_{UDS}	Input Data Valid before Rising Edge of \overline{UWR}	10		ns	
	t_{UDH}	Input Data Hold after Rising Edge of \overline{UWR}	20		ns	
	t_A	\overline{WRRDY} Delay from Rising Edge of \overline{UWR}		70	ns	

*This maximum frequency is attainable provided that this external baud clock has a duty cycle such that the high period includes two (2) falling edges of the CK2 clock.

20 MHz (Continued)

AC Electrical Characteristics

(See Notes 1 and 4 and Figure 1 through Figure 5.) $V_{CC} = 5V \pm 10\%$, $T_A = 0^\circ\text{C}$ to $+70^\circ\text{C}$ for HPC46164 and -40°C to $+85^\circ\text{C}$ for HPC36164.

	Symbol and Formula	Parameter	Min	Max	Units	Notes
Address Cycles	$t_{DC1ALER}$	Delay from CK1 Rising Edge to ALE Rising Edge	0	35	ns	(Notes 1, 2)
	$t_{DC1ALEF}$	Delay from CK1 Rising Edge to ALE Falling Edge	0	35	ns	(Notes 1, 2)
	$t_{DC2ALER} = \frac{1}{4} t_C + 20$	Delay from CK2 Rising Edge to ALE Rising Edge		45	ns	(Note 2)
	$t_{DC2ALEF} = \frac{1}{4} t_C + 20$	Delay from CK2 Falling Edge to ALE Falling Edge		45	ns	(Note 2)
	$t_{LL} = \frac{1}{2} t_C - 9$	ALE Pulse Width	41		ns	
	$t_{ST} = \frac{1}{4} t_C - 7$	Setup of Address Valid before ALE Falling Edge	18		ns	
	$t_{VP} = \frac{1}{4} t_C - 5$	Hold of Address Valid after ALE Falling Edge	20		ns	
Read Cycles	$t_{ARR} = \frac{1}{4} t_C - 5$	ALE Falling Edge to \overline{RD} Falling Edge	20		ns	
	$t_{ACC} = t_C + WS - 55$	Data Input Valid after Address Output Valid		145	ns	(Note 6)
	$t_{RD} = \frac{1}{2} t_C + WS - 65$	Data Input Valid after \overline{RD} Falling Edge		85	ns	
	$t_{RW} = \frac{1}{2} t_C + WS - 10$	\overline{RD} Pulse Width	140		ns	
	$t_{DR} = \frac{3}{4} t_C - 15$	Hold of Data Input Valid after \overline{RD} Rising Edge	0	60	ns	
	$t_{RDA} = t_C - 15$	Bus Enable after \overline{RD} Rising Edge	85		ns	
Write Cycles	$t_{ARW} = \frac{1}{2} t_C - 5$	ALE Falling Edge to \overline{WR} Falling Edge	45		ns	
	$t_{WW} = \frac{3}{4} t_C + WS - 15$	\overline{WR} Pulse Width	160		ns	
	$t_V = \frac{1}{2} t_C + WS - 5$	Data Output Valid before \overline{WR} Rising Edge	145		ns	
	$t_{HW} = \frac{1}{4} t_C - 5$	Hold of Data Valid after \overline{WR} Rising Edge	20		ns	
Ready Input	$t_{DAR} = \frac{1}{4} t_C + WS - 50$	Falling Edge of ALE to Falling Edge of RDY		75	ns	
	$t_{RWP} = t_C$	RDY Pulse Width	100		ns	

Note: $C_L = 40$ pF.

Note 1: These AC characteristics are guaranteed with external clock drive on CK1 having 50% duty cycle and with less than 15 pF load on CKO with rise and fall times (t_{CK1R} and t_{CK1L}) on CK1 input less than 2.5 ns.

Note 2: Do not design with these parameters unless CK1 is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CK1 or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{HLD} falling edge occurring at the latest time it can be accepted during the present CPU cycle being executed. If \overline{HLD} falling edge occurs later, t_{HAE} may be as long as $(3 t_C + 4WS + 72 t_C + 100)$ may occur depending on the following CPU instruction cycles, its wait states and ready input.

Note 4: WS (t_{WAIT}) \times (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $t_C = 20$ MHz, with one wait state programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

Note 6: This is guaranteed by design and not tested.

A/D Converter Specifications

$V_{CC} = 5V \pm 10\% (V_{SS} - 0.05V) \leq$ Any Input $\leq (V_{CC} + 0.05V)$, $f_C = 20$ MHz and Prescalar = $f_C/12$.

Parameter	Conditions	Min	Typ	Max	Units
Resolution				8	Bits
Reference Voltage Input	AGND = 0V	3		V_{CC}	V
Absolute Accuracy	$V_{CC} = 5.5V, V_{REF} = 5V,$ $V_{CC} = 5V, V_{REF} = 5V$ and $V_{CC} = 4.5V, V_{REF} = 4.5V$			± 2	LSB
Non-Linearity	$V_{CC} = 5.5V, V_{REF} = 5V,$ $V_{CC} = 5V, V_{REF} = 5V$ and $V_{CC} = 4.5V, V_{REF} = 4.5V$			$\pm 1/2$	LSB
Differential Non-Linearity	$V_{CC} = 5.5V, V_{REF} = 5V,$ $V_{CC} = 5V, V_{REF} = 5V$ and $V_{CC} = 4.5V, V_{REF} = 4.5V$			$\pm 1/2$	LSB

Pin Descriptions

The HPC46164 is available only in an 80-pin PQFP package.

I/O PORTS

Port A is a 16-bit bidirectional I/O port with a data direction register to enable each separate pin to be individually defined as an input or output. When accessing external memory, port A is used as the multiplexed address/data bus.

Port B is a 16-bit port with 12 bits of bidirectional I/O similar in structure to Port A. Pins B10, B11, B12 and B15 are general purpose outputs only in this mode. Port B may also be configured via a 16-bit function register BFUN to individually allow each pin to have an alternate function.

B0:	TDX	UART Data Output
B1:		
B2:	CKX	UART Clock (Input or Output)
B3:	T2IO	Timer2 I/O Pin
B4:	T3IO	Timer3 I/O Pin
B5:	SO	MICROWIRE/PLUS Output
B6:	SK	MICROWIRE/PLUS Clock (Input or Output)
B7:	HLDA	Hold Acknowledge Output
B8:	TS0	Timer Synchronous Output
B9:	TS1	Timer Synchronous Output
B10:	UA0	Address 0 Input for UPI Mode
B11:	WRDY	Write Ready Output for UPI Mode
B12:		
B13:	TS2	Timer Synchronous Output
B14:	TS3	Timer Synchronous Output
B15:	RDRDY	Read Ready Output for UPI Mode

When accessing external memory, four bits of port B are used as follows:

B10:	ALE	Address Latch Enable Output
B11:	WR	Write Output
B12:	HBE	High Byte Enable Output/Input (sampled at reset)
B15:	RD	Read Output

Port I is an 8-bit input port that can be read as general purpose inputs and is also used for the following functions:

I0:		
I1:	NMI	Nonmaskable Interrupt Input
I2:	INT2	Maskable Interrupt/Input Capture/ \overline{URD}
I3:	INT3	Maskable Interrupt/Input Capture/ \overline{UWR}
I4:	INT4	Maskable Interrupt/Input Capture
I5:	SI	MICROWIRE/PLUS Data Input
I6:	RDX	UART Data Input
I7:		External Start A/D Conversion

Port D is an 8-bit input port that can be used as general purpose digital inputs or as analog channel inputs for the A/D converter. These functions of Port D are mutually exclusive and under the control of software.

Port P is a 4-bit output port that can be used as general purpose data, or selected to be controlled by timers 4 through 7 in order to generate frequency, duty cycle and pulse width modulated outputs.

POWER SUPPLY PINS

V _{CC1} and V _{CC2}	Positive Power Supply
GND	Ground for On-Chip Logic
DGND	Ground for Output Buffers

Note: There are two electrically connected V_{CC} pins on the chip, GND and DGND are electrically isolated. Both V_{CC} pins and both ground pins must be used.

CLOCK PINS

CKI	The Chip System Clock Input
CKO	The Chip System Clock Output (inversion of CKI)

Pins CKI and CKO are usually connected across an external crystal.

CK2	Clock Output (CKI divided by 2)
-----	---------------------------------

OTHER PINS

\overline{WO}	This is an active low open drain output that signals an illegal situation has been detected by the WATCHDOG logic.
ST1	Bus Cycle Status Output: indicates first opcode fetch.
ST2	Bus Cycle Status Output: indicates machine states (skip, interrupt and first instruction cycle).
\overline{RESET}	Active low input that forces the chip to restart and sets the ports in a TRI-STATE mode.
RDY/ \overline{HLD}	Selected by a software bit. It's either a READY input to extend the bus cycle for slower memories, or a HOLD request input to put the bus in a high impedance state for DMA purposes.
V _{REF}	A/D converter reference voltage input.
EXM	External memory enable (active high) disables internal ROM and maps it to external memory.
EI	External interrupt with vector address FFF1:FFF0. (Rising/falling edge or high/low level sensitive). Alternately can be configured as 4th input capture.
\overline{EXUI}	External active low interrupt which is internally OR'ed with the UART interrupt with vector address FFF3:FFF2.

Ports A & B

The highly flexible A and B ports are similarly structured. The Port A (see *Figure 11*) consists of a data register and a direction register. Port B (see *Figures 12, 13 and 14*) has an alternate function register in addition to the data and direction registers. All the control registers are read/write registers.

The associated direction registers allow the port pins to be individually programmed as inputs or outputs. Port pins selected as inputs, are placed in a TRI-STATE mode by resetting corresponding bits in the direction register.

A write operation to a port pin configured as an input causes the value to be written into the data register, a read operation returns the value of the pin. Writing to port pins configured as outputs causes the pins to have the same value, reading the pins returns the value of the data register.

Primary and secondary functions are multiplexed onto Port B through the alternate function register (BFUN). The secondary functions are enabled by setting the corresponding bits in the BFUN register.

Operating Modes

To offer the user a variety of I/O and expanded memory options, the HPC46164 and HPC46104 have four operating modes. The ROMless HPC46104 has one mode of operation. The various modes of operation are determined by the state of both the EXM pin and the EA bit in the PSW register. The state of the EXM pin determines whether on-chip ROM will be accessed or external memory will be accessed within the address range of the on-chip ROM. The on-chip ROM range of the HPC46164 is C000 to FFFF (16k bytes). The HPC46104 has no on-chip ROM and is intended for use with external memory for program storage. A logic "0" state on the EXM pin will cause the HPC device to address on-chip ROM when the Program Counter (PC) contains addresses within the on-chip ROM address range. A logic "1" state on the EXM pin will cause the HPC device to address memory that is external to the HPC when the PC contains on-chip ROM addresses. The EXM pin should always be pulled high (logic "1") on the HPC46104 because no on-chip ROM is available. The function of the EA bit is to determine the legal addressing range of the HPC device. A logic "0" state in the EA bit of the PSW register does two things—addresses are limited to the on-chip ROM range

and on-chip RAM and Register range, and the "illegal address detection" feature of the WATCHDOG logic is engaged. A logic "1" in the EA bit enables accesses to be made anywhere within the 64k byte address range and the "illegal address detection" feature of the WATCHDOG logic is disabled. The EA bit should be set to "1" by software when using the HPC46104 to disable the "illegal address detection" feature of WATCHDOG.

All HPC devices can be used with external memory. External memory may be any combination of RAM and ROM. Both 8-bit and 16-bit external data bus modes are available. Upon entering an operating mode in which external memory is used, port A becomes the Address/Data bus. Four pins of port B become the control lines ALE, \overline{RD} , \overline{WR} and \overline{HBE} . The High Byte Enable pin (\overline{HBE}) is used in 16-bit mode to select high order memory bytes. The \overline{RD} and \overline{WR} signals are only generated if the selected address is off-chip. The 8-bit mode is selected by pulling \overline{HBE} high at reset. If \overline{HBE} is left floating or connected to a memory device chip select at reset, the 16-bit mode is entered. The following sections describe the operating modes of the HPC46164 and HPC46104.

Note: The HPC devices use 16-bit words for stack memory. Therefore, when using the 8-bit mode, User's Stack must be in internal RAM.

HPC46164 Operating Modes

SINGLE CHIP NORMAL MODE

In this mode, the HPC46164 functions as a self-contained microcomputer (see Figure 15) with all memory (RAM and ROM) on-chip. It can address internal memory only, consisting of 16k bytes of ROM (C000 to FFFF) and 512 bytes of on-chip RAM and Registers (0000 to 02FF). The "illegal address detection" feature of the WATCHDOG is enabled in the Single-Chip Normal mode and a WATCHDOG Output ($\overline{W0}$) will occur if an attempt is made to access addresses that are outside of the on-chip ROM and RAM range of the device. Ports A and B are used for I/O functions and not for addressing external memory. The EXM pin and the EA bit of the PSW register must both be logic "0" to enter the Single-Chip Normal mode.

TL/DD/9682-17

FIGURE 15. Single-Chip Mode

EXPANDED NORMAL MODE

The Expanded Normal mode of operation enables the HPC46164 to address external memory in addition to the

on-chip ROM and RAM (see Table I). WATCHDOG illegal address detection is disabled and memory accesses may be made anywhere in the 64k byte address range without triggering an illegal address condition. The Expanded Normal mode is entered with the EXM pin pulled low (logic "0") and setting the EA bit in the PSW register to "1".

SINGLE-CHIP ROMLESS MODE

In this mode, the on-chip mask programmed ROM of the HPC46164 is not used. The address space corresponding to the on-chip ROM is mapped into external memory so 16k of external memory may be used with the HPC46164 (see Table I). The WATCHDOG circuitry detects illegal addresses (addresses not within the on-chip ROM and RAM range). The Single-Chip ROMless mode is entered when the EXM pin is pulled high (logic "1") and the EA bit is logic "0".

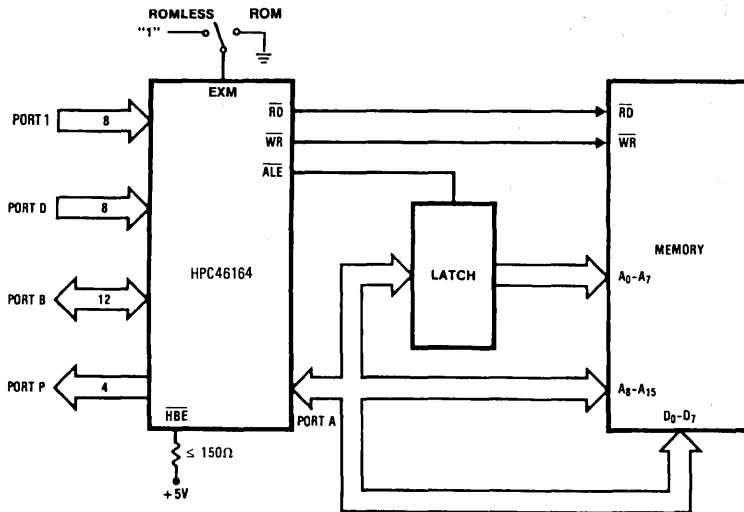

TABLE I. HPC46164 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Single-Chip Normal	0	0	C000:FFFF on-chip
Expanded Normal	0	1	C000:FFFF on-chip 0300:BFFF off-chip
Single-Chip ROMless	1	0	C000:FFFF off-chip
Expanded ROMless	1	1	0300:FFFF off-chip

Note: In all operating modes, the on-chip RAM and Registers (0000:02FF) may be accessed.

EXPANDED ROMLESS MODE

This mode of operation is similar to Single-Chip ROMless mode in that no on-chip ROM is used, however, a full 64k bytes of external memory may be used. The "illegal address detection" feature of WATCHDOG is disabled. The EXM pin must be pulled high (logic "1") and the EA bit in the PSW register set to "1" to enter this mode.

TL/DD/9682-18

FIGURE 16. 8-Bit External Memory

HPC46164 Operating Modes (Continued)

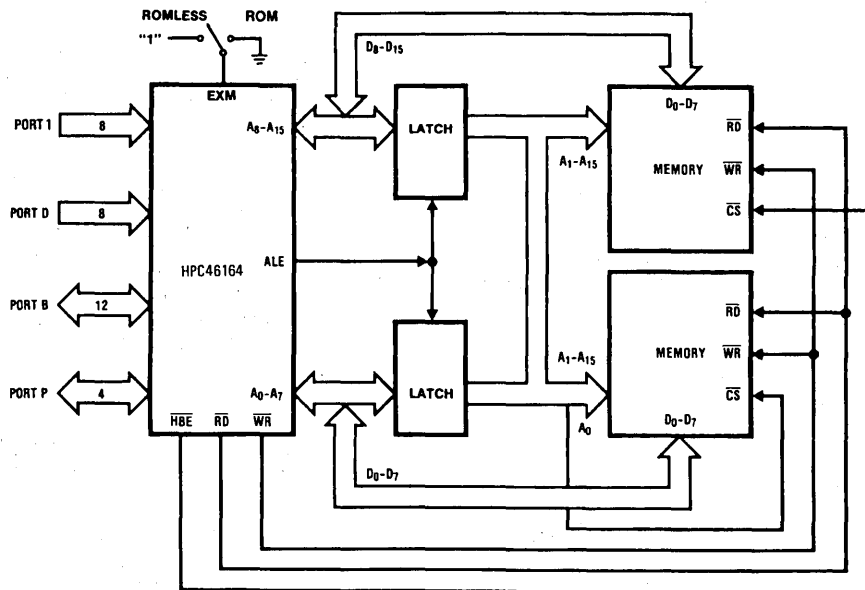

FIGURE 17. 16-Bit External Memory

TL/DD/9682-19

HPC46104 Operating Modes

EXPANDED ROMLESS MODE

Because the HPC46104 has no on-chip ROM, it has only one mode of operation, the Expanded ROMless Mode. The EXM pin must be pulled high (logic "1") on power up, the EA bit in the PSW register should be set to a "1". The HPC46104 is a ROMless device and is intended for use with external memory. The external memory may be any combination of ROM and RAM. Up to 64k bytes of external memory may be accessed. It is necessary to vector on reset to an address between C000 and FFFF, therefore the user should have external memory at these addresses. The EA bit in the PSW register must immediately be set to "1" at the beginning of the user's program to disable illegal address detection in the WATCHDOG logic.

TABLE II. HPC46104 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Expanded ROMless	1	1	0300:FFFF off-chip

Note: The on-chip RAM and Registers (0000:02FF) of the HPC46104 may be accessed at all times.

Wait States

The internal ROM can be accessed at the maximum operating frequency with one wait state. With 0 wait states, internal ROM accesses are limited to $\frac{2}{3} f_C$ max. The HPC46164 provides four software selectable Wait States that allow access to slower memories. The Wait States are selected by the state of two bits in the PSW register. Additionally, the RDY input may be used to extend the instruction cycle, allowing the user to interface with slow memories and peripherals.

Power Save Modes

Two power saving modes are available on the HPC46164: HALT and IDLE. In the HALT mode, all processor activities are stopped. In the IDLE mode, the on-board oscillator and timer T0 are active but all other processor activities are stopped. In either mode, all on-board RAM, registers and I/O are unaffected.

HALT MODE

The HPC46164 is placed in the HALT mode under software control by setting bits in the PSW. All processor activities, including the clock and timers, are stopped. In the HALT mode, power requirements for the HPC46164 are minimal and the applied voltage (V_{CC}) may be decreased without altering the state of the machine. There are two ways of exiting the HALT mode: via the RESET or the NMI. The RESET input reinitializes the processor. Use of the NMI input will generate a vectored interrupt and resume operation from that point with no initialization. The HALT mode can be enabled or disabled by means of a control register HALT enable. To prevent accidental use of the HALT mode the HALT enable register can be modified only once.

IDLE MODE

The HPC46164 is placed in the IDLE mode through the PSW. In this mode, all processor activity, except the on-board oscillator and Timer T0, is stopped. As with the HALT mode, the processor is returned to full operation by the RESET or NMI inputs, but without waiting for oscillator stabilization. A timer T0 overflow will also cause the HPC46164 to resume normal operation.

HPC46164 Interrupts

Complex interrupt handling is easily accomplished by the HPC46164's vectored interrupt scheme. There are eight possible interrupt sources as shown in Table III.

TABLE III. Interrupts

Vector Address	Interrupt Source	Arbitration Ranking
FFFF:FFFE	RESET	0
FFFD:FFFC	Nonmaskable external on rising edge of I1 pin	1
FFFB:FFFA	External interrupt on I2 pin	2
FFF9:FFF8	External interrupt on I3 pin	3
FFF7:FFF6	External interrupt on I4 pin	4
FFF5:FFF4	Overflow on internal timers	5
FFF3:FFF2	Internal on the UART transmit/receive complete or external on EXUI or A/D converter	6
FFF1:FFF0	External interrupt on EI pin	7

Interrupt Arbitration

The HPC46164 contains arbitration logic to determine which interrupt will be serviced first if two or more interrupts occur simultaneously. The arbitration ranking is given in Table III. The interrupt on Reset has the highest rank and is serviced first.

Interrupt Processing

Interrupts are serviced after the current instruction is completed except for the RESET, which is serviced immediately. RESET and EXUI are level-LOW-sensitive interrupts and EI is programmable for edge-(RISING or FALLING) or level-(HIGH or LOW) sensitivity. All other interrupts are edge-sensitive. NMI is positive-edge sensitive. The external interrupts on I2, I3 and I4 can be software selected to be rising or falling edge. External interrupt (EXUI) is shared with the on-board UART. The EXUI interrupt is level-LOW-sensitive. To select this interrupt, disable the ERI and ETI UART interrupts by resetting these enable bits in the ENUI register. To select the on-board UART interrupt, leave this pin floating.

Interrupt Control Registers

The HPC46164 allows the various interrupt sources and conditions to be programmed. This is done through the various control registers. A brief description of the different control registers is given below.

INTERRUPT ENABLE REGISTER (ENIR)

RESET and the External Interrupt on I1 are non-maskable interrupts. The other interrupts can be individually enabled

or disabled. Additionally, a Global Interrupt Enable Bit in the ENIR Register allows the Maskable interrupts to be collectively enabled or disabled. Thus, in order for a particular interrupt to request service, both the individual enable bit and the Global Interrupt bit (GIE) have to be set.

INTERRUPT PENDING REGISTER (IRPD)

The IRPD register contains a bit allocated for each interrupt vector. The occurrence of specified interrupt trigger conditions causes the appropriate bit to be set. There is no indication of the order in which the interrupts have been received. The bits are set independently of the fact that the interrupts may be disabled. IRPD is a Read/Write register. The bits corresponding to the maskable, external interrupts are normally cleared by the HPC46164 after servicing the interrupts.

For the interrupts from the on-board peripherals, the user has the responsibility of resetting the interrupt pending flags through software.

The NMI bit is read only and I2, I3, and I4 are designed as to only allow a zero to be written to the pending bit (writing a one has no affect). A LOAD IMMEDIATE instruction is to be the only instruction used to clear a bit or bits in the IRPD register. This allows a mask to be used, thus ensuring that the other pending bits are not affected.

INTERRUPT CONDITION REGISTER (IRCD)

Three bits of the register select the input polarity of the external interrupt on I2, I3, and I4.

Servicing the Interrupts

The Interrupt, once acknowledged, pushes the program counter (PC) onto the stack thus incrementing the stack pointer (SP) twice. The Global Interrupt Enable bit (GIE) is copied into the CGIE bit of the PSW register; it is then reset, thus disabling further interrupts. The program counter is loaded with the contents of the memory at the vector address and the processor resumes operation at this point. At the end of the interrupt service routine, the user does a RETI instruction to pop the stack and re-enable interrupts if the CGIE bit is set, or RET to just pop the stack if the CGIE bit is clear, and then returns to the main program. The GIE bit can be set in the interrupt service routine to nest interrupts if desired. *Figure 18* shows the Interrupt Enable Logic.

Reset

The RESET input initializes the processor and sets ports A and B in the TRI-STATE condition and Port P in the LOW state. RESET is an active-low Schmitt trigger input. The processor vectors to FFFF:FFFE and resumes operation at the address contained at that memory location (which must correspond to an on board location). The Reset vector address must be between C000 and FFFF when using the HPC46104.

FIGURE 18. Block Diagram of Interrupt Logic

Timer Overview

The HPC46164 contains a powerful set of flexible timers enabling the HPC46164 to perform extensive timer functions not usually associated with microcontrollers. The HPC46164 contains nine 16-bit timers. Timer T0 is a free-running timer, counting up at a fixed CKI/16 (Clock Input/16) rate. It is used for WATCHDOG logic, high speed event capture, and to exit from the IDLE mode. Consequently, it cannot be stopped or written to under software control. Timer T0 permits precise measurements by means of the capture registers I2CR, I3CR, and I4CR. A control bit in the register TMODE configures timer T1 and its associated register R1 as capture registers I3CR and I2CR. The capture registers I2CR, I3CR, and I4CR respectively, record the value of timer T0 when specific events occur on the interrupt pins I2, I3, and I4. The control register IRCD programs the capture registers to trigger on either a rising edge or a falling edge of its respective input. The specified edge can also be programmed to generate an interrupt (see Figure 19).

FIGURE 19. Timers T0, T1 and T8 with Four Input Capture Registers

The HPC46164 provides an additional 16-bit free running timer, T8, with associated input capture register EICR (External Interrupt Capture Register) and Configuration Register, EICON. EICON is used to select the mode and edge of the EI pin. EICR is a 16-bit capture register which records

the value of T8 (which is identical to T0) when a specific event occurs on the EI pin.

The timers T2 and T3 have selectable clock rates. The clock input to these two timers may be selected from the following two sources: an external pin, or derived internally by dividing the clock input. Timer T2 has additional capability of being clocked by the timer T3 underflow. This allows the user to cascade timers T3 and T2 into a 32-bit timer/counter. The control register DIVBY programs the clock input to timers T2 and T3 (see Figure 20).

The timers T1 through T7 in conjunction with their registers form Timer-Register pairs. The registers hold the pulse duration values. All the Timer-Register pairs can be read from or written to. Each timer can be started or stopped under software control. Once enabled, the timers count down, and upon underflow, the contents of its associated register are automatically loaded into the timer.

SYNCHRONOUS OUTPUTS

The flexible timer structure of the HPC46164 simplifies pulse generation and measurement. There are four synchronous timer outputs (TS0 through TS3) that work in conjunction with the timer T2. The synchronous timer outputs can be used either as regular outputs or individually programmed to toggle on timer T2 underflows (see Figure 20).

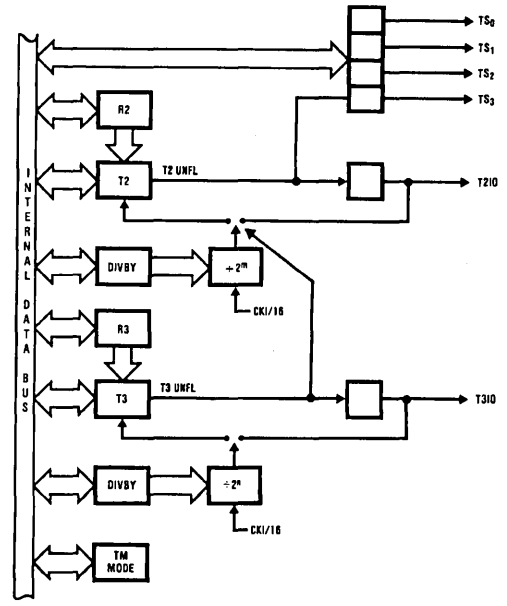

FIGURE 20. Timers T2-T3 Block

Timer Overview (Continued)

Timer/register pairs 4-7 form four identical units which can generate synchronous outputs on port P (see Figure 21). Maximum output frequency for any timer output can be obtained by setting timer/register pair to zero. This then will produce an output frequency equal to $\frac{1}{2}$ the frequency of the source used for clocking the timer.

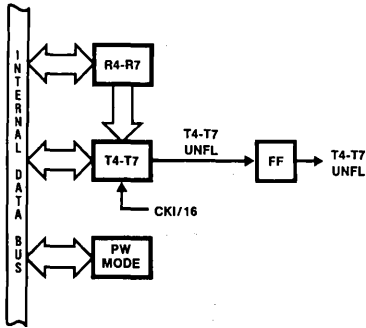

FIGURE 21. Timers T4-T7 Block

TL/DD/9682-23

Timer Registers

There are four control registers that program the timers. The divide by (DIVBY) register programs the clock input to timers T2 and T3. The timer mode register (TMMODE) contains control bits to start and stop timers T1 through T3. It also contains bits to latch, acknowledge and enable interrupts from timers T0 through T3. The control register PWMODE similarly programs the pulse width timers T4 through T7 by allowing them to be started, stopped, and to latch and enable interrupts on underflows. The PORTP register contains bits to preset the outputs and enable the synchronous timer output functions.

Timer Applications

The use of Pulse Width Timers for the generation of various waveforms is easily accomplished by the HPC46164.

Frequencies can be generated by using the timer/register pairs. A square wave is generated when the register value is a constant. The duty cycle can be controlled simply by changing the register value.

FIGURE 22. Square Wave Frequency Generation

TL/DD/9682-24

Synchronous outputs based on Timer T2 can be generated on the 4 outputs TS0-TS3. Each output can be individually programmed to toggle on T2 underflow. Register R2 contains the time delay between events. Figure 23 is an example of synchronous pulse train generation.

TL/DD/9682-25

FIGURE 23. Synchronous Pulse Generation

WATCHDOG Logic

The WATCHDOG Logic monitors the operations taking place and signals upon the occurrence of any illegal activity. The illegal conditions that trigger the WATCHDOG logic are potentially infinite loops and illegal addresses. Should the WATCHDOG register not be written to before Timer T0 overflows twice, or more often than once every 4096 counts, an infinite loop condition is assumed to have occurred. An illegal condition also occurs when the processor generates an illegal address when in the Single-Chip modes.* Any illegal condition forces the WATCHDOG Output ($\overline{W0}$) pin low. The $\overline{W0}$ pin is an open drain output and can be connected to the RESET or NMI inputs or to the users external logic.

*Note: See Operating Modes for details.

MICROWIRE/PLUS

MICROWIRE/PLUS is used for synchronous serial data communications (see Figure 24). MICROWIRE/PLUS has an 8-bit parallel-loaded, serial shift register using SI as the input and SO as the output. SK is the clock for the serial shift register (SIO). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. A DONE flag indicates when the data shift is completed.

The MICROWIRE/PLUS capability enables it to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., A/D converters, display drivers, EEPROMs).

MICROWIRE/PLUS (Continued)

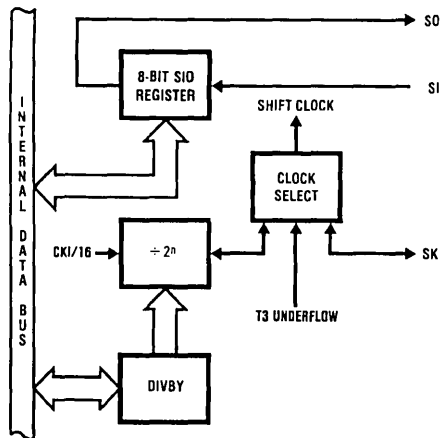

FIGURE 24. MICROWIRE/PLUS

TL/DD/9682-26

MICROWIRE/PLUS Operation

The HPC46164 can enter the MICROWIRE/PLUS mode as the master or a slave. A control bit in the IRCD register determines whether the HPC46164 is the master or slave. The shift clock is generated when the HPC46164 is configured as a master. An externally generated shift clock on the SK pin is used when the HPC46164 is configured as a slave. When the HPC46164 is a master, the DIVBY register programs the frequency of the SK clock. The DIVBY register allows the SK clock frequency to be programmed in 14 se-

lectable binary steps or T3 underflow from 153 Hz to 1.25 MHz with CKI at 20.0 MHz.

The contents of the SIO register may be accessed through any of the memory access instructions. Data waiting to be transmitted in the SIO register is clocked out on the falling edge of the SK clock. Serial data on the SI pin is clocked in on the rising edge of the SK clock.

MICROWIRE/PLUS Application

Figure 25 illustrates a MICROWIRE/PLUS arrangement for an automotive application. The microcontroller-based system could be used to interface to an instrument cluster and various parts of the automobile. The diagram shows two HPC46164 microcontrollers interconnected to other MICROWIRE peripherals. HPC46164 # 1 is set up as the master and initiates all data transfers. HPC46164 # 2 is set up as a slave answering to the master.

The master microcontroller interfaces the operator with the system and could also manage the instrument cluster in an automotive application. Information is visually presented to the operator by means of an LCD display controlled by the COP472 display driver. The data to be displayed is sent serially to the COP472 over the MICROWIRE/PLUS link. Data such as accumulated mileage could be stored and retrieved from the EEPROM COP494. The slave HPC46164 could be used as a fuel injection processor and generate timing signals required to operate the fuel valves. The master processor could be used to periodically send updated values to the slave via the MICROWIRE/PLUS link. To speed up the response, chip select logic is implemented by connecting an output from the master to the external interrupt input on the slave.

MICROWIRE/PLUS Application (Continued)

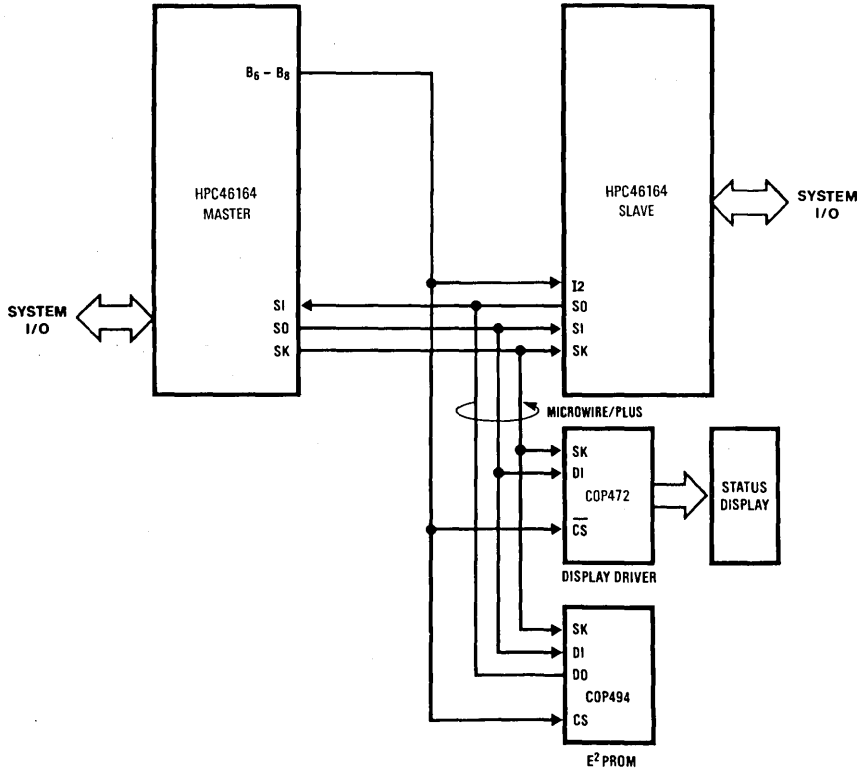

FIGURE 25. MICROWIRE/PLUS Application

TL/DD/9682-27

HPC46164 UART

The HPC46164 contains a software programmable UART. The UART (see *Figure 26*) consists of a transmit shift register, a receiver shift register and five addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR) and a UART interrupt and clock source register (ENUI). The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (8 or 9 bits) and the value of the ninth bit in transmission. The ENUR register flags framing and data overrun errors while the UART is receiving. Other functions of the ENUR register include saving the ninth bit received in the data frame and enabling or disabling the UART's Wake-up Mode of operation. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts.

The baud rate clock for the Receiver and Transmitter can be selected for either an internal or external source using two bits in the ENUI register. The internal baud rate is programmed by the DIVBY register. The baud rate may be selected from a range of 8 Hz to 128 kHz in binary steps or T3 underflow. By selecting a 9.83 MHz crystal, all standard baud rates from 75 baud to 38.4 kbaud can be generated. The external baud clock source comes from the CKX pin. The Transmitter and Receiver can be run at different rates by selecting one to operate from the internal clock and the other from an external source.

The HPC46164 UART supports two data formats. The first format for data transmission consists of one start bit, eight data bits and one or two stop bits. The second data format for transmission consists of one start bit, nine data bits, and one or two stop bits. Receiving formats differ from transmission only in that the Receiver always requires only one stop bit in a data frame.

UART Wake-up Mode

The HPC46164 UART features a Wake-up Mode of operation. This mode of operation enables the HPC46164 to be networked with other processors. Typically in such environments, the messages consist of addresses and actual data. Addresses are specified by having the ninth bit in the data frame set to 1. Data in the message is specified by having the ninth bit in the data frame reset to 0.

The UART monitors the communication stream looking for addresses. When the data word with the ninth bit set is received, the UART signals the HPC46164 with an interrupt. The processor then examines the content of the receiver buffer to decide whether it has been addressed and whether to accept subsequent data.

FIGURE 26. UART Block Diagram

TL/DD/9682-28

A/D Converter

The HPC46164 has an on-board eight-channel 8-bit Analog to Digital converter. Conversion is performed using a successive approximation technique. The A/D converter cell can operate in single-ended mode where the input voltage is applied across one of the eight input channels (D0–D7) and AGND or in differential mode where the input voltage is applied across two adjacent input channels. The A/D converter will convert up to eight channels in single-ended mode and up to four channel-pairs in differential mode.

OPERATING MODES

The operating modes of the converter are selected by 4 bits called ADMODE (CR2.4–7) see Table IV. Associated with the eight input channels in single-ended mode are eight result registers, one for each channel. The A/D converter can be programmed by software to convert on any specific channel storing the result in the result register associated with that channel. It can also be programmed to stop after one conversion or to convert continuously. If a brief history of the signal on any specific input channel is required, the converter can be programmed to convert on that channel and store the consecutive results in each of the result registers before stopping. As a final configuration in single-ended mode, the converter can be programmed to convert the signal on each input channel and store the result in its associated result register continuously.

Associated with each even-odd pair of input channels in differential mode of operation are four result register-pairs. The A/D converter performs two conversions on the selected pair of input channels. One conversion is performed assuming the positive connection is made to the even channel and the negative connection is made to the following odd channel. This result is stored in the result register associated with the even channel. Another conversion is performed assuming the positive connection is made to the odd channel and the negative connection is made to the preceding even channel. This result is stored in the result register associated with the odd channel. This technique does not require that the programmer know the polarity of the input signal. If the even channel result register is nonzero (meaning the odd channel result register is zero), then the input signal is positive with respect to the odd channel. If the odd channel result register is non-zero (meaning the even channel result register is zero), then the input signal is positive with respect to the even channel.

The same operating modes for single-ended operation also apply when the inputs are taken from channel-pairs in differential mode. The programmer can configure the A/D to con-

vert on any selected channel-pair and store the result in its associated result register-pair then stop. The A/D can also be programmed to do this continuously. Conversion can also be done on any channel-pair storing the result into four result register-pairs for a history of the differential input. Finally, all input channel-pairs can be converted continuously.

The final mode of operation suppresses the external address/data bus activity during the single conversion modes. These quiet modes of operation utilize the RDY function of the HPC Core to insert wait states in the instruction being executed in order to limit digital noise in the environment due to external bus activity when addressing external memory. The overall effect is to increase the accuracy of the A/D.

CONTROL

The conversion clock supplied to the A/D converter can be selected by three bits in CR1 used as a prescaler on CKI. These bits can be used to ensure that the A/D is clocked as fast as possible when different external crystal frequencies are used. Controlling the starting of conversion cycles in each of the operating modes can be done by four different methods. The method is selected by two bits called SC (CR3.0–1). Conversion cycles can be initiated through software by resetting a bit in a control register, through hardware by an underflow of Timer T2, or externally by a rising or falling edge of a signal input on I7.

INTERRUPTS

The A/D converter can interrupt the HPC when it completes a conversion cycle if one of the noncontinuous modes has been selected. If one of the cycle modes was selected, then the converter will request an interrupt after eight conversions. If one of the one-shot modes was selected, then the converter will request an interrupt after every conversion. When this interrupt is generated, the HPC vectors to the on-board peripheral interrupt vector location at address FFF2. The service routine must then determine if the A/D converter requested the interrupt by checking the A/D done flag which doubles as the A/D interrupt pending flag.

Analog Input and Source Resistance Considerations

Figure 27 shows the A/D pin model for the HPC46164 in single ended mode. The differential mode has similar A/D pin model. The leads to the analog inputs should be kept as short as possible. Both noise and digital clock coupling to an A/D input can cause conversion errors. The clock lead should be kept away from the analog input line to reduce coupling. The A/D channel input pins do not have any internal output driver circuitry connected to them because this circuitry would load the analog input signals due to output buffer leakage current.

*The analog switch is closed only during the sample time.

FIGURE 27. Port D Input Structure

A/D Converter (Continued)

TABLE IV. A/D Operating Modes

Mode 0	Single-ended, single channel, single result register, one-shot (default value on power-up)
Mode 1	Single-ended, single channel, single result register, continuous
Mode 2	Single-ended, single channel, multiple result registers, stop after 8
Mode 3	Single-ended, multiple channel, multiple result registers, continuous
Mode 4	Differential, single channel-pair, single result register-pair, one-shot
Mode 5	Differential, single channel-pair, single result register-pair, continuous
Mode 6	Differential, single channel-pair, multiple result register-pairs, stop after 4 pairs
Mode 7	Differential, multiple channel-pair, multiple result register-pairs, continuous
Mode 8	Single-ended, single channel, single result register, one-shot (default value on power-up), quiet address/data bus
Mode C	Differential, single channel-pair, single result register-pair, one-shot, quiet address/data bus

Universal Peripheral Interface

The Universal Peripheral Interface (UPI) allows the HPC46164 to be used as an intelligent peripheral to another processor. The UPI could thus be used to tightly link two HPC46164's and set up systems with very high data exchange rates. Another area of application could be where an HPC46164 is programmed as an intelligent peripheral to a host system such as the Series 32000[®] microprocessor. Figure 28 illustrates how an HPC46164 could be used as an intelligent peripheral for a Series 32000-based application.

The interface consists of a Data Bus (port A), a Read Strobe (\overline{URD}), a Write Strobe (\overline{UWR}), a Read Ready Line (\overline{RDRDY}), a Write Ready Line (\overline{WRRDY}) and one Address Input (UA0). The data bus can be either eight or sixteen bits wide.

The \overline{URD} and \overline{UWR} inputs may be used to interrupt the HPC46164. The \overline{RDRDY} and \overline{WRRDY} outputs may be used to interrupt the host processor.

The UPI contains an Input Buffer (IBUF), an Output Buffer (OBUF) and a Control Register (UPIC). In the UPI mode, port A on the HPC46164 is the data bus. UPI can only be used if the HPC46164 is in the Single-Chip mode.

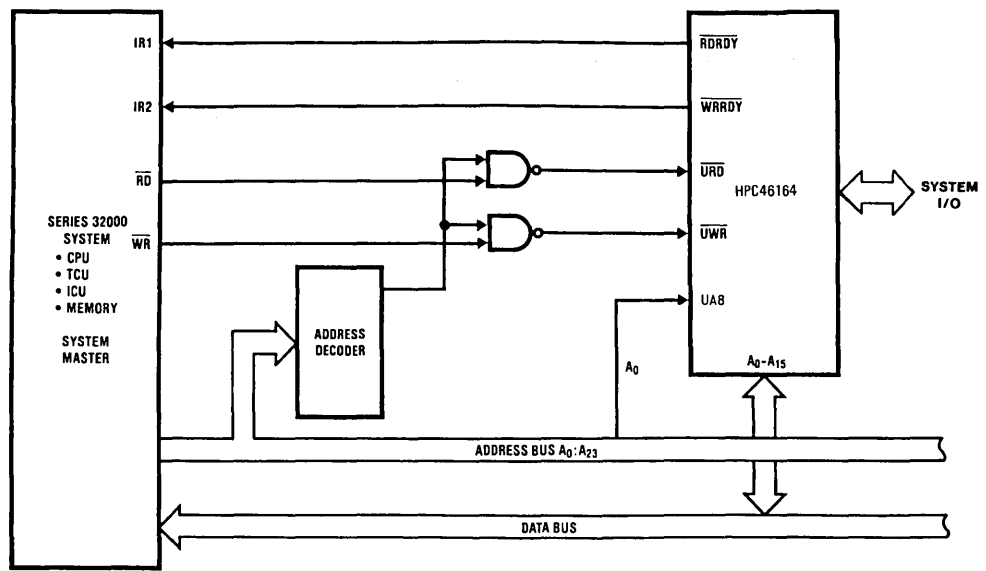

FIGURE 28. HPC46164 as a Peripheral: (UPI Interface to Series 32000 Application)

TL/DD/9682-30

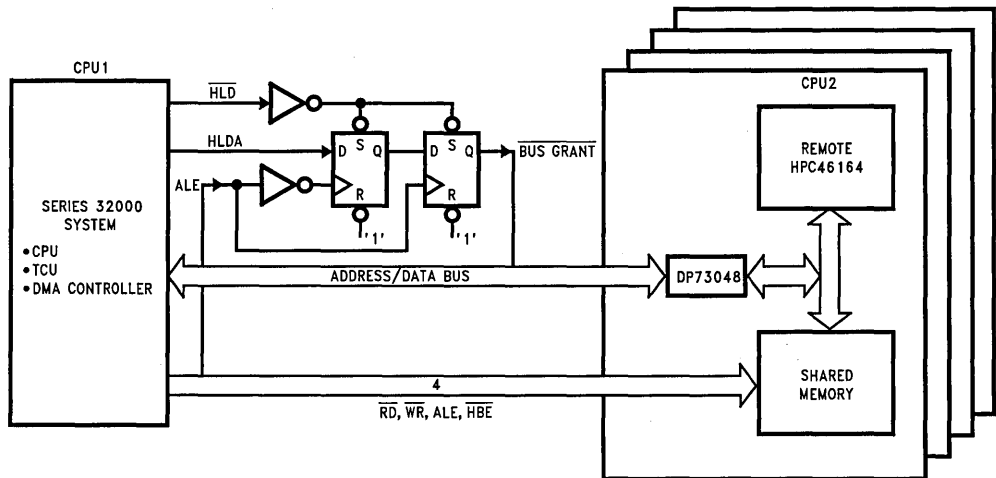

Shared Memory Support

Shared memory access provides a rapid technique to exchange data. It is effective when data is moved from a peripheral to memory or when data is moved between blocks of memory. A related area where shared memory access proves effective is in multiprocessing applications where two CPUs share a common memory block. The HPC46164 supports shared memory access with two pins. The pins are the RDY/HLD input pin and the HLDA output pin. The user can software select either the Hold or Ready function by the state of a control bit. The HLD output is multiplexed onto port B.

The host uses DMA to interface with the HPC46164. The host initiates a data transfer by activating the HLD input of

the HPC46164. In response, the HPC46164 places its system bus in a TRI-STATE Mode, freeing it for use by the host. The host waits for the acknowledge signal (HLDA) from the HPC46164 indicating that the system bus is free. On receiving the acknowledge, the host can rapidly transfer data into, or out of, the shared memory by using a conventional DMA controller. Upon completion of the message transfer, the host removes the HOLD request and the HPC46164 resumes normal operations.

To insure proper operation, the interface logic shown is recommended as the means for enabling and disabling the user's bus. Figure 29 illustrates an application of the shared memory interface between the HPC46164 and a Series 32000 system.

TL/DD/9682-31

FIGURE 29. Shared Memory Application: HPC46164 Interface to Series 32000 System

Memory

The HPC46164 has been designed to offer flexibility in memory usage. A total address space of 64 kbytes can be addressed with 16 kbytes of ROM and 512 bytes of RAM available on the chip itself. The ROM may contain program instructions, constants or data. The ROM and RAM share the same address space allowing instructions to be executed out of RAM.

Program memory addressing is accomplished by the 16-bit program counter on a byte basis. Memory can be addressed

directly by instructions or indirectly through the B, X and SP registers. Memory can be addressed as words or bytes. Words are always addressed on even-byte boundaries. The HPC46164 uses memory-mapped organization to support registers, I/O and on-chip peripheral functions.

The HPC46164 memory address space extends to 64 kbytes and registers and I/O are mapped as shown in Table V.

Design Considerations

Designs using the HPC family of 16-bit high speed CMOS microcontrollers need to follow some general guidelines on usage and board layout.

Floating inputs are a frequently overlooked problem. CMOS inputs have extremely high impedance and, if left open, can float to any voltage. You should thus tie unused inputs to V_{CC} or ground, either through a resistor or directly. Unlike the inputs, unused output should be left floating to allow the output to switch without drawing any DC current.

To reduce voltage transients, keep the supply line's parasitic inductances as low as possible by reducing trace lengths, using wide traces, ground planes, and by decoupling the supply with bypass capacitors. In order to prevent additional voltage spiking, this local bypass capacitor must exhibit low inductive reactance. You should therefore use high frequency ceramic capacitors and place them very near the IC to minimize wiring inductance.

- Keep V_{CC} bus routing short. When using double sided or multilayer circuit boards, use ground plane techniques.
- Keep ground lines short, and on PC boards make them as wide as possible, even if trace width varies. Use separate ground traces to supply high current devices such as relay and transmission line drivers.
- In systems mixing linear and logic functions and where supply noise is critical to the analog components' performance, provide separate supply buses or even separate supplies.
- If you use local regulators, bypass their inputs with a tantalum capacitor of at least 1 μF and bypass their outputs with a 10 μF to 50 μF tantalum or aluminum electrolytic capacitor.
- If the system uses a centralized regulated power supply, use a 10 μF to 20 μF tantalum electrolytic capacitor or a 50 μF to 100 μF aluminum electrolytic capacitor to decouple the V_{CC} bus connected to the circuit board.
- Provide localized decoupling. For random logic, a rule of thumb dictates approximately 10 nF (spaced within 12 cm) per every two to five packages, and 100 nF for every 10 packages. You can group these capacitances, but it's more effective to distribute them among the ICs. If the design has a fair amount of synchronous logic with outputs that tend to switch simultaneously, additional decoupling might be advisable. Octal flip-flop and buffers in bus-oriented circuits might also require more decoupling. Note that wire-wrapped circuits can require more decoupling than ground plane or multilayer PC boards.

A recommended crystal oscillator circuit to be used with the HPC is shown in *Figure 30*. See table for recommended component values. The recommended values given in Table VI have yielded consistent results and are made to match a crystal with a 20 pF load capacitance, with some small allowance for layout capacitance.

A recommended layout for the oscillator network should be as close to the processor as physically possible, entirely within "1" distance. This is to reduce lead inductance from long PC traces, as well as interference from other components, and reduce trace capacitance. The layout contains a large ground plane either on the top or bottom surface of the board to provide signal shielding, and a convenient location to ground both the HPC and the case of the crystal.

It is very critical to have an extremely clean power supply for the HPC crystal oscillator. Ideally one would like a V_{CC} and ground plane that provide low inductance power lines to the

chip. The power planes in the PC board should be decoupled with three decoupling capacitors as close to the chip as possible. A 1.0 μF , a 0.1 μF , and a 0.001 μF dipped mica or ceramic cap mounted as close to the HPC as is physically possible on the board, using the shortest leads, or surface mount components. This should provide a stable power supply, and noiseless ground plane which will vastly improve the performance of the crystal oscillator network.

FIGURE 30. Recommended Crystal Circuit

HPC46164 CPU

The HPC46164 CPU has a 16-bit ALU and six 16-bit registers:

Arithmetic Logic Unit (ALU)

The ALU is 16 bits wide and can do 16-bit add, subtract and shift or logic AND, OR and exclusive OR in one timing cycle. The ALU can also output the carry bit to a 1-bit C register.

HPC46164 CPU (Continued)

Accumulator (A) Register

The 16-bit A register is the source and destination register for most I/O, arithmetic, logic and data memory access operations.

Address (B and X) Registers

The 16-bit B and X registers can be used for indirect addressing. They can automatically count up or down to sequence through data memory.

Boundary (K) Register

The 16-bit K register is used to set limits in repetitive loops of code as register B sequences through data memory.

Stack Pointer (SP) Register

The 16-bit SP register is the pointer that addresses the stack. The SP register is incremented by two for each push or call and decremented by two for each pop or return. The stack can be placed anywhere in user memory and be as deep as the available memory permits.

Program (PC) Register

The 16-bit PC register addresses program memory.

Addressing Modes

ADDRESSING MODES—ACCUMULATOR AS DESTINATION

Register Indirect

This is the "normal" mode of addressing for the HPC46164 (instructions are single-byte). The operand is the memory addressed by the B register (or X register for some instructions).

Direct

The instruction contains an 8-bit or 16-bit address field that directly points to the memory for the operand.

Indirect

The instruction contains an 8-bit address field. The contents of the WORD addressed points to the memory for the operand.

Indexed

The instruction contains an 8-bit address field and an 8- or 16-bit displacement field. The contents of the WORD addressed is added to the displacement to get the address of the operand.

Immediate

The instruction contains an 8-bit or 16-bit immediate field that is used as the operand.

Register Indirect (Auto Increment and Decrement)

The operand is the memory addressed by the X register. This mode automatically increments or decrements the X register (by 1 for bytes and by 2 for words).

Register Indirect (Auto Increment and Decrement) with Conditional Skip

The operand is the memory addressed by the B register. This mode automatically increments or decrements the B register (by 1 for bytes and by 2 for words). The B register is then compared with the K register. A skip condition is generated if B goes past K.

ADDRESSING MODES—DIRECT MEMORY AS DESTINATION

Direct Memory to Direct Memory

The instruction contains two 8- or 16-bit address fields. One field directly points to the source operand and the other field directly points to the destination operand.

Immediate to Direct Memory

The instruction contains an 8- or 16-bit address field and an 8- or 16-bit immediate field. The immediate field is the operand and the direct field is the destination.

Double Register Indirect Using the B and X Registers

Used only with Reset, Set and IF bit instructions; a specific bit within the 64 kbyte address range is addressed using the B and X registers. The address of a byte of memory is formed by adding the contents of the B register to the most significant 13 bits of the X register. The specific bit to be modified or tested within the byte of memory is selected using the least significant 3 bits of register X.

HPC Instruction Set Description

Code Efficiency

One of the most important criteria of a single chip microcontroller is code efficiency. The more efficient the code, the more features that can be put on a chip. The memory size on a chip is fixed so if code is not efficient, features may have to be sacrificed or the programmer may have to buy a larger, more expensive version of the chip.

The HPC46164 has been designed to be extremely code-efficient. The HPC46164 looks very good in all the standard coding benchmarks; however, it is not realistic to rely only on benchmarks. Many large jobs have been programmed onto the HPC46164, and the code savings over other popular microcontrollers has been considerable.

Reasons for this saving of code include the following:

SINGLE BYTE INSTRUCTIONS

The majority of instructions on the HPC46164 are single-byte. There are two especially code-saving instructions: JP is a 1-byte jump. True, it can only jump within a range of plus or minus 32, but many loops and decisions are often within a small range of program memory. Most other micros need 2-byte instructions for any short jumps.

JSRP is a 1-byte call subroutine. The user makes a table of the 16 most frequently called subroutines and these calls will only take one byte. Most other micros require two and even three bytes to call a subroutine. The user does not have to decide which subroutine addresses to put into this table; the assembler can give this information.

EFFICIENT SUBROUTINE CALLS

The 2-byte JSR instructions can call any subroutine within plus or minus 1k of program memory.

MULTIFUNCTION INSTRUCTIONS FOR DATA MOVEMENT AND PROGRAM LOOPING

The HPC46164 has single-byte instructions that perform multiple tasks. For example, the XS instruction will do the following:

1. Exchange A and memory pointed to by the B register
2. Increment or decrement the B register
3. Compare the B register to the K register
4. Generate a conditional skip if B has passed K

The value of this multipurpose instruction becomes evident when looping through sequential areas of memory and exiting when the loop is finished.

BIT MANIPULATION INSTRUCTIONS

Any bit of memory, I/O or registers can be set, reset or tested by the single byte bit instructions. The bits can be addressed directly or indirectly. Since all registers and I/O are mapped into the memory, it is very easy to manipulate specific bits to do efficient control.

DECIMAL ADD AND SUBTRACT

This instruction is needed to interface with the decimal user world.

It can handle both 16-bit words and 8-bit bytes.

The 16-bit capability saves code since many variables can be stored as one piece of data and the programmer does not have to break his data into two bytes. Many applications store most data in 4-digit variables. The HPC46164 supplies 8-bit byte capability for 2-digit variables and literal variables.

MULTIPLY AND DIVIDE INSTRUCTIONS

The HPC46164 has 16-bit multiply, 16-bit by 16-bit divide, and 32-bit by 16-bit divide instructions. This saves both code and time. Multiply and divide can use immediate data or data from memory. The ability to multiply and divide by immediate data saves code since this function is often needed for scaling, base conversion, computing indexes of arrays, etc.

Development Support

HPC MICROCONTROLLER DEVELOPMENT SYSTEM

The HPC microcontroller development system is an in-system emulator (ISE) designed to support the entire family of HPC Microcontrollers. The complete package of hardware and software tools combined with a host system provides a powerful system for design, development and debug of HPC based designs. Software tools are available for IBM PC-AT® (MS-DOS, PC-DOS) and for Unix based multi-user Sun SparcStation (SunOSTM).

The stand alone units comes complete with a power supply and external emulation POD. This unit can be connected to various host systems through an RS-232 link. The software package includes an ANSI compatible C-Compiler, Linker, Assembler and librarian package. Source symbolic debug capability is provided through a user friendly MS-windows 3.0 interface for IBM PC-AT environment and through a line debugger under Sunview for Sun SparcStations.

The ISE provides fully transparent in-system emulation at speeds up to 20 MHz 1 waitstate. A 2k word (48-bit wide) trace buffer gives trace trigger and non intrusive monitoring of the system. External triggering is also available through an external logic interface socket on the POD. Direct EPROM programming can be done through the use of externally mounted EPROM socket. Form-Fit-Function emulator programming is supported by a programming board included with the system. Comprehensive on-line help and diagnostics features reduced user's design and debug time. 8 hardware breakpoints (Address/range), 64 kbytes of user memory, and break on external events are some of the other features offered.

Hewlett Packard model HP64775 Emulator/Analyzer providing in-system emulation for up to 30 MHz 1 waitstate is also available. Contact your local sales office for technical details and support.

How to Order

To order a complete development package, select the section for the microcontroller to be developed and order the parts listed.

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. Dial-A-Helper is an Electronic Bulletin Board Information system and additionally, provides the capability of remotely accessing the development system at a customer site.

INFORMATION SYSTEM

The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communications to and from the Micro-

controller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities can be found. The minimum requirement for accessing Dial-A-Helper is a Hayes compatible modem.

If the user has a PC with a communications package then files from the FILE SECTION can be down loaded to disk for later use.

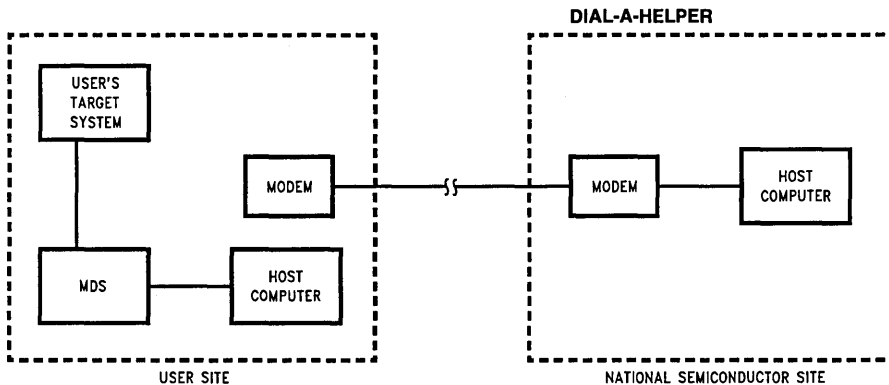

Order P/N: MDS-DIAL-A-HLP

Information System Package Contains:
Dial-A-Helper Users Manual
Public Domain Communications Software

FACTORY APPLICATIONS SUPPORT

Dial-A-Helper also provides immediate factory applications support. If a user is having difficulty in operating a MDS, he can leave messages on our electronic bulletin board, which we will respond to.

Voice: (408) 721-5582
 Modem: (408) 739-1162
 Baud: 300 or 1200 baud
 Set-Up: Length: 8-Bit
 Parity: None
 Stop Bit: 1
 Operation: 24 Hrs. 7 Days

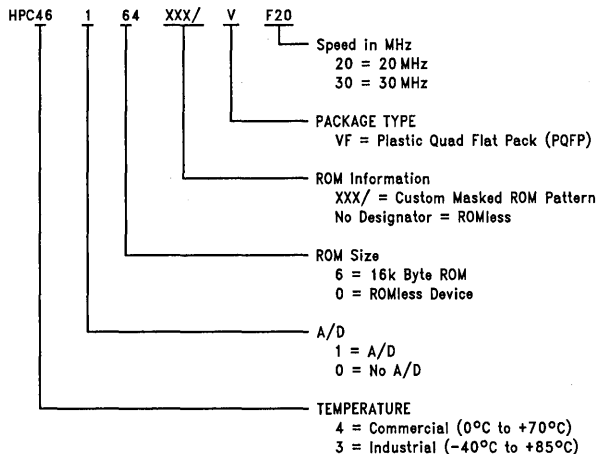

TL/DD/9682-37

Part Selection

The HPC family includes devices with many different options and configurations to meet various application needs. The number HPC46164 has been generically used throughout this datasheet to represent the whole family of parts. The following chart explains how to order various options available when ordering HPC family members.

Note: All options may not currently be available.

TL/DD/9682-46

HPC16064/26064/36064/46064/16004/26004/ 36004/46004 High-Performance microController

General Description

The HPC46064 and HPC46004 are members of the HPC™ family of High Performance microControllers. Each member of the family has the same core CPU with a unique memory and I/O configuration to suit specific applications. The HPC46064 has 16k bytes of on-chip ROM. The HPC46004 has no on-chip ROM and is intended for use with external memory. Each part is fabricated in National's advanced microCMOS technology. This process combined with an advanced architecture provides fast, flexible I/O control, efficient data manipulation, and high speed computation.

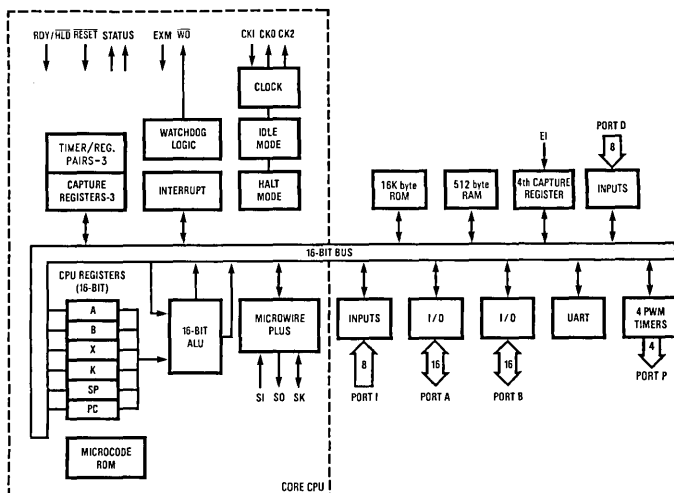

The HPC devices are complete microcomputers on a single chip. All system timing, internal logic, ROM, RAM, and I/O are provided on the chip to produce a cost effective solution for high performance applications. On-chip functions such as UART, up to eight 16-bit timers with 4 input capture registers, vectored interrupts, WATCHDOG™ logic and MICROWIRE/PLUS™ provide a high level of system integration. The ability to address up to 64k bytes of external memory enables the HPC to be used in powerful applications typically performed by microprocessors and expensive peripheral chips. The term "HPC46064" is used throughout this data-sheet to refer to the HPC46064 and HPC46004 devices unless otherwise specified.

The microCMOS process results in very low current drain and enables the user to select the optimum speed/power product for his system. The IDLE and HALT modes provide further current savings. The HPC is available in 68-pin PLCC, LDCC, PGA and 80-pin PQFP package.

Features

- HPC family—core features:
 - 16-bit architecture, both byte and word
 - 16-bit data bus, ALU, and registers
 - 64k bytes of external direct memory addressing
 - FAST—200 ns for fastest instruction when using 20.0 MHz clock, 134 ns at 30.0 MHz
 - High code efficiency—most instructions are single byte
 - 16 x 16 multiply and 32 x 16 divide
 - Eight vectored interrupt sources
 - Four 16-bit timer/counters with 4 synchronous outputs and WATCHDOG logic
 - MICROWIRE/PLUS serial I/O interface
 - CMOS—very low power with two power save modes: IDLE and HALT
- UART—full duplex, programmable baud rate
- Four additional 16-bit timer/counters with pulse width modulated outputs
- Four input capture registers
- 52 general purpose I/O lines (memory mapped)
- 16k bytes of ROM, 512 bytes of RAM on-chip
- ROMless version available (HPC46004)
- Commercial (0°C to +70°C), industrial (-40°C to +85°C), automotive (-40°C to +105°C) and military (-55°C to +125°C) temperature ranges

Block Diagram (HPC46064 with 16k ROM shown)

HPC16064/26064/36064/46064/16004/26004/36004/46004

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Total Allowable Source or Sink Current	100 mA
Storage Temperature Range	-65°C to +150°C
Lead Temperature (Soldering, 10 sec.)	300°C

V_{CC} with Respect to GND -0.5V to 7.0V
 All Other Pins ($V_{CC} + 0.5$)V to (GND - 0.5)V
 Note: Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.

DC Electrical Characteristics

$V_{CC} = 5V \pm 10\%$, $T_A = 0^\circ\text{C}$ to $+70^\circ\text{C}$ for HPC46064/46004, -40°C to $+85^\circ\text{C}$ for HPC36064/36004, -40°C to $+105^\circ\text{C}$ for HPC26064/26004, -55°C to $+125^\circ\text{C}$ for HPC16064/16004

Symbol	Parameter	Test Conditions	Min	Max	Units
I_{CC1}	Supply Current	$V_{CC} = 5.5V, f_{in} = 30\text{ MHz}$ (Note 1)		65	mA
		$V_{CC} = 5.5V, f_{in} = 20\text{ MHz}$ (Note 1)		47	mA
		$V_{CC} = 5.5V, f_{in} = 2.0\text{ MHz}$ (Note 1)		10	mA
I_{CC2}	IDLE Mode Current	$V_{CC} = 5.5V, f_{in} = 30\text{ MHz}$ (Note 1)		5	mA
		$V_{CC} = 5.5V, f_{in} = 20\text{ MHz}$ (Note 1)		3.0	mA
		$V_{CC} = 5.5V, f_{in} = 2.0\text{ MHz}$ (Note 1)		1	mA
I_{CC3}	HALT Mode Current	$V_{CC} = 5.5V, f_{in} = 0\text{ kHz}$ (Note 1)		300	μA
		$V_{CC} = 2.5V, f_{in} = 0\text{ kHz}$ (Note 1)		100	μA

INPUT VOLTAGE LEVELS FOR SCHMITT TRIGGERED INPUTS, RESET, NMI, AND $\overline{W0}$; AND ALSO CKI

V_{IH1}	Logic High		$0.9 V_{CC}$		V
V_{IL1}	Logic Low			$0.1 V_{CC}$	V

ALL OTHER INPUTS

V_{IH2}	Logic High		$0.7 V_{CC}$		V
V_{IL2}	Logic Low			$0.2 V_{CC}$	V
I_{L11}	Input Leakage Current	$V_{IN} = 0$ and $V_{IN} = V_{CC}$		± 2	μA
I_{L12}	Input Leakage Current RDY/HLD, EXUI	$V_{IN} = 0$	-3	-50	μA
I_{L13}	Input Leakage Current B12	$\overline{\text{RESET}} = 0, V_{IN} = V_{CC}$	0.5	7	μA
C_I	Input Capacitance	(Note 2)		10	pF
C_{IO}	I/O Capacitance	(Note 2)		20	pF

OUTPUT VOLTAGE LEVELS

V_{OH1}	Logic High (CMOS)	$I_{OH} = -10\ \mu\text{A}$ (Note 2)	$V_{CC} - 0.1$		V
V_{OL1}	Logic Low (CMOS)	$I_{OH} = 10\ \mu\text{A}$ (Note 2)		0.1	V
V_{OH2}	Port A/B Drive, CK2 (A ₀ -A ₁₅ , B ₁₀ , B ₁₁ , B ₁₂ , B ₁₅)	$I_{OH} = -7\text{ mA}$	2.4		V
V_{OL2}		$I_{OL} = 3\text{ mA}$		0.4	V
V_{OH3}	Other Port Pin Drive, $\overline{W0}$ (open drain) (B ₀ -B ₉ , B ₁₃ , B ₁₄ , P ₀ -P ₃)	$I_{OH} = -1.6\text{ mA}$ (except $\overline{W0}$)	2.4		V
V_{OL3}		$I_{OL} = 0.5\text{ mA}$		0.4	V
V_{OH4}	ST1 and ST2 Drive	$I_{OH} = -6\text{ mA}$	2.4		V
V_{OL4}		$I_{OL} = 1.6\text{ mA}$		0.4	V
V_{OH5}	Port A/B Drive (A ₀ -A ₁₅ , B ₁₀ , B ₁₁ , B ₁₂ , B ₁₅) When Used as External Address/Data Bus	$I_{OH} = -1\text{ mA}$	2.4		V
V_{OL5}		$I_{OL} = 3\text{ mA}$		0.4	V
V_{RAM}	RAM Keep-Alive Voltage	(Note 3)	2.5	V_{CC}	V
I_{OZ}	TRI-STATE® Leakage Current	$V_{IN} = 0$ and $V_{IN} = V_{CC}$		± 5	μA

Note 1: I_{CC1} , I_{CC2} , I_{CC3} measured with no external drive (I_{OH} and $I_{OL} = 0$, I_{IH} and $I_{IL} = 0$). I_{CC1} is measured with $\overline{\text{RESET}} = V_{SS}$. I_{CC3} is measured with $\text{NMI} = V_{CC}$. CKI driven to V_{IH1} and V_{IL1} with rise and fall times less than 10 ns.

Note 2: This is guaranteed by design and not tested.

Note 3: Test duration is 100 ms.

20 MHz
AC Electrical Characteristics

 (See Notes 1 and 4 and Figure 1 through Figure 5). $V_{CC} = 5V \pm 10\%$, $T_A = 0^\circ\text{C}$ to $+70^\circ\text{C}$ for HPC46064/46004, -40°C to $+85^\circ\text{C}$ for HPC36064/36004, -40°C to $+105^\circ\text{C}$ for HPC26064/26004, -55°C to $+125^\circ\text{C}$ for HPC16064/16004

*This maximum frequency is attainable provided that this external baud clock has a duty cycle such that the high period includes two (2) falling edges of the CK2 clock.

20 MHz (Continued)

AC Electrical Characteristics

(See Notes 1 and 4 and Figure 1 through Figure 5). $V_{CC} = 5V \pm 10\%$, $T_A = 0^\circ C$ to $+70^\circ C$ for HPC46064/46004, $-40^\circ C$ to $+85^\circ C$ for HPC36064/36004, $-40^\circ C$ to $+105^\circ C$ for HPC26064/26004, $-55^\circ C$ to $+125^\circ C$ for HPC16064/16004

	Symbol and Formula	Parameter and Notes	Min	Max	Units	Notes
Address Cycles	$t_{DC1ALER}$	Delay from CK1 Rising Edge to ALE Rising Edge	0	35	ns	(Notes 1, 2)
	$t_{DC1ALEF}$	Delay from CK1 Rising Edge to ALE Falling Edge	0	35	ns	(Notes 1, 2)
	$t_{DC2ALER} = \frac{1}{4} t_C + 20$	Delay from CK2 Rising Edge to ALE Rising Edge		45	ns	(Note 2)
	$t_{DC2ALEF} = \frac{1}{4} t_C + 20$	Delay from CK2 Falling Edge to ALE Falling Edge		45	ns	(Note 2)
	$t_{LL} = \frac{1}{2} t_C - 9$	ALE Pulse Width	41		ns	
	$t_{ST} = \frac{1}{4} t_C - 7$	Setup of Address Valid before ALE Falling Edge	18		ns	
	$t_{VP} = \frac{1}{4} t_C - 5$	Hold of Address Valid after ALE Falling Edge	20		ns	
Read Cycles	$t_{ARR} = \frac{1}{4} t_C - 5$	ALE Falling Edge to \overline{RD} Falling Edge	20		ns	
	$t_{ACC} = t_C + WS - 55$	Data Input Valid after Address Output Valid		145	ns	(Note 6)
	$t_{RD} = \frac{1}{2} t_C + WS - 65$	Data Input Valid after \overline{RD} Falling Edge		85	ns	
	$t_{RW} = \frac{1}{2} t_C + WS - 10$	\overline{RD} Pulse Width	140		ns	
	$t_{DR} = \frac{3}{4} t_C - 15$	Hold of Data Input Valid after \overline{RD} Rising Edge	0	60	ns	
	$t_{RDA} = t_C - 15$	Bus Enable after \overline{RD} Rising Edge	85		ns	
Write Cycles	$t_{ARW} = \frac{1}{2} t_C - 5$	ALE Falling Edge to \overline{WR} Falling Edge	45		ns	
	$t_{WW} = \frac{3}{4} t_C + WS - 15$	\overline{WR} Pulse Width	160		ns	
	$t_V = \frac{1}{2} t_C + WS - 5$	Data Output Valid before \overline{WR} Rising Edge	145		ns	
	$t_{HW} = \frac{1}{4} t_C - 5$	Hold of Data Valid after \overline{WR} Rising Edge	20		ns	
Ready Input	$t_{DAR} = \frac{1}{4} t_C + WS - 50$	Falling Edge of ALE to Falling Edge of RDY		75	ns	
	$t_{RWP} = t_C$	RDY Pulse Width	100		ns	

Note: $C_L = 40$ pF.

Note 1: These AC characteristics are guaranteed with external clock drive on CK1 having 50% duty cycle and with less than 15 pF load on CK0 with rise and fall times (t_{CK1R} and t_{CK1L}) on CK1 input less than 2.5 ns.

Note 2: Do not design with these parameters unless CK1 is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CK1 or CK0 is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{FLD} falling edge occurring at the latest time it can be accepted during the present CPU cycle being executed. If \overline{FLD} falling edge occurs later, t_{HAE} may be as long as $(3 t_C + 4WS + 72 t_C + 100)$ may occur depending on the following CPU instruction cycles, its wait states and ready input.

Note 4: $WS (t_{WAIT}) \times$ (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $t_C = 20$ MHz, with one wait state programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

Note 6: This is guaranteed by design and not tested.

30 MHz

	$t_{LL} = \frac{1}{2}t_C - 9$	ALE Pulse Width	24		ns	
	$t_{ST} = \frac{1}{4}t_C - 7$	Setup of Address Valid before ALE Falling Edge	9		ns	
	$t_{VP} = \frac{1}{4}t_C - 5$	Hold of Address Valid after ALE Falling Edge	11		ns	
Read Cycles	$t_{ARR} = \frac{1}{4}t_C - 5$	ALE Falling Edge to \overline{RD} Falling Edge	11		ns	
	$t_{ACC} = t_C + WS - 32$	Data Input Valid after Address Output Valid		100	ns	(Note 6)
	$t_{RD} = \frac{1}{2}t_C + WS - 39$	Data Input Valid after \overline{RD} Falling Edge		60	ns	
	$t_{RW} = \frac{1}{2}t_C + WS - 14$	\overline{RD} Pulse Width	85		ns	
	$t_{DR} = \frac{3}{4}t_C - 15$	Hold of Data Input Valid after \overline{RD} Rising Edge	0	35	ns	
	$t_{RDA} = t_C - 15$	Bus Enable after \overline{RD} Rising Edge	51		ns	
Write Cycles	$t_{ARW} = \frac{1}{2}t_C - 5$	ALE Falling Edge to \overline{WR} Falling Edge	28		ns	
	$t_{WW} = \frac{3}{4}t_C + WS - 15$	\overline{WR} Pulse Width	101		ns	
	$t_V = \frac{1}{2}t_C + WS - 5$	Data Output Valid before \overline{WR} Rising Edge	94		ns	
	$t_{HW} = \frac{1}{4}t_C - 10$	Hold of Data Valid after \overline{WR} Rising Edge	7		ns	
Ready Input	$t_{DAR} = \frac{1}{4}t_C + WS - 50$	Falling Edge of ALE to Falling Edge of RDY		33	ns	
	$t_{RWP} = t_C$	RDY Pulse Width	66		ns	

Note: $C_L = 40$ pF.

Note 1: These AC characteristics are guaranteed with external clock drive on CK1 having 50% duty cycle and with less than 15 pF load on CKO with rise and fall times (t_{CK1R} and t_{CK1F}) on CK1 input less than 2.5 ns.

Note 2: Do not design with these parameters unless CK1 is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CK1 or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{HLD} falling edge occurring at the latest time it can be accepted during the present CPU cycle being executed. If \overline{HLD} falling edge occurs later, t_{HAE} may be as long as $(3t_C + 4WS + 72t_C + 100)$ may occur depending on the following CPU instruction cycles, its wait states and ready input.

Note 4: $WS (t_{WAIT}) \times$ (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $t_C = 20$ MHz, with one wait state programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

Note 6: This is guaranteed by design and not tested.

Pin Descriptions

The HPC46064 is available only in 68-pin PLCC, LDCC, PGA, and 80-pin PQFP packages.

I/O PORTS

Port A is a 16-bit bidirectional I/O port with a data direction register to enable each separate pin to be individually defined as an input or output. When accessing external memory, port A is used as the multiplexed address/data bus.

Port B is a 16-bit port with 12 bits of bidirectional I/O similar in structure to Port A. Pins B10, B11, B12 and B15 are general purpose outputs only in this mode. Port B may also be configured via a 16-bit function register BFUN to individually allow each pin to have an alternate function.

B0:	TDX	UART Data Output
B1:		
B2:	CKX	UART Clock (Input or Output)
B3:	T2IO	Timer2 I/O Pin
B4:	T3IO	Timer3 I/O Pin
B5:	SO	MICROWIRE/PLUS Output
B6:	SK	MICROWIRE/PLUS Clock (Input or Output)
B7:	H \overline{LDA}	Hold Acknowledge Output
B8:	TS0	Timer Synchronous Output
B9:	TS1	Timer Synchronous Output
B10:	UA0	Address 0 Input for UPI Mode
B11:	W \overline{RRDY}	Write Ready Output for UPI Mode
B12:		
B13:	TS2	Timer Synchronous Output
B14:	TS3	Timer Synchronous Output
B15:	R \overline{DRDY}	Read Ready Output for UPI Mode

When accessing external memory, four bits of port B are used as follows:

B10:	ALE	Address Latch Enable Output
B11:	W \overline{R}	Write Output
B12:	H \overline{BE}	High Byte Enable Output/Input (sampled at reset)
B15:	R \overline{D}	Read Output

Port I is an 8-bit input port that can be read as general purpose inputs and is also used for the following functions:

I0:		
I1:	NMI	Nonmaskable Interrupt Input
I2:	INT2	Maskable Interrupt/Input Capture/ \overline{URD}
I3:	INT3	Maskable Interrupt/Input Capture/ \overline{UWR}
I4:	INT4	Maskable Interrupt/Input Capture
I5:	SI	MICROWIRE/PLUS Data Input
I6:	RDX	UART Data Input
I7:		

Port D is an 8-bit input port that can be used as general purpose digital inputs.

Port P is a 4-bit output port that can be used as general purpose data, or selected to be controlled by timers 4 through 7 in order to generate frequency, duty cycle and pulse width modulated outputs.

POWER SUPPLY PINS

V $\overline{CC1}$ and V $\overline{CC2}$	Positive Power Supply
GND	Ground for On-Chip Logic
DGND	Ground for Output Buffers

Note: There are two electrically connected V \overline{CC} pins on the chip, GND and DGND are electrically isolated. Both V \overline{CC} pins and both ground pins must be used.

CLOCK PINS

CKI	The Chip System Clock Input
CKO	The Chip System Clock Output (inversion of CKI)

Pins CKI and CKO are usually connected across an external crystal.

CK2	Clock Output (CKI divided by 2)
-----	---------------------------------

OTHER PINS

W \overline{O}	This is an active low open drain output that signals an illegal situation has been detected by the WATCHDOG logic.
ST1	Bus Cycle Status Output: indicates first opcode fetch.
ST2	Bus Cycle Status Output: indicates machine states (skip, interrupt and first instruction cycle).
R \overline{ESET}	Active low input that forces the chip to restart and sets the ports in a TRI-STATE mode.
R $\overline{DY}/\overline{HLD}$	Selected by a software bit. It's either a READY input to extend the bus cycle for slower memories, or a HOLD request input to put the bus in a high impedance state for DMA purposes.
N/C	(No connection) do not connect anything to this pin.
EXM	External memory enable (active high) disables internal ROM and maps it to external memory.
EI	External interrupt with vector address FFF1:FFF0. (Rising/falling edge or high/low level sensitive). Alternately can be configured as 4th input capture.
EXUI	External active low interrupt which is internally OR'ed with the UART interrupt with vector address FFF3:FFF2.

Ports A & B

The highly flexible A and B ports are similarly structured. The Port A (see *Figure 11*) consists of a data register and a direction register. Port B (see *Figures 12, 13 and 14*) has an alternate function register in addition to the data and direction registers. All the control registers are read/write registers.

The associated direction registers allow the port pins to be individually programmed as inputs or outputs. Port pins selected as inputs, are placed in a TRI-STATE mode by resetting corresponding bits in the direction register.

A write operation to a port pin configured as an input causes the value to be written into the data register, a read operation returns the value of the pin. Writing to port pins configured as outputs causes the pins to have the same value, reading the pins returns the value of the data register.

Primary and secondary functions are multiplexed onto Port B through the alternate function register (BFUN). The secondary functions are enabled by setting the corresponding bits in the BFUN register.

Operating Modes

To offer the user a variety of I/O and expanded memory options, the HPC46064 and HPC46004 have four operating modes. The ROMless HPC46004 has one mode of operation. The various modes of operation are determined by the state of both the EXM pin and the EA bit in the PSW register. The state of the EXM pin determines whether on-chip ROM will be accessed or external memory will be accessed within the address range of the on-chip ROM. The on-chip ROM range of the HPC46064 is C000 to FFFF (16k bytes). The HPC46004 has no on-chip ROM and is intended for use with external memory for program storage. A logic "0" state on the EXM pin will cause the HPC device to address on-chip ROM when the Program Counter (PC) contains addresses within the on-chip ROM address range. A logic "1" state on the EXM pin will cause the HPC device to address memory that is external to the HPC when the PC contains on-chip ROM addresses. The EXM pin should always be pulled high (logic "1") on the HPC46004 because no on-chip ROM is available. The function of the EA bit is to determine the legal addressing range of the HPC device. A logic "0" state in the EA bit of the PSW register does two things—addresses are limited to the on-chip ROM range

and on-chip RAM and Register range, and the "illegal address detection" feature of the WATCHDOG logic is engaged. A logic "1" in the EA bit enables accesses to be made anywhere within the 64k byte address range and the "illegal address detection" feature of the WATCHDOG logic is disabled. The EA bit should be set to "1" by software when using the HPC46004 to disable the "illegal address detection" feature of WATCHDOG.

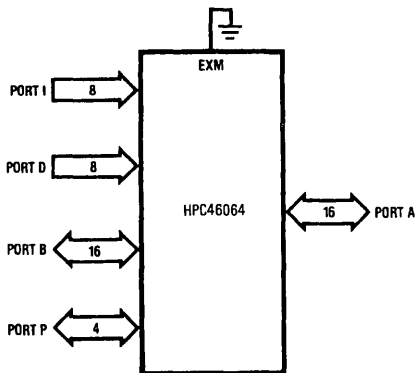

All HPC devices can be used with external memory. External memory may be any combination of RAM and ROM. Both 8-bit and 16-bit external data bus modes are available. Upon entering an operating mode in which external memory is used, port A becomes the Address/Data bus. Four pins of port B become the control lines ALE, RD, WR and HBE. The High Byte Enable pin (HBE) is used in 16-bit mode to select high order memory bytes. The RD and WR signals are only generated if the selected address is off-chip. The 8-bit mode is selected by pulling HBE high at reset. If HBE is left floating or connected to a memory device chip select at reset, the 16-bit mode is entered. The following sections describe the operating modes of the HPC46064 and HPC46004.

Note: The HPC devices use 16-bit words for stack memory. Therefore, when using the 8-bit mode, User's Stack must be in internal RAM.

HPC46064 Operating Modes

SINGLE CHIP NORMAL MODE

In this mode, the HPC46064 functions as a self-contained microcomputer (see Figure 15) with all memory (RAM and ROM) on-chip. It can address internal memory only, consisting of 16k bytes of ROM (C000 to FFFF) and 512 bytes of on-chip RAM and Registers (0000 to 02FF). The "illegal address detection" feature of the WATCHDOG is enabled in the Single-Chip Normal mode and a WATCHDOG Output (WO) will occur if an attempt is made to access addresses that are outside of the on-chip ROM and RAM range of the device. Ports A and B are used for I/O functions and not for addressing external memory. The EXM pin and the EA bit of the PSW register must both be logic "0" to enter the Single-Chip Normal mode.

TL/DD/11372-13

FIGURE 15. Single-Chip Mode

EXPANDED NORMAL MODE

The Expanded Normal mode of operation enables the HPC46064 to address external memory in addition to the

on-chip ROM and RAM (see Table I). WATCHDOG illegal address detection is disabled and memory accesses may be made anywhere in the 64k byte address range without triggering an illegal address condition. The Expanded Normal mode is entered with the EXM pin pulled low (logic "0") and setting the EA bit in the PSW register to "1".

SINGLE-CHIP ROMLESS MODE

In this mode, the on-chip mask programmed ROM of the HPC46064 is not used. The address space corresponding to the on-chip ROM is mapped into external memory so 16k of external memory may be used with the HPC46064 (see Table I). The WATCHDOG circuitry detects illegal addresses (addresses not within the on-chip ROM and RAM range). The Single-Chip ROMless mode is entered when the EXM pin is pulled high (logic "1") and the EA bit is logic "0".

TABLE I. HPC46064 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Single-Chip Normal	0	0	C000:FFFF on-chip
Expanded Normal	0	1	C000:FFFF on-chip 0300:BFFF off-chip
Single-Chip ROMless	1	0	C000:FFFF off-chip
Expanded ROMless	1	1	0300:FFFF off-chip

Note: In all operating modes, the on-chip RAM and Registers (0000:02FF) may be accessed.

EXPANDED ROMLESS MODE

This mode of operation is similar to Single-Chip ROMless mode in that no on-chip ROM is used, however, a full 64k bytes of external memory may be used. The "illegal address detection" feature of WATCHDOG is disabled. The EXM pin must be pulled high (logic "1") and the EA bit in the PSW register set to "1" to enter this mode.

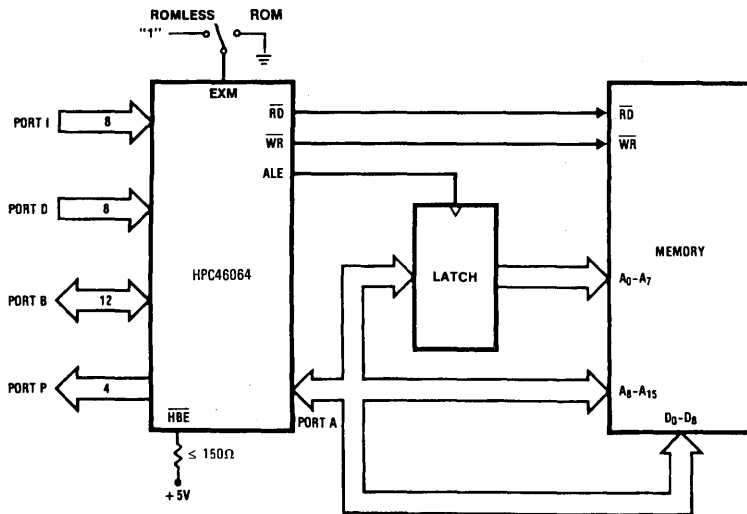

FIGURE 16. 8-Bit External Memory

TL/DD/11372-14

HPC46064 Operating Modes (Continued)

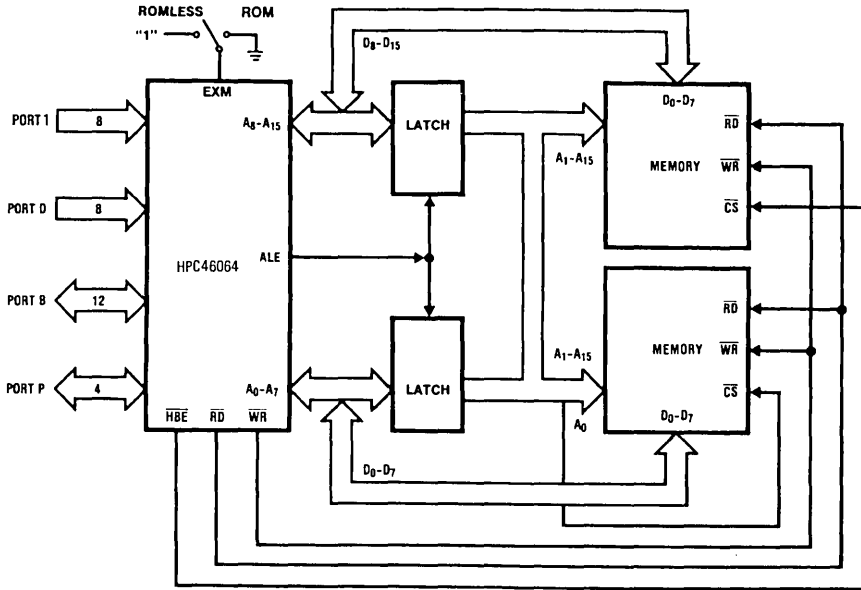

FIGURE 17. 16-Bit External Memory

TL/DD/11372-15

HPC46004 Operating Modes

EXPANDED ROMLESS MODE

Because the HPC46004 has no on-chip ROM, it has only one mode of operation, the Expanded ROMless Mode. The EXM pin must be pulled high (logic "1") on power up, the EA bit in the PSW register should be set to a "1". The HPC46004 is a ROMless device and is intended for use with external memory. The external memory may be any combination of ROM and RAM. Up to 64k bytes of external memory may be accessed. It is necessary to vector on reset to an address between C000 and FFFF, therefore the user should have external memory at these addresses. The EA bit in the PSW register must immediately be set to "1" at the beginning of the user's program to disable illegal address detection in the WATCHDOG logic.

TABLE II. HPC46004 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Expanded ROMless	1	1	0300:FFFF off-chip

Note: The on-chip RAM and Registers (0000:02FF) of the HPC46004 may be accessed at all times.

Wait States

The internal ROM can be accessed at the maximum operating frequency with one wait state. With 0 wait states, internal ROM accesses are limited to $\frac{1}{3} f_C$ max. The HPC46064 provides four software selectable Wait States that allow access to slower memories. The Wait States are selected by the state of two bits in the PSW register. Additionally, the RDY input may be used to extend the instruction cycle, allowing the user to interface with slow memories and peripherals.

Power Save Modes

Two power saving modes are available on the HPC46064: HALT and IDLE. In the HALT mode, all processor activities are stopped. In the IDLE mode, the on-board oscillator and timer T0 are active but all other processor activities are stopped. In either mode, all on-board RAM, registers and I/O are unaffected.

HALT MODE

The HPC46064 is placed in the HALT mode under software control by setting bits in the PSW. All processor activities, including the clock and timers, are stopped. In the HALT mode, power requirements for the HPC46064 are minimal and the applied voltage (V_{CC}) may be decreased without altering the state of the machine. There are two ways of exiting the HALT mode: via the \overline{RESET} or the NMI. The \overline{RESET} input reinitializes the processor. Use of the NMI input will generate a vectored interrupt and resume operation from that point with no initialization. The HALT mode can be enabled or disabled by means of a control register HALT enable. To prevent accidental use of the HALT mode the HALT enable register can be modified only once.

IDLE MODE

The HPC46064 is placed in the IDLE mode through the PSW. In this mode, all processor activity, except the on-board oscillator and Timer T0, is stopped. As with the HALT mode, the processor is returned to full operation by the \overline{RESET} or NMI inputs, but without waiting for oscillator stabilization. A timer T0 overflow will also cause the HPC46064 to resume normal operation.

HPC46064 Interrupts

Complex interrupt handling is easily accomplished by the HPC46064's vectored interrupt scheme. There are eight possible interrupt sources as shown in Table III.

TABLE III. Interrupts

Vector Address	Interrupt Source	Arbitration Ranking
FFFF:FFFE	RESET	0
FFFD:FFFC	Nonmaskable external on rising edge of I1 pin	1
FFFB:FFFA	External interrupt on I2 pin	2
FFF9:FFF8	External interrupt on I3 pin	3
FFF7:FFF6	External interrupt on I4 pin	4
FFF5:FFF4	Overflow on internal timers	5
FFF3:FFF2	Internal on the UART transmit/receive complete	6
FFF1:FFF0	External interrupt on EI pin	7

Interrupt Arbitration

The HPC46064 contains arbitration logic to determine which interrupt will be serviced first if two or more interrupts occur simultaneously. The arbitration ranking is given in Table III. The interrupt on Reset has the highest rank and is serviced first.

Interrupt Processing

Interrupts are serviced after the current instruction is completed except for the RESET, which is serviced immediately. RESET and EXUI are level-LOW-sensitive interrupts and EI is programmable for edge-(RISING or FALLING) or level-(HIGH or LOW) sensitivity. All other interrupts are edge-sensitive. NMI is positive-edge sensitive. The external interrupts on I2, I3 and I4 can be software selected to be rising or falling edge. External interrupt (EXUI) is shared with the on-board UART. The EXUI interrupt is level-LOW-sensitive. To select this interrupt, disable the ERI and ETI UART interrupts by resetting these enable bits in the ENUI register. To select the on-board UART interrupt, leave this pin floating.

Interrupt Control Registers

The HPC46064 allows the various interrupt sources and conditions to be programmed. This is done through the various control registers. A brief description of the different control registers is given below.

INTERRUPT ENABLE REGISTER (ENIR)

RESET and the External Interrupt on I1 are non-maskable interrupts. The other interrupts can be individually enabled

or disabled. Additionally, a Global Interrupt Enable Bit in the ENIR Register allows the Maskable interrupts to be collectively enabled or disabled. Thus, in order for a particular interrupt to request service, both the individual enable bit and the Global Interrupt bit (GIE) have to be set.

INTERRUPT PENDING REGISTER (IRPD)

The IRPD register contains a bit allocated for each interrupt vector. The occurrence of specified interrupt trigger conditions causes the appropriate bit to be set. There is no indication of the order in which the interrupts have been received. The bits are set independently of the fact that the interrupts may be disabled. IRPD is a Read/Write register. The bits corresponding to the maskable, external interrupts are normally cleared by the HPC46064 after servicing the interrupts.

For the interrupts from the on-board peripherals, the user has the responsibility of resetting the interrupt pending flags through software.

The NMI bit is read only and I2, I3, and I4 are designed as to only allow a zero to be written to the pending bit (writing a one has no affect). A LOAD IMMEDIATE instruction is to be the only instruction used to clear a bit or bits in the IRPD register. This allows a mask to be used, thus ensuring that the other pending bits are not affected.

INTERRUPT CONDITION REGISTER (IRCD)

Three bits of the register select the input polarity of the external interrupt on I2, I3, and I4.

Servicing the Interrupts

The Interrupt, once acknowledged, pushes the program counter (PC) onto the stack thus incrementing the stack pointer (SP) twice. The Global Interrupt Enable bit (GIE) is copied into the CGIE bit of the PSW register; it is then reset, thus disabling further interrupts. The program counter is loaded with the contents of the memory at the vector address and the processor resumes operation at this point. At the end of the interrupt service routine, the user does a RETI instruction to pop the stack and re-enable interrupts if the CGIE bit is set, or RET to just pop the stack if the CGIE bit is clear, and then returns to the main program. The GIE bit can be set in the interrupt service routine to nest interrupts if desired. *Figure 18* shows the Interrupt Enable Logic.

Reset

The RESET input initializes the processor and sets ports A and B in the TRI-STATE condition and Port P in the LOW state. RESET is an active-low Schmitt trigger input. The processor vectors to FFFF:FFFE and resumes operation at the address contained at that memory location (which must correspond to an on board location). The Reset vector address must be between C000 and FFFF when using the HPC46004.

Servicing the Interrupts (Continued)

FIGURE 18. Block Diagram of Interrupt Logic

HPC16064/26064/36064/46064/16004/26004/36004/46004

Timer Overview

The HPC46064 contains a powerful set of flexible timers enabling the HPC46064 to perform extensive timer functions not usually associated with microcontrollers. The HPC46064 contains nine 16-bit timers. Timer T0 is a free-running timer, counting up at a fixed CKI/16 (Clock Input/16) rate. It is used for WATCHDOG logic, high speed event capture, and to exit from the IDLE mode. Consequently, it cannot be stopped or written to under software control. Timer T0 permits precise measurements by means of the capture registers I2CR, I3CR, and I4CR. A control bit in the register TMMODE configures timer T1 and its associated register R1 as capture registers I3CR and I2CR. The capture registers I2CR, I3CR, and I4CR respectively, record the value of timer T0 when specific events occur on the interrupt pins I2, I3, and I4. The control register IRCD programs the capture registers to trigger on either a rising edge or a falling edge of its respective input. The specified edge can also be programmed to generate an interrupt (see Figure 19).

FIGURE 19. Timers T0, T1 and T8 with Four Input Capture Registers

The HPC46064 provides an additional 16-bit free running timer, T8, with associated input capture register EICR (External Interrupt Capture Register) and Configuration Register, EICON. EICON is used to select the mode and edge of the EI pin. EICR is a 16-bit capture register which records

the value of T8 (which is identical to T0) when a specific event occurs on the EI pin.

The timers T2 and T3 have selectable clock rates. The clock input to these two timers may be selected from the following two sources: an external pin, or derived internally by dividing the clock input. Timer T2 has additional capability of being clocked by the timer T3 underflow. This allows the user to cascade timers T3 and T2 into a 32-bit timer/counter. The control register DIVBY programs the clock input to timers T2 and T3 (see Figure 20).

The timers T1 through T7 in conjunction with their registers form Timer-Register pairs. The registers hold the pulse duration values. All the Timer-Register pairs can be read from or written to. Each timer can be started or stopped under software control. Once enabled, the timers count down, and upon underflow, the contents of its associated register are automatically loaded into the timer.

SYNCHRONOUS OUTPUTS

The flexible timer structure of the HPC46064 simplifies pulse generation and measurement. There are four synchronous timer outputs (TS0 through TS3) that work in conjunction with the timer T2. The synchronous timer outputs can be used either as regular outputs or individually programmed to toggle on timer T2 underflows (see Figure 20).

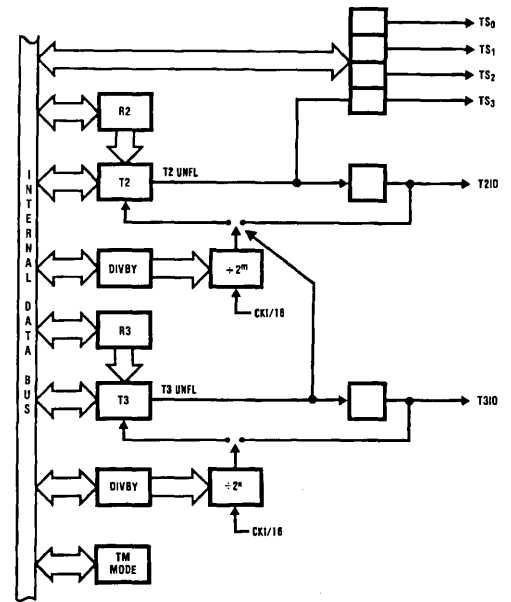

FIGURE 20. Timers T2-T3 Block

Timer Overview (Continued)

Timer/register pairs 4–7 form four identical units which can generate synchronous outputs on port P (see *Figure 21*). Maximum output frequency for any timer output can be obtained by setting timer/register pair to zero. This then will produce an output frequency equal to $\frac{1}{2}$ the frequency of the source used for clocking the timer.

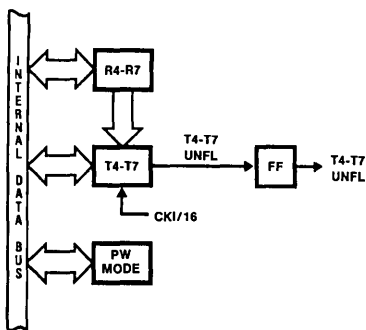

FIGURE 21. Timers T4–T7 Block

TL/DD/11372-19

Timer Registers

There are four control registers that program the timers. The divide by (DIVBY) register programs the clock input to timers T2 and T3. The timer mode register (TMMODE) contains control bits to start and stop timers T1 through T3. It also contains bits to latch, acknowledge and enable interrupts from timers T0 through T3. The control register PWMODE similarly programs the pulse width timers T4 through T7 by allowing them to be started, stopped, and to latch and enable interrupts on underflows. The PORTP register contains bits to preset the outputs and enable the synchronous timer output functions.

Timer Applications

The use of Pulse Width Timers for the generation of various waveforms is easily accomplished by the HPC46064.

Frequencies can be generated by using the timer/register pairs. A square wave is generated when the register value is a constant. The duty cycle can be controlled simply by changing the register value.

FIGURE 22. Square Wave Frequency Generation

TL/DD/11372-20

Synchronous outputs based on Timer T2 can be generated on the 4 outputs TS0–TS3. Each output can be individually programmed to toggle on T2 underflow. Register R2 contains the time delay between events. *Figure 23* is an example of synchronous pulse train generation.

TL/DD/11372-21

FIGURE 23. Synchronous Pulse Generation

WATCHDOG Logic

The WATCHDOG Logic monitors the operations taking place and signals upon the occurrence of any illegal activity. The illegal conditions that trigger the WATCHDOG logic are potentially infinite loops and illegal addresses. Should the WATCHDOG register not be written to before Timer T0 overflows twice, or more often than once every 4096 counts, an infinite loop condition is assumed to have occurred. An illegal condition also occurs when the processor generates an illegal address when in the Single-Chip modes.* Any illegal condition forces the WATCHDOG Output (\overline{WO}) pin low. The \overline{WO} pin is an open drain output and can be connected to the \overline{RESET} or NMI inputs or to the users external logic.

*Note: See Operating Modes for details.

MICROWIRE/PLUS

MICROWIRE/PLUS is used for synchronous serial data communications (see *Figure 24*). MICROWIRE/PLUS has an 8-bit parallel-loaded, serial shift register using SI as the input and SO as the output. SK is the clock for the serial shift register (SIO). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. A DONE flag indicates when the data shift is completed.

The MICROWIRE/PLUS capability enables it to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., A/D converters, display drivers, EEPROMs).

MICROWIRE/PLUS (Continued)

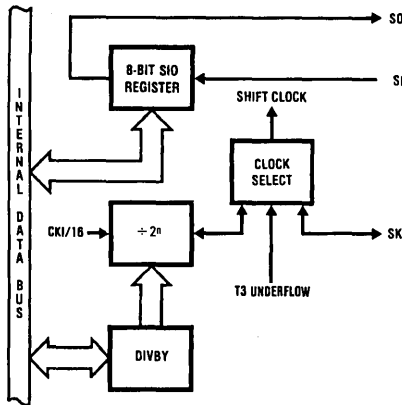

FIGURE 24. MICROWIRE/PLUS

MICROWIRE/PLUS Operation

The HPC46064 can enter the MICROWIRE/PLUS mode as the master or a slave. A control bit in the IRCD register determines whether the HPC46064 is the master or slave. The shift clock is generated when the HPC46064 is configured as a master. An externally generated shift clock on the SK pin is used when the HPC46064 is configured as a slave. When the HPC46064 is a master, the DIVBY register programs the frequency of the SK clock. The DIVBY register allows the SK clock frequency to be programmed in 14 se-

lectable binary steps or T3 underflow from 153 Hz to 1.25 MHz with CKI at 20.0 MHz.

The contents of the SIO register may be accessed through any of the memory access instructions. Data waiting to be transmitted in the SIO register is clocked out on the falling edge of the SK clock. Serial data on the SI pin is clocked in on the rising edge of the SK clock.

MICROWIRE/PLUS Application

Figure 25 illustrates a MICROWIRE/PLUS arrangement for an automotive application. The microcontroller-based system could be used to interface to an instrument cluster and various parts of the automobile. The diagram shows two HPC46064 microcontrollers interconnected to other MICROWIRE peripherals. HPC46064 #1 is set up as the master and initiates all data transfers. HPC46064 #2 is set up as a slave answering to the master.

The master microcontroller interfaces the operator with the system and could also manage the instrument cluster in an automotive application. Information is visually presented to the operator by means of an LCD display controlled by the COP472 display driver. The data to be displayed is sent serially to the COP472 over the MICROWIRE/PLUS link. Data such as accumulated mileage could be stored and retrieved from the EEPROM COP494. The slave HPC46064 could be used as a fuel injection processor and generate timing signals required to operate the fuel valves. The master processor could be used to periodically send updated values to the slave via the MICROWIRE/PLUS link. To speed up the response, chip select logic is implemented by connecting an output from the master to the external interrupt input on the slave.

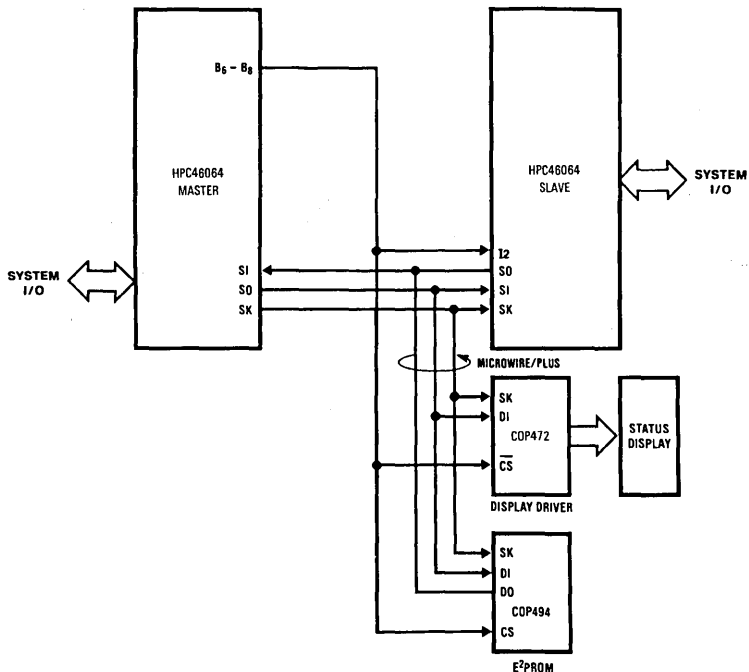

FIGURE 25. MICROWIRE/PLUS Application

TL/DD/11372-23

HPC46064 UART

The HPC46064 contains a software programmable UART. The UART (see Figure 26) consists of a transmit shift register, a receiver shift register and five addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR) and a UART interrupt and clock source register (ENUI). The ENUI register contains flags for transmit and receive functions; this register also determines the length of the data frame (8 or 9 bits) and the value of the ninth bit in transmission. The ENUR register flags framing and data overrun errors while the UART is receiving. Other functions of the ENUR register include saving the ninth bit received in the data frame and enabling or disabling the UART's Wake-up Mode of operation. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts.

The baud rate clock for the Receiver and Transmitter can be selected for either an internal or external source using two bits in the ENUI register. The internal baud rate is programmed by the DIVBY register. The baud rate may be selected from a range of 8 Hz to 128 kHz in binary steps or T3 underflow. By selecting a 9.83 MHz crystal, all standard baud rates from 75 baud to 38.4 kBaud can be generated. The external baud clock source comes from the CKX pin. The Transmitter and Receiver can be run at different rates by selecting one to operate from the internal clock and the other from an external source.

The HPC46064 UART supports two data formats. The first format for data transmission consists of one start bit, eight data bits and one or two stop bits. The second data format for transmission consists of one start bit, nine data bits, and one or two stop bits. Receiving formats differ from transmission only in that the Receiver always requires only one stop bit in a data frame.

UART Wake-up Mode

The HPC46064 UART features a Wake-up Mode of operation. This mode of operation enables the HPC46064 to be networked with other processors. Typically in such environments, the messages consist of addresses and actual data. Addresses are specified by having the ninth bit in the data frame set to 1. Data in the message is specified by having the ninth bit in the data frame reset to 0.

The UART monitors the communication stream looking for addresses. When the data word with the ninth bit set is received, the UART signals the HPC46064 with an interrupt. The processor then examines the content of the receiver buffer to decide whether it has been addressed and whether to accept subsequent data.

FIGURE 26. UART Block Diagram

TL/DD/11372-24

Universal Peripheral Interface

The Universal Peripheral Interface (UPI) allows the HPC46064 to be used as an intelligent peripheral to another processor. The UPI could thus be used to tightly link two HPC46064's and set up systems with very high data exchange rates. Another area of application could be where an HPC46064 is programmed as an intelligent peripheral to a host system such as the Series 32000[®] microprocessor. *Figure 27* illustrates how an HPC46064 could be used as an intelligent peripheral for a Series 32000-based application. The interface consists of a Data Bus (port A), a Read Strobe (\overline{URD}), a Write Strobe (\overline{UWR}), a Read Ready Line (\overline{RDRDY}),

a Write Ready Line (\overline{WRRDY}) and one Address Input (UA0). The data bus can be either eight or sixteen bits wide.

The \overline{URD} and \overline{UWR} inputs may be used to interrupt the HPC46064. The \overline{RDRDY} and \overline{WRRDY} outputs may be used to interrupt the host processor.

The UPI contains an Input Buffer (IBUF), an Output Buffer (OBUF) and a Control Register (UPIC). In the UPI mode, port A on the HPC46064 is the data bus. UPI can only be used if the HPC46064 is in the Single-Chip mode.

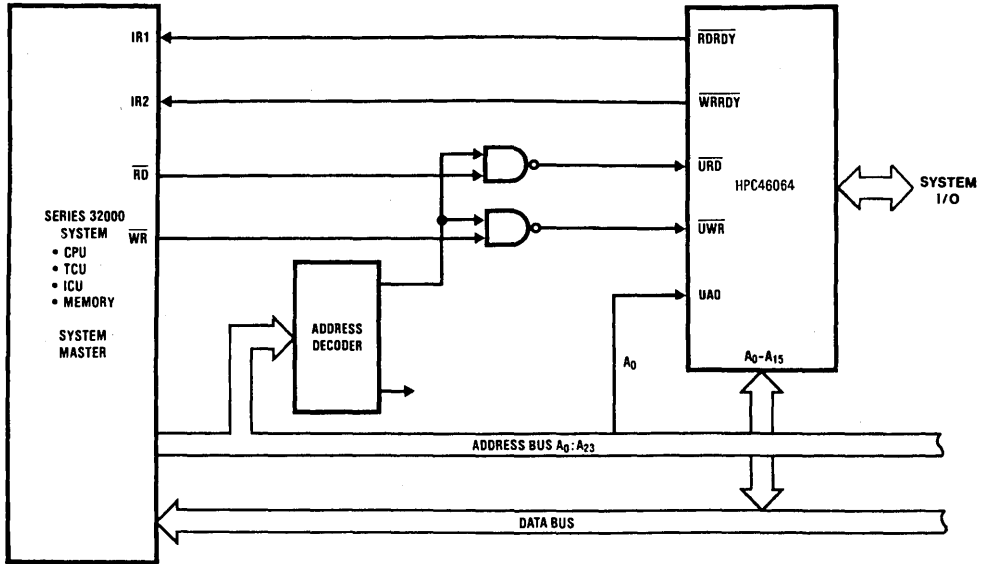

FIGURE 27. HPC46064 as a Peripheral: (UPI Interface to Series 32000 Application)

TL/DD/11372-25

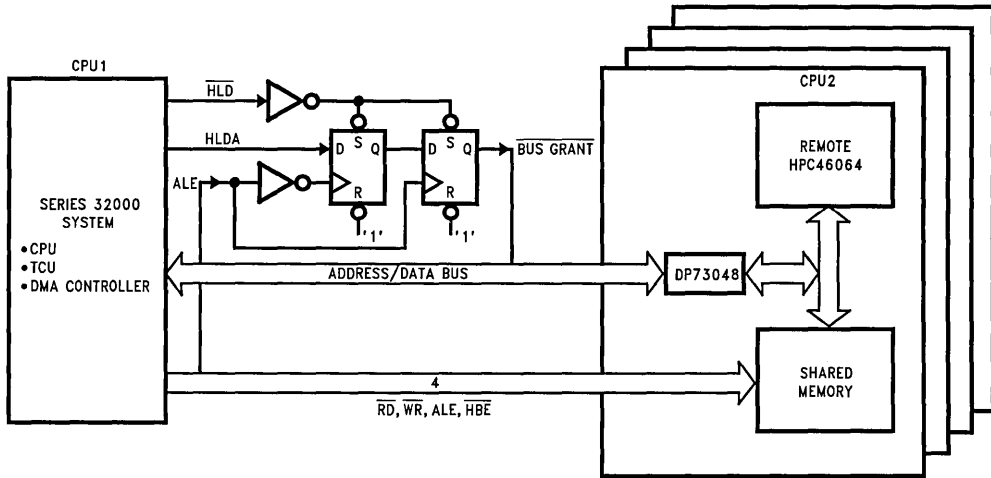

Shared Memory Support

Shared memory access provides a rapid technique to exchange data. It is effective when data is moved from a peripheral to memory or when data is moved between blocks of memory. A related area where shared memory access proves effective is in multiprocessing applications where two CPUs share a common memory block. The HPC46064 supports shared memory access with two pins. The pins are the RDY/HLD input pin and the HLD \bar{A} output pin. The user can software select either the Hold or Ready function by the state of a control bit. The HLD \bar{A} output is multiplexed onto port B.

The host uses DMA to interface with the HPC46064. The host initiates a data transfer by activating the HLD input of

the HPC46064. In response, the HPC46064 places its system bus in a TRI-STATE Mode, freeing it for use by the host. The host waits for the acknowledge signal (HLD \bar{A}) from the HPC46064 indicating that the system bus is free. On receiving the acknowledge, the host can rapidly transfer data into, or out of, the shared memory by using a conventional DMA controller. Upon completion of the message transfer, the host removes the HOLD request and the HPC46064 resumes normal operations.

To insure proper operation, the interface logic shown is recommended as the means for enabling and disabling the user's bus. *Figure 28* illustrates an application of the shared memory interface between the HPC46064 and a Series 32000 system.

TL/DD/11372-26

FIGURE 28. Shared Memory Application: HPC46064 Interface to Series 32000 System

Memory

The HPC46064 has been designed to offer flexibility in memory usage. A total address space of 64 Kbytes can be addressed with 16 Kbytes of ROM and 512 bytes of RAM available on the chip itself. The ROM may contain program instructions, constants or data. The ROM and RAM share the same address space allowing instructions to be executed out of RAM.

Program memory addressing is accomplished by the 16-bit program counter on a byte basis. Memory can be addressed

directly by instructions or indirectly through the B, X and SP registers. Memory can be addressed as words or bytes. Words are always addressed on even-byte boundaries. The HPC46064 uses memory-mapped organization to support registers, I/O and on-chip peripheral functions.

The HPC46064 memory address space extends to 64 Kbytes and registers and I/O are mapped as shown in Table IV.

Design Considerations

Designs using the HPC family of 16-bit high speed CMOS microcontrollers need to follow some general guidelines on usage and board layout.

Floating inputs are a frequently overlooked problem. CMOS inputs have extremely high impedance and, if left open, can float to any voltage. You should thus tie unused inputs to V_{CC} or ground, either through a resistor or directly. Unlike the inputs, unused output should be left floating to allow the output to switch without drawing any DC current.

To reduce voltage transients, keep the supply line's parasitic inductances as low as possible by reducing trace lengths, using wide traces, ground planes, and by decoupling the supply with bypass capacitors. In order to prevent additional voltage spiking, this local bypass capacitor must exhibit low inductive reactance. You should therefore use high frequency ceramic capacitors and place them very near the IC to minimize wiring inductance.

- Keep V_{CC} bus routing short. When using double sided or multilayer circuit boards, use ground plane techniques.
- Keep ground lines short, and on PC boards make them as wide as possible, even if trace width varies. Use separate ground traces to supply high current devices such as relay and transmission line drivers.
- In systems mixing linear and logic functions and where supply noise is critical to the analog components' performance, provide separate supply buses or even separate supplies.
- If you use local regulators, bypass their inputs with a tantalum capacitor of at least $1\ \mu\text{F}$ and bypass their outputs with a $10\ \mu\text{F}$ to $50\ \mu\text{F}$ tantalum or aluminum electrolytic capacitor.
- If the system uses a centralized regulated power supply, use a $10\ \mu\text{F}$ to $20\ \mu\text{F}$ tantalum electrolytic capacitor or a $50\ \mu\text{F}$ to $100\ \mu\text{F}$ aluminum electrolytic capacitor to decouple the V_{CC} bus connected to the circuit board.
- Provide localized decoupling. For random logic, a rule of thumb dictates approximately $10\ \text{nF}$ (spaced within $12\ \text{cm}$) per every two to five packages, and $100\ \text{nF}$ for every 10 packages. You can group these capacitances, but it's more effective to distribute them among the ICs. If the design has a fair amount of synchronous logic with outputs that tend to switch simultaneously, additional decoupling might be advisable. Octal flip-flop and buffers in bus-oriented circuits might also require more decoupling. Note that wire-wrapped circuits can require more decoupling than ground plane or multilayer PC boards.

A recommended crystal oscillator circuit to be used with the HPC is shown in Figure 29. See Table V for recommended component values. The recommended values given in Table V have yielded consistent results and are made to match a crystal with a $20\ \text{pF}$ load capacitance, with some small allowance for layout capacitance.

A recommended layout for the oscillator network should be as close to the processor as physically possible, entirely within "1" distance. This is to reduce lead inductance from long PC traces, as well as interference from other components, and reduce trace capacitance. The layout contains a large ground plane either on the top or bottom surface of the board to provide signal shielding, and a convenient location to ground both the HPC and the case of the crystal.

It is very critical to have an extremely clean power supply for the HPC crystal oscillator. Ideally one would like a V_{CC} and ground plane that provide low inductance power lines to the

chip. The power planes in the PC board should be decoupled with three decoupling capacitors as close to the chip as possible. A $1.0\ \mu\text{F}$, a $0.1\ \mu\text{F}$, and a $0.001\ \mu\text{F}$ dipped mica or ceramic cap mounted as close to the HPC as is physically possible on the board, using the shortest leads, or surface mount components. This should provide a stable power supply, and noiseless ground plane which will vastly improve the performance of the crystal oscillator network.

FIGURE 29. Recommended Crystal Circuit

HPC46064 CPU

The HPC46064 CPU has a 16-bit ALU and six 16-bit registers:

Arithmetic Logic Unit (ALU)

The ALU is 16 bits wide and can do 16-bit add, subtract and shift or logic AND, OR and exclusive OR in one timing cycle. The ALU can also output the carry bit to a 1-bit C register.

HPC46064 CPU (Continued)

Accumulator (A) Register

The 16-bit A register is the source and destination register for most I/O, arithmetic, logic and data memory access operations.

Address (B and X) Registers

The 16-bit B and X registers can be used for indirect addressing. They can automatically count up or down to sequence through data memory.

Boundary (K) Register

The 16-bit K register is used to set limits in repetitive loops of code as register B sequences through data memory.

Stack Pointer (SP) Register

The 16-bit SP register is the pointer that addresses the stack. The SP register is incremented by two for each push or call and decremented by two for each pop or return. The stack can be placed anywhere in user memory and be as deep as the available memory permits.

Program (PC) Register

The 16-bit PC register addresses program memory.

Addressing Modes

ADDRESSING MODES—ACCUMULATOR AS DESTINATION

Register Indirect

This is the "normal" mode of addressing for the HPC46064 (instructions are single-byte). The operand is the memory addressed by the B register (or X register for some instructions).

Direct

The instruction contains an 8-bit or 16-bit address field that directly points to the memory for the operand.

Indirect

The instruction contains an 8-bit address field. The contents of the WORD addressed points to the memory for the operand.

Indexed

The instruction contains an 8-bit address field and an 8- or 16-bit displacement field. The contents of the WORD addressed is added to the displacement to get the address of the operand.

Immediate

The instruction contains an 8-bit or 16-bit immediate field that is used as the operand.

Register Indirect (Auto Increment and Decrement)

The operand is the memory addressed by the X register. This mode automatically increments or decrements the X register (by 1 for bytes and by 2 for words).

Register Indirect (Auto Increment and Decrement) with Conditional Skip

The operand is the memory addressed by the B register. This mode automatically increments or decrements the B register (by 1 for bytes and by 2 for words). The B register is then compared with the K register. A skip condition is generated if B goes past K.

ADDRESSING MODES—DIRECT MEMORY AS DESTINATION

Direct Memory to Direct Memory

The instruction contains two 8- or 16-bit address fields. One field directly points to the source operand and the other field directly points to the destination operand.

Immediate to Direct Memory

The instruction contains an 8- or 16-bit address field and an 8- or 16-bit immediate field. The immediate field is the operand and the direct field is the destination.

Double Register Indirect Using the B and X Registers

Used only with Reset, Set and IF bit instructions; a specific bit within the 64 kbyte address range is addressed using the B and X registers. The address of a byte of memory is formed by adding the contents of the B register to the most significant 13 bits of the X register. The specific bit to be modified or tested within the byte of memory is selected using the least significant 3 bits of register X.

Code Efficiency

One of the most important criteria of a single chip microcontroller is code efficiency. The more efficient the code, the more features that can be put on a chip. The memory size on a chip is fixed so if code is not efficient, features may have to be sacrificed or the programmer may have to buy a larger, more expensive version of the chip.

The HPC46064 has been designed to be extremely code-efficient. The HPC46064 looks very good in all the standard coding benchmarks; however, it is not realistic to rely only on benchmarks. Many large jobs have been programmed onto the HPC46064, and the code savings over other popular microcontrollers has been considerable.

Reasons for this saving of code include the following:

SINGLE BYTE INSTRUCTIONS

The majority of instructions on the HPC46064 are single-byte. There are two especially code-saving instructions: JP is a 1-byte jump. True, it can only jump within a range of plus or minus 32, but many loops and decisions are often within a small range of program memory. Most other micros need 2-byte instructions for any short jumps.

JSRP is a 1-byte call subroutine. The user makes a table of the 16 most frequently called subroutines and these calls will only take one byte. Most other micros require two and even three bytes to call a subroutine. The user does not have to decide which subroutine addresses to put into this table; the assembler can give this information.

EFFICIENT SUBROUTINE CALLS

The 2-byte JSR instructions can call any subroutine within plus or minus 1k of program memory.

MULTIFUNCTION INSTRUCTIONS FOR DATA MOVEMENT AND PROGRAM LOOPING

The HPC46064 has single-byte instructions that perform multiple tasks. For example, the XS instruction will do the following:

1. Exchange A and memory pointed to by the B register
2. Increment or decrement the B register
3. Compare the B register to the K register
4. Generate a conditional skip if B has passed K

The value of this multipurpose instruction becomes evident when looping through sequential areas of memory and exiting when the loop is finished.

BIT MANIPULATION INSTRUCTIONS

Any bit of memory, I/O or registers can be set, reset or tested by the single byte bit instructions. The bits can be addressed directly or indirectly. Since all registers and I/O are mapped into the memory, it is very easy to manipulate specific bits to do efficient control.

DECIMAL ADD AND SUBTRACT

This instruction is needed to interface with the decimal user world.

It can handle both 16-bit words and 8-bit bytes.

The 16-bit capability saves code since many variables can be stored as one piece of data and the programmer does not have to break his data into two bytes. Many applications store most data in 4-digit variables. The HPC46064 supplies 8-bit byte capability for 2-digit variables and literal variables.

MULTIPLY AND DIVIDE INSTRUCTIONS

The HPC46064 has 16-bit multiply, 16-bit by 16-bit divide, and 32-bit by 16-bit divide instructions. This saves both code and time. Multiply and divide can use immediate data or data from memory. The ability to multiply and divide by immediate data saves code since this function is often needed for scaling, base conversion, computing indexes of arrays, etc.

Development Support

HPC Microcontroller Development System

The HPC microcontroller development system is an in-system emulator (ISE) designed to support the entire family of HPC Microcontrollers. The complete package of hardware and software tools combined with a host system provides a powerful system for design, development and debug of HPC based designs. Software tools are available for IBM® PC-AT® (MS-DOS, PC-DOS) and for Unix based multi-user Sun® Sparcstation (SunOST™).

The stand alone units comes complete with a power supply and external emulation POD. This unit can be connected to various host systems through an RS-232 link. The software package includes an ANSI compatible C-Compiler, Linker, Assembler and librarian package. Source symbolic debug capability is provided through a user friendly MS-windows 3.0 interface for IBM PC-AT environment and through a line debugger under Sunview for Sun Sparcstations.

The ISE provides fully transparent in-system emulation at speeds up to 20 MHz 1 waitstate. A 2k word (48-bit wide) trace buffer gives trace trigger and non-intrusive monitoring of the system. External triggering is also available through an external logic interface socket on the POD. Direct EPROM programming can be done through the use of externally mounted EPROM socket. Form-Fit-Function emulator programming is supported by a programming board included with the system. Comprehensive on-line help and diagnostics features reduce user's design and debug time. 8 hardware breakpoints (Address/range), 64 Kbytes of user memory, and break on external events are some of the other features offered.

Hewlett Packard model HP64775 Emulator/Analyzer providing in-system emulation for up to 30 MHz 1 waitstate is also available. Contact your local sales office for technical details and support.

How to Order

To order a complete development package, select the section for the microcontroller to be developed and order the parts listed.

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. Dial-A-Helper is an Electronic Bulletin Board Information system and additionally, provides the capability of remotely accessing the development system at a customer site.

INFORMATION SYSTEM

The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION

(electronic mail) for communications to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities can be found. The minimum requirement for accessing Dial-A-Helper is a Hayes compatible modem.

If the user has a PC with a communications package then files from the FILE SECTION can be down loaded to disk for later use.

Order P/N: MDS-DIAL-A-HLP

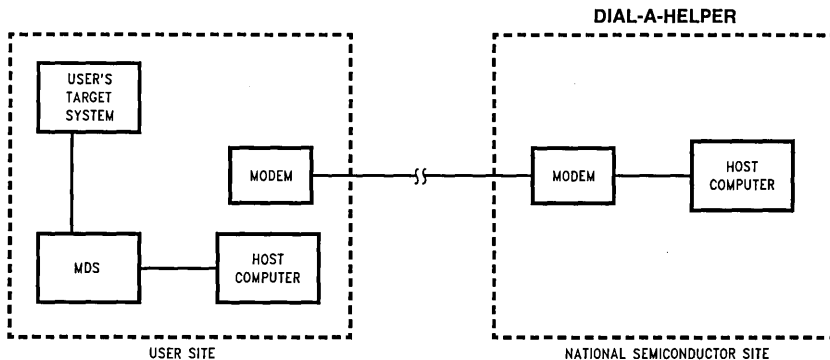

Information System Package Contains:
Dial-A-Helper Users Manual
Public Domain Communications Software

Development Support (Continued)

FACTORY APPLICATIONS SUPPORT

Dial-A-Helper also provides immediate factory applications support. If a user is having difficulty in operating a development system, he can leave messages on our electronic bulletin board, which we will respond to.

Voice: (408) 721-5582
 Modem: (408) 739-1162
 Baud: 300 or 1200 baud
 Set-Up: Length: 8-Bit
 Parity: None
 Stop Bit: 1
 Operation: 24 Hrs. 7 Days

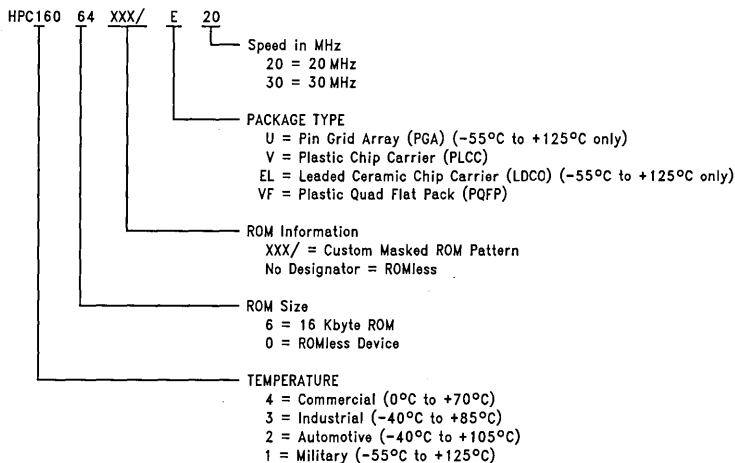

TL/DD/11372-35

Part Selection

The HPC family includes devices with many different options and configurations to meet various application needs. The number HPC46064 has been generically used throughout this datasheet to represent the whole family of parts. The following chart explains how to order various options available when ordering HPC family members.

Note: All options may not currently be available.

TL/DD/11372-36

FIGURE 8. HPC Family Part Numbering Scheme

Examples

- HPC46004V20 — ROMless, Commercial temperature (0°C to 70°C), PLCC
- HPC16064XXX/U20— 16k masked ROM, Military temperature (-55°C to 125°C), PGA
- HPC26004XXX/V20— ROMless, Automotive temperature (-40°C to +105°C), PLCC

HPC36400E/HPC46400E

High-Performance Communications microController

General Description

The HPC46400E is an upgraded HPC16400. Features have been added to support V.120, the 8-bit mode has been enhanced to support all instructions, and the UART has been changed to provide more flexibility and power. The HPC46400E is fully upward compatible with the HPC16400.

The HPC46400E has 4 functional blocks to support a wide range of communication application—2 HDLC channels, 4 channel DMA controller to facilitate data flow for the HDLC channels, programmable serial interface and UART.

The serial interface decoder allows the 2 HDLC channels to be used with devices using interchip serial link for point-to-point and multipoint data exchanges. The decoder generates enable signals for the HDLC channels allowing multiplexed D and B channel data to be accessed.

The HDLC channels manage the link by providing sequencing using the HDLC framing along with error control based upon a cyclic redundancy check (CRC). Multiple address recognition modes, and both bit and byte modes of operation are supported.

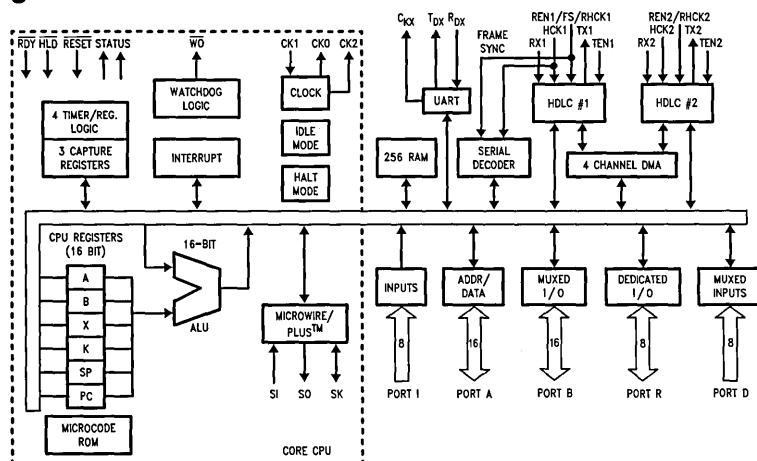

The HPC36400E and HPC46400E are available in 68-pin PLCC and LDCC packages.

Features

- HPCTM family—core features:
 - 16-bit data bus, ALU, and registers
 - 64 kbytes of external memory addressing
 - FAST!—20.0 MHz system clock
 - Four 16-bit timer/counters with WATCHDOG™ logic
 - MICROWIRE/PLUS™ serial I/O interface
 - CMOS—low power with two power save modes

- Two full duplex HDLC channels
 - Optimized for ISDN, X.25, V.120, and LAPD applications
 - Programmable frame address recognition
 - Up to 4.65 Mbps serial data rate
 - Built in diagnostics
 - Synchronous bypass mode
 - Optional CRC generation
 - Received CRC bytes can be read by the CPU
- Four channel DMA controller
- 8- or 16-bit external data bus
- UART
 - Full duplex
 - 7, 8, or 9 data bits
 - Even, odd, mark, space or no parity
 - 7/8, 1 or 2 stop bit generation
 - Accurate internal baud rate generation up to 625k baud without penalty of using expensive crystal
 - Synchronous and asynchronous modes of operation
- Serial Decoder
 - Supports 6 popular time division multiplexing protocols for inter-chip communications
 - Optional rate adaptation of 64 kbit/s data rate to 56 kbit/s
- Over 1/2 Mbyte of extended addressing
- Easy interface to National's DASL, 'U' and 'S' transceivers—TP3400, TP3410 and TP3420
- Commercial (0°C to +70°C) and industrial (-40°C to +85°C)

Block Diagram

TL/DD/10422-1

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Total Allowable Source or Sink Current	100 mA
Storage Temperature Range	-65°C to +150°C
Lead Temperature (Soldering, 10 sec.)	300°C

V_{CC} with Respect to GND -0.5V to 7.0V
 All Other Pins ($V_{CC} + 0.5$)V to (GND - 0.5)V
 Note: Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.

DC Electrical Characteristics $V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 0^\circ C$ to $+70^\circ C$ for HPC46400E, $-40^\circ C$ to $+85^\circ C$ for HPC36400E

Symbol	Parameter	Test Conditions	Min	Max	Units
I_{CC1}	Supply Current	$V_{CC} = 5.5V, f_{in} = 20.0$ MHz (Note 1)		70	mA
		$V_{CC} = 5.5V, f_{in} = 2.0$ MHz (Note 1)		10	mA
I_{CC2}	IDLE Mode Current	$V_{CC} = 5.5V, f_{in} = 20.0$ MHz (Note 1)		10	mA
		$V_{CC} = 5.5V, f_{in} = 2.0$ MHz (Note 1)		2	mA
I_{CC3}	HALT Mode Current	$V_{CC} = 5.5V, f_{in} = 0$ kHz (Note 1)		500	μA
		$V_{CC} = 2.5V, f_{in} = 0$ kHz (Note 1)		150	μA
INPUT VOLTAGE LEVELS—SCHMITT TRIGGERED: RESET, CKI, WO, D0, I1, I2, I3					
V_{IH1}	Logic High		$0.9 V_{CC}$		V
V_{IL1}	Logic Low			$0.1 V_{CC}$	V
INPUT VOLTAGE LEVELS—PORT A					
V_{IH2}	Logic High		2.0		V
V_{IL2}	Logic Low			0.8	V
INPUT VOLTAGE LEVELS—ALL OTHERS					
V_{IH3}	Logic High		$0.7 V_{CC}$		V
V_{IL3}	Logic Low			$0.2 V_{CC}$	V
I_{LI}	Input Leakage Current	(Note 2)		± 1	μA
C_I	Input Capacitance	(Note 3)		10	pF
C_{IO}	I/O Capacitance	(Note 3)		20	pF
OUTPUT VOLTAGE LEVELS					
V_{OH1}	Logic High (CMOS)	$I_{OH} = -10 \mu A$ (Note 3)	$V_{CC} - 0.1$		V
V_{OL1}	Logic Low (CMOS)	$I_{OH} = 10 \mu A$ (Note 3)		0.1	V
V_{OH2}	Port A/B Drive, CK2 (A ₀ -A ₁₅ , B ₁₀ , B ₁₁ , B ₁₂ , B ₁₅)	$I_{OH} = -1$ mA	2.4		V
		$I_{OL} = 3$ mA		0.4	V
V_{OH3}	Other Port Pin Drive, WO (open drain) (B ₀ -B ₉ , B ₁₃ , B ₁₄ , R ₀ -R ₇ , D ₅ , D ₇)	$I_{OH} = -1.6$ mA (except WO)	2.4		V
		$I_{OL} = 0.5$ mA		0.4	V
V_{OH4}	ST1 and ST2 Drive	$I_{OH} = -6$ mA	2.4		V
		$I_{OL} = 1.6$ mA (Note 4)		0.4	V
V_{RAM}	RAM Keep-Alive Voltage	(Note 5)	2.5		V
I_{OZ}	TRI-STATE Leakage Current			± 5	μA

Note 1: I_{CC1} , I_{CC2} , I_{CC3} measured with no external drive (I_{OH} and $I_{OL} = 0$, I_{IH} and $I_{IL} = 0$). I_{CC1} is measured with RESET = V_{SS} . I_{CC3} is measured with NMI = V_{CC} . CKI driven to V_{IH1} and V_{IL1} with rise and fall times less than 10 ns.

Note 2: RDY/HLD and RDY/I4 pins have internal pullups and meet this spec only at $V_{IN} = V_{CC}$.

Note 3: These parameters are guaranteed by design and are not tested.

Note 4: ST2 drive will not meet this spec under condition of RESET pin = low.

Note 5: Test duration is 100 ms.

AC Electrical Characteristics

(see Notes 1 and 4 and Figures 1 thru 5), $V_{CC} = 5V \pm 10\%$, $T_A = 0^\circ\text{C}$ to $+70^\circ\text{C}$ for HPC46400E, -40°C to $+85^\circ\text{C}$ for HPC36400E

	Symbol and Formula	Parameter and Notes	Min	Max	Units	Note
Clocks	f_C	CKI Operating Frequency	2	20	MHz	
	$t_{C1} = 1/f_C$	CKI Period	50	500	ns	
	t_{C1R}	CKI Rise Time		7	ns	(Note 1)
	t_{C1F}	CKI Fall Time		7	ns	(Note 1)
	$100 t_{C1H}/t_{C1}$	CKI Duty Cycle	45	55	%	(Note 1)
	$t_C = 2/t_C$	CPU or DMA Timing Cycle	100		ns	
	$t_{WAIT} = t_C$	CPU or DMA Wait State Period	100		ns	
	t_{DC1C2R}	Delay of CK2 Rising Edge after CK1 Falling Edge	0	55	ns	(Note 2)
	t_{DC1C2F}	Delay of CK2 Falling Edge after CK1 Falling Edge	0	55	ns	(Note 2)
Timers	$f_U = f_C/8$	External UART Clock Input Frequency		2.5	MHz	
	$f_{MW} = f_C/19$	External MICROWIRE/PLUS Clock Input Frequency		1.052	MHz	
	$t_{HCK} = 4t_{C1} + 14$	HDL Clock Input Period	214		ns	
MICROWIRE/ PLUS	$f_{XIN} = f_C/19$	External Timer Input Frequency		1052	kHz	
	$t_{XIN} = t_C$	Pulse Width for Timer Inputs	100		ns	
	$f_{XOUT} = f_C/16$	Timer Output Frequency		1.25	MHz	
External Hold	t_{UWS}	MICROWIRE Setup Time — Master — Slave	100 20		ns ns	
	t_{UWH}	MICROWIRE Hold Time — Master — Slave	20 50		ns ns	
	t_{UWV}	MICROWIRE Output Valid Time — Master — Slave		50 150	ns ns	
External Hold	$t_{SALE} = 3/4 t_C + 40$	\overline{HLD} Falling Edge before \overline{ALE} Rising Edge	115		ns	(Note 3)
	$t_{HWP} = 3/4 t_C + 35$	\overline{HLD} Pulse Width	110		ns	
	$t_{HAE} = 3/4 t_C + 100$	\overline{HLDA} Falling Edge after \overline{HLD} Falling Edge		175	ns	
	$t_{HAD} = 5/4 t_C + 85$	\overline{HLDA} Rising Edge after \overline{HLD} Rising Edge		210	ns	
	t_{BF}	Bus Float after \overline{HLDA} Falling Edge		66	ns	
	$t_{BE} = t_C - 66$	Bus Enable after \overline{HLDA} Rising Edge	34		ns	

Note 1: These AC characteristics are guaranteed with external clock drive on CKI having 50% duty cycle and with less than 15 pF load on CKO. Spec'd t_{C1R} , t_{C1F} , and CKI duty cycle limits are not tested but are guaranteed functional by design.

Note 2: Do not design with this parameter unless CKI is driven with an active signal meeting T_{C1R} and T_{C1F} specs. When using a passive crystal circuit, its stability is not guaranteed if either CKI or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{HLD} falling edge occurring at the latest time it can be accepted during the present CPU or DMA cycle being executed. If \overline{HLD} falling edge occurs later, t_{HAE} as long as $(3 t_C + 4 WS + 72 t_C + 100)$ may occur depending on the following CPU instruction or DMA cycle, its wait states and ready input.

Note 4: $WS (t_{WAIT}) \times$ (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $f_C = 20$ MHz, with one wait state preprogrammed. These values are guaranteed with AC loading of 100 pF on Port A, 50 pF on CK2, 80 pF on other outputs, and DC loading of the pin's DC spec non CMOS I_{OL} or I_{OH} .

AC Electrical Characteristics (Continued)

CPU and DMA Timing (see Notes 1 and 4 and Figures 2, 4, 6, 7, 8, and 9), $V_{CC} = 5V \pm 10\%$, $T_A = 0^\circ\text{C}$ to $+70^\circ\text{C}$ for HPC46400E, -40°C to $+85^\circ\text{C}$ for HPC36400E

	Symbol	Formula	Cycle	Parameter	Min	Max	Units	Note
Address Cycles	t_{1ALR}		CPU DMA	Delay of ALE Rising Edge after CKI Rising Edge Delay of ALE Rising Edge after CKI Falling Edge	0 0	35 35	ns ns	(Note 2) (Note 2)
	t_{1ALF}		CPU DMA	Delay of ALE Falling Edge after CKI Rising Edge Delay of ALE Falling Edge after CKI Falling Edge	0 0	35 35	ns ns	(Note 2) (Note 2)
	t_{2ALR}	$\frac{1}{4} t_C + 20$	CPU	ALE Rising Edge after CK2 Rising Edge		45	ns	
	t_{2ALF}	$\frac{1}{4} t_C + 20$	CPU	ALE Falling Edge after CK2 Falling Edge		45	ns	
	t_{LL}	$\frac{1}{2} t_C - 9$		ALE Pulse Width	41		ns	
	t_{ST}	$\frac{1}{4} t_C - 20$		Setup of Address Valid before ALE Falling Edge	5		ns	(Note 3)
	t_{VP}	$\frac{1}{4} t_C - 10$ $\frac{1}{2} t_C - 10$	CPU DMA	Hold of Address Valid after ALE Falling Edge	15 40		ns ns	
Read Cycles	t_{ARR}	$\frac{1}{2} t_C - 20$		ALE Falling Edge to \overline{RD} Falling Edge	30		ns	
	t_{ACC}	$t_C + WS - 55$ $\frac{5}{4} t_C + WS - 75$	CPU DMA	Data Input Valid after Address Output Valid		145 150	ns ns	
	t_{RD}	$\frac{1}{4} t_C + WS - 35$ $\frac{1}{2} t_C + WS$	CPU DMA	Data Input Valid after \overline{RD} Falling Edge		90 115	ns ns	
	t_{RW}	$\frac{1}{4} t_C + WS - 15$ $\frac{1}{2} t_C + WS - 15$	CPU DMA	\overline{RD} Pulse Width	110 135		ns ns	
	t_{DR}	$t_C - 15$ $\frac{3}{4} t_C - 15$	CPU DMA	Hold of Data Input Valid after \overline{RD} Rising Edge	0 0	85 60	ns ns	(Note 5) (Note 5)
	t_{RDA}	$t_C - 5$ $\frac{3}{4} t_C - 10$	CPU DMA	Bus Enable after \overline{RD} Rising Edge	95 65		ns ns	(Note 5) (Note 5)
Write Cycles	t_{ARW}	$\frac{1}{2} t_C - 20$		ALE Falling Edge to \overline{WR} Falling Edge	30		ns	
	t_{WW}	$\frac{3}{4} t_C + WS - 15$ $\frac{1}{2} t_C + WS - 15$	CPU DMA	\overline{WR} Pulse Width	160 135		ns ns	
	t_V	$\frac{1}{2} t_C + WS - 40$ $\frac{1}{2} t_C + WS - 50$	CPU DMA	Data Output Valid before \overline{WR} Rising Edge	110 100		ns ns	
	t_{HW}	$\frac{1}{4} t_C - 10$		Hold of Data Output Valid after \overline{WR} Rising Edge	15		ns	
Ready Input	t_{RDYS}			\overline{RDY} Falling Edge before CK2 Rising Edge	45		ns	
	t_{RDYH}			\overline{RDY} Rising Edge after CK2 Rising Edge	0		ns	
	t_{RDYV}	$WS - \frac{1}{4} t_C - 47$ $t_C - 47$	CPU DMA	\overline{RDY} Falling Edge after \overline{RD} or \overline{WR} Falling Edge		28 53	ns ns	(Note 6)

Note 1: These AC characteristics are guaranteed with external clock drive on CKI having 50% duty cycle and with less than 15 pF load on CKO. Spec'd t_{C1R} , t_{C1F} , and CKI duty cycle limits are not tested but are guaranteed functional by design.

Note 2: Do not design with this parameter unless CKI is driven with an active signal meeting T_{C1R} and T_{C1F} specs. When using a passive crystal circuit, its stability is not guaranteed if either CKI or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: Setup of HBE valid before ALE falling edge is 0 ns minimum.

Note 4: WS (t_{WAIT}) \times (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $f_C = 20$ MHz, with one wait state preprogrammed. These values are guaranteed with AC loading of 100 pF on Port A, 50 pF on CK2, 80 pF on other outputs, and DC loading of the pin's DC spec non CMOS I_{OL} or I_{OH} .

Note 5: Formula has $\frac{1}{4} t_C$ for CPU read followed by DMA $\frac{1}{4} t_C$ for DMA read followed by CPU.

Note 6: In HPC in-circuit emulators the t_{RDYV} formulas are $WS - \frac{1}{4} t_C - 57$ and $t_C - 57$ yielding minimums of 18 ns and 43 ns for CPU and DMA cycles, respectively.

Timing Waveforms

FIGURE 1. CKI Input Signal

Note: AC testing inputs are driven at V_{IH} for a logic "1" and V_{IL} for a logic "0". Output timing measurements are made at 2.0V for a logic "1" hold or rising edge and at 0.8V for a logic "0" hold or falling edge.

Pin Descriptions

I/O PORTS

Port A is a 16-bit multiplexed address/data bus used for accessing external program and data memory. Four associated bus control signals are available on port B. The Address Latch Enable (ALE) signal is used to provide timing to demultiplex the bus. Reading from and writing to external memory are signalled by \overline{RD} and \overline{WR} respectively. External memory can be addressed as either bytes or words with the decoding controlled by two lines, Bus High Byte enable (\overline{HBE}) and Address/Data Line 0 (A0).

Port B is a 16-bit port, with 12 bits of bidirectional I/O. Pins B10, B11, B12 and B15 are the control bus signals for the address/data bus. Port B may also be configured via a function register BFUN to individually allow each bidirectional I/O pin to have an alternate function.

B0:	TDX	UART Data Output
B1:	CFLG1	Closing Flag Output for HDLC #1 Transmitter
B2:	CKX	UART Clock (Input or Output)
B3:	T2IO	Timer2 I/O Pin
B4:	T3IO	Timer3 I/O Pin
B5:	SO	MICROWIRE/PLUS Output
B6:	SK	MICROWIRE/PLUS Clock (Input or Output)
B7:	\overline{HLDA}	Hold Acknowledge Output
B8:	TS0	Timer Synchronous Output
B9:	TS1	Timer Synchronous Output
B10:	ALE	Address Latch Enable Output for Address/Data Bus
B11:	\overline{WR}	Address/Data Bus Write Output
B12:	\overline{HBE}	High Byte Enable Output for Address/Data Bus; also 8-Bit Mode Strap Input on Reset.
B13:	TS2	Timer Synchronous Output
B14:	TS3	Timer Synchronous Output
B15:	\overline{RD}	Address/Data Bus Read Output

When operating in the extended memory addressing mode, four bits of port B can be used as follows—

B8:	BS0	Memory bank switch output 0 (LSB)
B9:	BS1	Memory bank switch output 1

B13:	BS2	Memory bank switch output 2
B14:	BS3	Memory bank switch output 3 (MSB)

Port I is an 8-bit input port that can be read as general purpose inputs and can also be used for the following functions:

I0:	HCK2	HLDC #2 Clock Input
I1:	NMI	Nonmaskable Interrupt Input
I2:	INT2	Maskable Interrupt/Input Capture
I3:	INT3	Maskable Interrupt/Input Capture
I4:	INT4/RDY	Maskable Interrupt/Input Capture/Ready Input
I5:	SI	MICROWIRE/PLUS Data Input
I6:	RDX	UART Data Input
I7:	HCK1	HDLC #1 Clock and Serial Decoder Clock Input

Port D is an 8-bit input port that can be read as general purpose inputs and can also be used for the following functions:

D0:	REN1/FS/ RHCK1	Receiver #1 Enable/Serial Decoder Frame Sync Input/Receiver #1 Clock Input
D1:	TEN1	Transmitter #1 Enable Input
D2:	REN2/ RHCK2	Receiver #2 Enable Input/Receiver #2 Clock Input
D3:	TEN2	Transmitter #2 Enable Input
D4:	RX1	Receiver #1 Data Input
D5:	TX1	Transmitter #1 Data Output
D6:	RX2	Receiver #2 Data Input
D7:	TX2	Transmitter #2 Data Output

Note: Any of these pins can be read by software. Therefore, unused functions can be used as general purpose inputs, notably external enable lines when the internal serial decoder is used.

Port R is an 8-bit bidirectional I/O port available for general purpose I/O operations. Port R has a direction register to enable each separate pin to be individually defined as an input or output. It has a data register which contains the value to be output. In addition, the Port R pins can be read directly using the Port R pins address.

Pin Descriptions (Continued)

POWER SUPPLIES

- V_{CC1}, V_{CC2} Positive Power Supply (two pins)
- GND Ground for On-Chip Logic
- DGND Ground for Output Buffers

Note: There are two electrically connected V_{CC} pins on the chip, GND and DGND are electrically isolated. Both V_{CC} pins and both ground pins must be used.

CLOCK PINS

- CKI The System Clock Input
 - CKO The System Clock Output (Inversion of CKI)
- Pins CKI and CKO are usually connected across an external crystal.
- CK2 Clock Output (CKI divided by 2)

OTHER PINS

- W_O This is an active low open drain output which signals an illegal situation has been detected by the Watch Dog logic.
- ST1 Bus Cycle Status Output indicates first op-code fetch.
- ST2 Bus Cycle Status Output indicates machine states (skip and interrupt).
- RESET Active low input that forces the chip to restart and sets the ports in a TRI-STATE mode.
- RDY/HLD Has two uses, selected by a software bit. This pin is either a READY input to extend the bus cycle for slower memories or a HOLD-REQUEST input to put the bus in a high impedance state for external DMA purposes. In the second case the I4 pin can become the READY input.

Wait States

The HPC46400E provides software selectable Wait States for access to slower memories and for shared bus applications. The number of Wait States for the CPU are selected by two bits in the PSW register. The number of Wait States for DMA are selected by a bit in the Message System Configuration register. Additionally, the RDY input may be used to extend the RD or WR cycle, allowing the HPC to be used in shared memory applications and allowing the user to interface with slow memories and peripherals.

Power Save Modes

Two power saving modes are available on the HPC46400E: HALT and IDLE. In the HALT mode, all processor activities are stopped. In the IDLE mode, the on-board oscillator and timer T0 are active but all other processor activities are stopped. In either mode, on-board RAM, registers and I/O are unaffected (except the HDLC and UART which are reset).

HALT MODE

The HPC46400E is placed in the HALT mode under software control by setting bits in the PSW. All processor activities, including the clock and timers, are stopped. In the HALT mode, power requirements for the HPC46400E are minimal and the applied voltage (V_{CC}) may be decreased without altering the state of the machine. There are two ways of exiting the HALT mode: via the RESET or the NMI. The RESET input reinitializes the processor. Use of the NMI input will generate a vectored interrupt and resume operation from that point with no initialization. The HALT mode can be enabled or disabled by means of a control register HALT enable. To prevent accidental use of the HALT mode the HALT enable register can be modified only once.

IDLE MODE

The HPC46400E is placed in the IDLE mode through the PSW. In this mode, all processor activity, except the on-board oscillator and Timer T0, is stopped. The HPC46400E resumes normal operation upon timer T0 overflow. As with the HALT mode, the processor is also returned to full operation by the RESET or NMI inputs, but without waiting for oscillator stabilization.

HPC46400E Interrupts

Complex interrupt handling is easily accomplished by the HPC46400E's vectored interrupt scheme. There are eight possible interrupt sources as shown in Table I.

TABLE I. Interrupts

Vector/ Address	Interrupt Source	Arbitration Ranking
FFFF FFFE	Reset	0
FFFD FFFC	Nonmaskable Ext (NMI)	1
FFFB FFFA	External on I2	2
FFF9 FFF8	External on I3	3
FFF7 FFF6	External on I4	4
FFF5 FFF4	Internal on Timers	5
FFF3 FFF2	Internal on UART	6
FFF1 FFF0	End of Message (EOM)	7

The 46400E contains arbitration logic to determine which interrupt will be serviced first if two or more interrupts occur simultaneously. Interrupts are serviced after the current instruction is completed except for the RESET which is serviced immediately.

The NMI interrupt will immediately stop DMA activity. Byte transfers in progress will finish thereby allowing an orderly transition to the interrupt service vector (see DMA description). The HDLC channels continue to operate, and the user must service data errors that might have occurred during the NMI service routine.

Interrupt Processing

Interrupts are serviced after the current instruction is completed except for the RESET, which is serviced immediately. RESET holds on-chip logic in a reset state while low, and triggers the RESET interrupt on its rising edge. All other interrupts are edge-sensitive. NMI is positive-edge sensitive. The external interrupts on I2, I3, and I4 can be software selected to be rising or falling edge sensitive.

Interrupt Control Registers

The HPC46400E allows the various interrupt sources and conditions to be programmed. This is done through the various control registers. A brief description of the different control registers is given below.

INTERRUPT ENABLE REGISTER (ENIR)

RESET and the External Interrupt on I1 are non-maskable interrupts. The other interrupts can be individually enabled or disabled. Additionally, a Global Interrupt Enable Bit in the ENIR Register allows the Maskable interrupts to be collectively enabled or disabled. Thus, in order for a particular interrupt to request service, both the individual enable bit and the Global Interrupt bit (GIE) have to be set.

INTERRUPT PENDING REGISTER (IRPD)

The IRPD register contains a bit allocated for each interrupt vector. The occurrence of specified interrupt trigger conditions causes the appropriate bit to be set. There is no indication of the order in which the interrupts have been received. The bits are set independently of the fact that the interrupts may be disabled. IRPD is a Read/Write register. The bits corresponding to the external interrupts are normally cleared by the HPC46400E upon entering the interrupt servicing routine.

For the interrupts from the on-board peripherals, the user has the responsibility of acknowledging the interrupt through software.

INTERRUPT CONDITION REGISTER (IRCD)

Three bits of the register select the input polarity of the external interrupt on I2, I3, and I4.

Servicing the Interrupts

The Interrupt, once acknowledged, pushes the program counter (PC) onto the stack thus incrementing the stack pointer (SP) twice. The Global Interrupt Enable (GIE) bit is reset, thus disabling further interrupts. The program counter is loaded with the contents of the memory at the vector address and the processor resumes operation at this point. At the end of the interrupt service routine, the user does a RETI instruction to pop the stack, set the GIE bit and return to the main program. The GIE bit can be set in the interrupt service routine to nest interrupts if desired. Figure 10 shows the Interrupt Enable Logic.

Reset

The RESET input initializes the processor and sets all pins at TRI-STATE except CK0, CK2, and WO. HBE and ST2 have pull-downs designed to withstand override. RESET is an active-low Schmitt trigger input. The processor vectors to FFFF:FFFF and resumes operation at the address contained at that memory location.

The RESET pin must be asserted low for at least 16 cycles of the CK2 clock. In applications using the Watchdog feature, RESET should be asserted for at least 64 cycles of the CK2 clock.

On application of power, RESET must be held low for at least five times the power supply rise time to ensure that the on-chip oscillator circuit has time to stabilize.

Timer Overview

The HPC46400E contains a powerful set of flexible timers enabling the HPC46400E to perform extensive timer functions; not usually associated with microcontrollers.

The HPC46400E contains four 16-bit timers. Three of the timers have an associated 16-bit register. Timer T0 is a free-running timer, counting up at a fixed CKI/16 (Clock Input/16) rate. It is used for WATCHDOG logic, high speed event capture, and to exit from the IDLE mode. Consequently, it cannot be stopped or written to under software control. Timer T0 permits precise measurements by means of the capture registers I2CR, I3CR, and I4CR. A control bit in the register TOCON configures timer T1 and its associated register R1 as capture registers I3CR and I2CR. The capture registers I2CR, I3CR, and I4CR respectively, record the value of timer T0 when specific events occur on the interrupt pins I2, I3, and I4. The control register IRCD programs the capture registers to trigger on either a rising edge or a falling edge of its respective input. The specified edge can also be programmed to generate an interrupt (see Figure 11).

The timers T2 and T3 have selectable clock rates. The clock input to these two timers may be selected from the following two sources: an external pin, or derived internally by dividing the clock input. Timer T2 has additional capability of being clocked by the timer T3 underflow. This allows the user to cascade timers T3 and T2 into a 32-bit timer/counter. The control register DIVBY programs the clock input to timers T2 and T3 (see Figure 12).

Timer Overview (Continued)

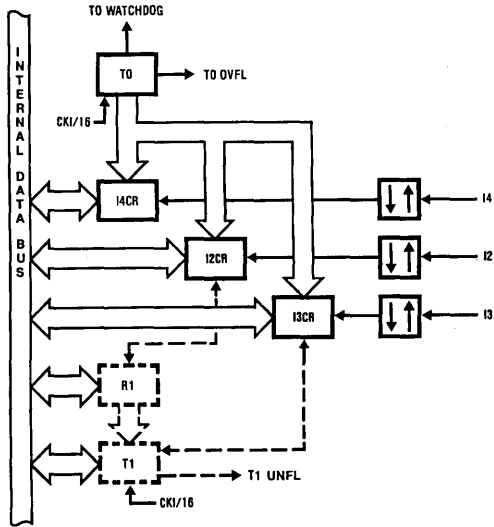

FIGURE 11. Timers T0-T1 Block

TL/DD/10422-21

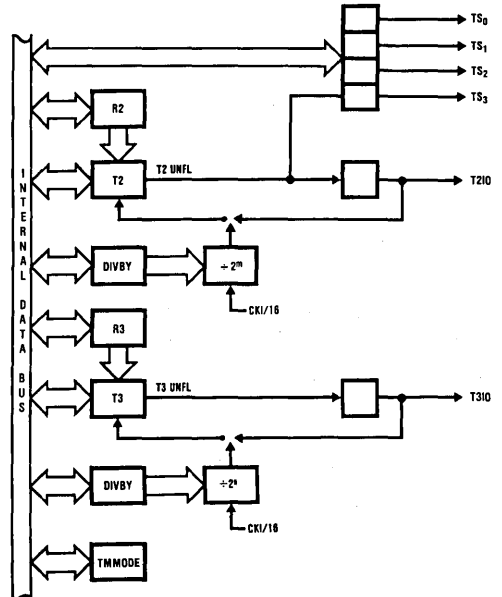

FIGURE 12. Timers T2-T3 Block

TL/DD/10422-20

Timer Overview (Continued)

The timers T1 through T3 in conjunction with their registers form Timer-Register pairs. The registers hold the pulse duration values. All the Timer-Register pairs can be read from or written to. Each timer can be started or stopped under software control. Once enabled, the timers count down, and upon underflow, the contents of its associated register are automatically loaded into the timer.

SYNCHRONOUS OUTPUTS

The flexible timer structure of the HPC46400E simplifies pulse generation and measurement. There are four synchronous timer outputs (TS0 through TS3) that work in conjunction with the timer T2. The synchronous timer outputs can be used either as regular outputs or individually programmed to toggle on timer T2 underflows (see *Figure 12*). Maximum output frequency for any timer output can be obtained by setting timer/register pair to zero. This then will produce an output frequency equal to 1/2 the frequency of the source used for clocking the timer.

Timer Registers

There are four control registers that program the timers. The divide by (DIVBY) register programs the clock input to timers T2 and T3. The timer mode register (TMMODE) contains control bits to start and stop timers T1 through T3. It also contains bits to latch, acknowledge and enable interrupts from timers T0 through T3.

Timer Applications

The use of Pulse Width Timers for the generation of various waveforms is easily accomplished by the HPC46400E.

Frequencies can be generated by using the timer/register pairs. A square wave is generated when the register value is a constant. The duty cycle can be controlled simply by changing the register value.

FIGURE 13. Square Wave Frequency Generation

Synchronous outputs based on Timer T2 can be generated on the 4 outputs TS0–TS3. Each output can be individually programmed to toggle on T2 underflow. Register R2 contains the time delay between events. *Figure 14* is an example of synchronous pulse train generation.

FIGURE 14. Synchronous Pulse Generation

WATCHDOG Logic

The WATCHDOG Logic monitors the operations taking place and signals upon the occurrence of any illegal activity. The illegal conditions that trigger the Watch Dog logic are potentially infinite loops. Should the Watch Dog register not be written to before Timer T0 overflows twice, or more often than once every 4096 counts, an infinite loop condition is assumed to have occurred. The illegal condition forces the Watch Out (WO) pin low. The WO pin is an open drain output and can be connected to the RESET or NMI inputs or to the users external logic.

MICROWIRE/PLUS

MICROWIRE/PLUS is used for synchronous serial data communications (see *Figure 15*). MICROWIRE/PLUS has an 8-bit parallel-loaded, serial shift register using SI as the input and SO as the output. SK is the clock for the serial shift register (SIO). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. A DONE flag indicates when the data shift is completed.

The MICROWIRE/PLUS capability enables it to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., ISDN Transceivers, A/D converters, display drivers, EEPROMs).

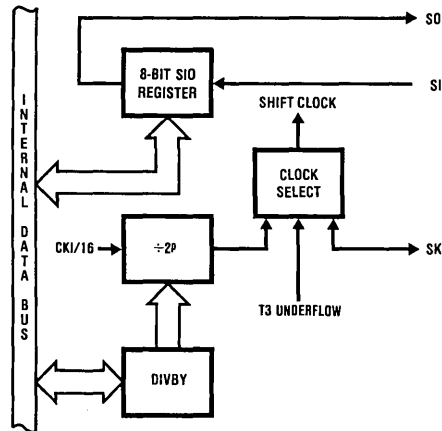

FIGURE 15. MICROWIRE/PLUS

TL/DD/10422-24

MICROWIRE/PLUS Operation

The HPC46400E can enter the MICROWIRE/PLUS mode as the master or a slave. A control bit in the IRCD register determines whether the HPC46400E is the master or slave. The shift clock is generated when the HPC46400E is configured as a master. An externally generated shift clock on the SK pin is used when the HPC46400E is configured as a slave. When the HPC46400E is a master, the DIVBY register programs the frequency of the SK clock. The DIVBY register allows the SK clock frequency to be programmed in 14 selectable steps from 122 Hz to 1 MHz with CKI at 16 MHz.

The contents of the SIO register may be accessed through any of the memory access instructions. Data waiting to be transmitted in the SIO register is shifted out on the falling edge of the SK clock. Serial data on the SI pin is latched in on the rising edge of the SK clock.

HPC46400E UART

The HPC46400E contains a software programmable UART. The UART (see Figure 16) consists of a transmit shift register, a receiver shift register and five addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR) and a UART interrupt and clock source register (ENUI). The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (7, 8 or 9 bits) and the value of the ninth bit in transmission. The ENUR register flags framing, parity, and data overrun errors while the UART is receiving. Other functions of the ENUR register include saving the ninth bit received in the data frame, reporting receiving and transmitting status,

and enabling or disabling the UART's Wake-up Mode of operation. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits ($7/8$, 1, $1\frac{1}{8}$, 2), selecting between the synchronous or asynchronous mode and enabling or disabling transmit and receive interrupts.

The clock inputs to the Transmitter and Receiver sections of the UART can be individually selected to come from either an off-chip source on the CKX pin or one of the three on-chip sources. Presently, two of the on-chip sources, the Divide-By (DIVBY) Register and the Precision UART Timer (PUT), are primarily for reasons of upward compatibility from earlier HPC family members. The most flexible and accurate on-chip clocking is provided by the third source: the Baud Rate Generator (BRG).

The Baud Rate Generator is controlled by the register pair PSR and BAUD, shown below.

The Prescaler factor is selected by the upper 5 bits of the PSR register (the PRESCALE field), in units of the CK2 clock from 1 to 16 in $1/2$ step increments. The lower 3 bits of the PSR register, in conjunction with the 8 bits of the baud register, form the 11-bit BAUDRATE field, which defines a baud rate divisor ranging from 1 to 2048, in units of the prescaled clock selected by the PRESCALE field.

In Asynchronous Mode, the resulting baud rate is $1/16$ of the clocking rate selected through the BRG circuit. The maximum baud rate generated using the BRG is 625 kbaud.

In the Synchronous Mode data is transmitted on the rising edge and received on the falling edge of the external clock. Although the data is transmitted and received synchronously, it is still contained within an asynchronous frame; i.e., a start bit, parity bit (if selected) and stop bit(s) are still present.

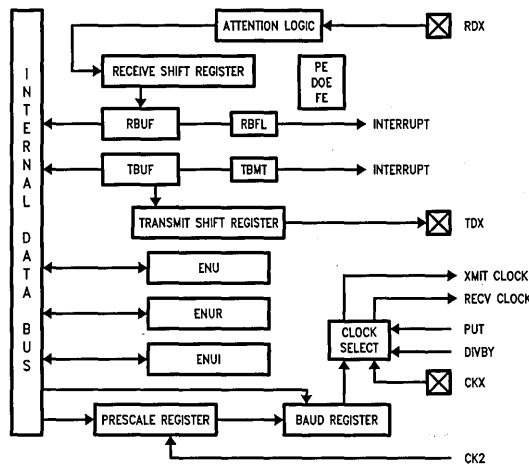

FIGURE 16. UART Block Diagram

TL/DD/10422-25

UART Baud Rate Generator (BRG) Registers PSR and BAUD

TL/DD/10422-26

UART Attention Mode

The HPC46400E UART features an Attention Mode of operation. This mode of operation enables the HPC46400E to be networked with other processors. Typically in such environments, the messages consist of addresses and actual data. Addresses are specified by having the ninth bit in the data frame set to 1. Data in the message is specified by having the ninth bit in the data frame reset to 0.

The UART monitors the communication stream looking for addresses. When the data word with the ninth bit set is received, the UART signals the HPC46400E with an interrupt. The processor then examines the content of the receiver buffer to decide whether it has been addressed and whether to accept subsequent data.

Programmable Serial Decoder Interface

The programmable serial decoder interface allows the two HDLC channels to be used with devices employing several popular Time Division Multiplexing (TDM) serial protocols for point-to-point and multipoint data exchanges. These protocols combine the 'B' and 'D' channels onto common pins—received data, transmit data, clock and Sync, which normally occurs at an 8 KHz rate and provides framing for the particular protocol.

The decoder uses the serial link clock and Sync signals to generate internal enables for the 'D' and 'B' channels, thereby allowing the HDLC channels to access the appropriate channel data from the multiplexed link.

Additionally, 64 kbit/s to 56 kbits/s rate adaptation can be done using the Serial Decoder generated enable signals B1 or B2. The rate adaption to 56 kbits/s is accomplished by using only the first 7 bits of each B channel time slot for each TDM frame. The transmitter will insert a "1" in the eighth bit of each frame. The receiver will only receive the first seven data bits and skip the eighth bit. See *Figure 17* 65 kbit/56 kbit Rate Adaption Timing Diagram.

HDLC Channel Description

HDLC/DMA Structure

HDLC 1		HDLC 2	
HDLC1 Receive	HDLC1 Transmit	HDLC2 Receive	HDLC2 Transmit
DMAR1	DMAT1	DMAR2	DMAT2

GENERAL INFORMATION

Both HDLC channels on the HPC46400E are identical and operate up to 4.65 Mbps. When used in an ISDN Basic Rate access application, HDLC channel # 1 has been designated for use with the 16 kbps D-channel or either B channel and HDLC #2 can be used with either of the 64 kbps B-channels. If the 'D' and 'B' channels are present on a common serial link, the programmable serial decoder interface generates the necessary enable signals needed to access the D and B channel data.

There are two sources for the receive and transmit channel enable signals. They can be internally generated from the serial decoder interface or they can be externally enabled.

LAPD, the Link Access Protocol for the D channel is derived from the X.25 packet switching LAPB protocol. LAPD specifies the procedure for a terminal to use the D channel for the transfer of call control or user-data information. The pro-

cedure is used in both point-to-point and point-to-multipoint configurations. On the 46400E, the HDLC controller contains user programmable features that allow for the efficient processing of LAPD Information.

HDLC Channel Pin Description

Each HDLC channel has the following pins associated with it.

- HCK — HDLC Channel Clock Input Signal.
- RX — Receive Serial Data Input. Data latched on the negative HCK edge.
- REN/RHCK — HDLC Channel Receiver Enable Input/Receiver Clock Input.
- TEN — HDLC Channel Transmitter Enable Input.
- TX — Transmit Serial Data Output. Data clocked out on the positive HCK edge. Data (not including CRC) is sent LSB first. TRI-STATE when transmitter not enabled.
- CFLG1 — Closing Flag output for Channel 1.

HDLC Functional Description

TRANSMITTER DESCRIPTION

Data is transferred from external memory through the DMA controller into the transmit buffer register, from which it is loaded into a 8-bit serial shift register. The CRC is computed and appended to the frame prior to the closing flag being transmitted. Data is output at the TX output pin. If no further transmit commands are given the transmitter sends out continuous flags, aborts, or the idle pattern as selected by the control register.

An interrupt is generated when the DMA has transferred the last byte from RAM to the HDLC channel for a particular message or on a transmit error condition. An associated transmit status register will contain the status information indicating the specific interrupt source.

To support transmitting data packets at an "R" interface for V.120 in synchronous UI mode, to support the use of the HPC in test equipment, or to support proprietary CRC algorithms the transmitter has the option of preventing the transmitting of the hardware generated CRC bytes.

TRANSMITTER FEATURES

Interframe fill: the transmitter can send either continuous '1's or repeated flags or aborts between the closing flag of one packet and the opening flag of the next. When the CPU commands the transmitter to open a new frame, the interframe fill is terminated immediately.

Abort: the abort sequence, a zero followed by seven ones, will be immediately sent on command from the CPU or on an underrun condition in the DMA.

Bit/Byte boundaries: The message length between packet headers may have any number of bits and is not confined to an integral number of bytes. Three bits in the control register are used to indicate the number of valid bits in the last byte. These bits are loaded by the users software.

RECEIVER DESCRIPTION

Data is input to the receiver on the RX pin. The receive clock can be externally input at either the HCK pin or the REN/RHCK pin.

Incoming data is routed through one of several paths depending on whether it is the flag, data, or CRC.

Once the receiver is enabled it waits for the opening flag of the incoming frame, then starts the zero bit deletion, ad-

HDLC Functional Description (Continued)

FIGURE 17. 64 kbit/56 kbit Rate Adaption Timing Diagram

addressing handling and CRC checking. All data between the flags is shifted through two 8-bit serial shift registers before being loaded into the buffer register. The user programmable address register values are compared to the incoming data while it resides in the shift registers. If an address match occurs or if operating in the transparent address recognition mode, the DMA channel is signaled that attention is required and the data is transferred by it to external memory. Appropriate interrupts are generated to the CPU on the reception of a complete frame, or on the occurrence of a frame error.

The receive interrupt, in conjunction with status data in the control registers allows interrupts to be generated on the following conditions—frame length error, CRC error, receive error, abort and receive complete.

To support V.120 UI data packets at the "R" interface, proprietary CRC algorithms, and test equipment the two bytes preceding the closing flag (usually the CRC bytes) will be loaded into registers. The two bytes can then be read by the CPU and placed into memory. The DMA address pointers used for that particular message will already contain the address that the first byte should be placed into.

RECEIVER FEATURES

Flag sharing: the closing flag of one packet may be shared as the opening flag of the next. Receiver will also be able to share a zero between flags—0111111011111110 is a valid two flag sequence for receive (not transmit).

Interframe fill: the receiver automatically accepts either repeated flags, repeated aborts, or all '1's as the interframe fill.

Idle: Reception of successive flags as the interframe fill sequence to be signaled to the user by setting the Flag bit in the Receiver Status register.

Short Frame Rejection: Reception of greater than 2 bytes but less than 4 bytes between flags will generate a frame error, terminating reception of the current frame and setting the Frame Error (FER) status bit in the Receive Control and Status register. Reception of less than 2 bytes will be ignored.

Abort: the 7 '1's abort sequence will be immediately recognized and will cause the receiver to reinitialize and return to searching the incoming data for an opening flag. Reception of the abort will cause the abort status bit in the Interrupt Error Status register to be set and will signal an End of Message (EOMR).

Bit/Byte boundaries: The message length between packet headers may have any number of bits and it is not confined to an integral number of bytes. Three bits in the status register are used to indicate the number of valid bits in the last byte.

Address Recognition: Two user programmable bytes are available to allow frame address recognition on the two bytes immediately following the opening flag. When the received address matches the programmed value(s), the frame is passed through to the DMA channel. If no match occurs, the received frame address information is disregarded and the receiver returns to searching for the next opening flag and the address recognition process starts anew.

Support is provided to allow recognition of the Broadcast address. Additionally, a transparent mode of operation is available where no address decoding is done.

HDLC INTERRUPT CONDITIONS

The end of message interrupt (EOM) indicates that a complete frame has been received or transmitted by the HDLC controller. Thus, there are four separate sources for this interrupt, two each from each HDLC channel. The Message Control Register contains the pending bits for each source.

HDLC ERROR DETECTION

The HDLC/DMA detects several error conditions and reports them in the two Error Status Registers. These conditions are a DMA transmitter underrun, a DMA receiver overrun, a CRC error, a frame too long, a frame too short, and an aborted message.

HDLC CHANNEL CLOCK

Each HDLC channel uses the falling edge of the clock to sample the receive data. Outgoing transmit data is shifted out on the rising edge of the external clock. The maximum data rate when using the externally provided clocks is 4.65 Mb/s.

The receiver/transmitter pair can share a single clock input to save I/O pins, or the inputs can be separated to allow different receive and transmit clocks. This feature allows the receiver and transmitter to operate at different frequencies or enables them to each be synchronized to different parts of the user's system.

CYCLIC REDUNDACY CHECK

There are two standard CRC codes used in generating the 16-bit Frame Check Sequence (FCS) that is appended to the end of the data frame. Both codes are supported and

HDLC Functional Description (Continued)

the user selects the error checking code to be used through software control (HDLC control reg). The two error checking polynomials available are:

- (1) CRC-16 ($x^{16} + x^{15} + x^2 + 1$)
- (2) CCITT CRC ($x^{16} + x^{12} + x^5 + 1$)

SYNCHRONOUS BYPASS MODE

When the BYPAS bit is set in the HDLC control register, all HDLC framing/formatting functions for the specified HDLC channel are disabled.

This allows byte-oriented data to be transmitted and received synchronously thus "bypassing" the HDLC functions.

LOOP BACK OPERATIONAL MODE

The user has the ability, by setting the appropriate bit in the register to internally route the transmitter output to the receiver input, and to internally route the RX pin to the TX pin.

DMA Controller

GENERAL INFORMATION

The HPC46400E uses Direct Memory Access (DMA) logic to facilitate data transfer between the 2 full Duplex HDLC channels and external packet RAM. There are four DMA channels to support the four individual HDLC channels. Control of the DMA channels is accomplished through registers which are configured by the CPU. These control registers define specific operation of each channel and changes are immediately reflected in DMA operation. In addition to individual control registers, global control bits (MSS and MSSC in Message Control Register) are available so that the HDLC channels may be globally controlled.

The DMA issues a bus request to the CPU when one or more of the individual HDLC channels request service. Upon receiving a bus acknowledge from the CPU, the DMA completes all requests pending and any requests that may have occurred during DMA operation before returning control to the CPU. If no further DMA transfers are pending, the DMA relinquishes the bus and the CPU can again initiate a bus cycle.

Four memory expansion bits have been added for each of the four channels to support data transfers into the expanded memory bank areas.

The DMA has priority logic for servicing DMA requests. The priorities are:

- 1st priorityReceiver channel 1
- 2nd priorityTransmit channel 1
- 3rd priorityReceive channel 2
- 4th priorityTransmit channel 2

RECEIVER DMA OPERATION

The receiver DMA consists of a shift register and two buffers. A receiver DMA operation is initiated by the buffer registers. Once a byte has been placed in a buffer register from the HDLC, it generates a request and upon obtaining control of the bus, the DMA places the byte in external memory.

RECEIVER REGISTERS

All the following registers are Read/Write

A. Frame Length Register

This user programmable 16-bit register contains the maximum number of bytes to be placed in a data "block". If

this number is exceeded, a Frame Too Long error is generated. DMA is stopped to prevent memory from being overwritten, however the receiver continues until the closing flag is received in order to check the CRC.

B. CNTRL ADDR 1 For split frame operation, the CNTRL ADDR register contains the external memory address where the Frame Header (Control & Address fields) are to be stored and the DATA ADDR register contains an equivalent address for the Information field.

For non-split frame operation, the CNTRL and DATA ADDR registers each contain the external memory address for entire frames.

TRANSMITTER DMA OPERATION

The transmitter DMA consists of a shift register and two buffers. A transmitter DMA cycle is initiated by the TX data buffers. The TX data buffers generate a request when either one is empty and the DMA responds by placing a byte in the buffer. The HDLC transmitter can then accept the byte to send when needed, upon which the DMA will issue another request, resulting in a subsequent DMA cycle.

TRANSMITTER REGISTERS

The following registers are Read/Write:

- FIELD ADDRESS 1 Field Address 1 and Field Address 2 are starting addresses of blocks of information to be transmitted.
- BYTE COUNT 1 Byte Count 1 and Byte Count 2 are the number of bytes in the block to be transmitted.
- FIELD ADDRESS 2
- BYTE COUNT 2

Shared Memory Support

Shared memory access provides a rapid technique to exchange data. It is effective when data is moved from a peripheral to memory or when data is moved between blocks of memory. A related area where shared memory access proves effective is in multiprocessing applications where two CPUs share a common memory block. The HPC46400E supports shared memory access with two pins. The pins are the RDY/HLD input pin and the HLD \bar{A} output pin. The user can software select either the Hold or Ready function on the RDY/HLD pin by the state of a control bit. The HLD \bar{A} output must be selected as the HLD \bar{A} output on pin B7 by software.

The host uses DMA to interface with the HPC46400E. The host initiates a data transfer by activating the HLD input of the HPC46400E. In response, the HPC46400E places its system bus in a TRI-STATE Mode, freeing it for use by the host. The host waits for the acknowledge signal (HLD \bar{A}) from the HPC46400E indicating that the system bus is free. On receiving the acknowledge, the host can rapidly transfer data into, or out of, the shared memory by using a conventional DMA controller. Upon completion of the message transfer, the host removes the HOLD request and the HPC46400E resumes normal operations. See *Figure 18* (HPC46400E shared Memory Using HOLD).

An alternate approach is to use the Ready function available on either the RDY/HLD pin or the INT4/RDY pin. See *Figure 19* (HPC46400E Shared Memory Using READY). This technique is often required when the HPC is sharing memory over a system backplane bus.

Shared Memory Support (Continued)

Memory

The HPC46400E has been designed to offer flexibility in memory usage. A total address space of 64 kbytes can be addressed with 256 bytes of RAM available on the chip itself.

Program memory addressing is accomplished by the 16-bit program counter on a byte basis. Memory can be addressed directly by instructions or indirectly through the B, X and SP registers. Memory can be addressed as words or bytes. Words are always accessed on even-byte boundaries. The HPC46400E uses memory-mapped organization to support registers, I/O and on-chip peripheral functions.

The HPC46400E memory address space extends to 64 kbytes and registers and I/O are mapped as shown in Table II.

Extended Memory Addressing

If more than 64k of addressing is desired in a HPC46400E system, on board bank select circuitry is available that al-

lows four I/O lines of Port B (B8, B9, B13, B14) to be used in extending the address range. This gives the user a main routine area of 32k and 16 banks of 32k each for subroutine and data, thus getting a total of 536.5k of memory.

Note: If all four lines are not needed for memory expansion, the unused lines can be used as general purpose inputs.

The Extended Memory Addressing mode is entered by setting the EMA control bit in the Message Control Register. If this bit is not set, the port B lines (B8, B9, B13, B14) are available as general purpose I/O or synchronous outputs as selected by the BFUN register.

The main memory area contains the interrupt vectors & service routines, stack memory, and common memory for the bank subroutines to use. The 16 banks of memory can contain program or data memory (note: since the on chip resources are mapped into addresses 0000-01FF, the first 512 bytes of each bank are not usable, actual available memory is 536.5k).

Design Considerations

Designs using the HPC family of 16-bit high speed CMOS microcontrollers need to follow some general guidelines on usage and board layout.

Floating inputs are a frequently overlooked problem. CMOS inputs have extremely high impedance and, if left open, can float to any voltage possibly causing internal devices to go into active mode and draw DC current. You should thus tie unused inputs to V_{CC} or ground, either through a resistor or directly. Unlike the inputs, unused outputs should be left floating to allow the output to switch without drawing any DC current.

To reduce voltage transients, keep the supply line's parasitic inductances as low as possible by reducing trace lengths, using wide traces, ground planes, and by decoupling the supply with bypass capacitors. In order to prevent additional voltage spiking, this local bypass capacitor must exhibit low inductive reactance. You should therefore use high frequency ceramic capacitors and place them very near the IC to minimize wiring inductance.

- Keep V_{CC} bus routing short. When using double sided or multilayer circuit boards, use ground plane techniques.
- Keep ground lines short, and on PC boards make them as wide as possible, even if trace width varies. Use separate ground traces to supply high current devices such as relay and transmission line drivers.
- In systems mixing linear and logic functions and where supply noise is critical to the analog components' performance, provide separate supply buses or even separate supplies.
- When using local regulators, bypass their inputs with a tantalum capacitor of at least $1 \mu\text{F}$ and bypass their outputs with a $10 \mu\text{F}$ to $50 \mu\text{F}$ tantalum or aluminum electrolytic capacitor.
- If the system uses a centralized regulated power supply, use a $10 \mu\text{F}$ to $20 \mu\text{F}$ tantalum electrolytic capacitor or a $50 \mu\text{F}$ to $100 \mu\text{F}$ aluminum electrolytic capacitor to decouple the V_{CC} bus connected to the circuit board.
- Provide localized decoupling. For random logic, a rule of thumb dictates approximately 10 nF (spaced within 12 cm) per every two to five packages, and 100 nF for every 10 packages. You can group these capacitances, but it's more effective to distribute them among the ICs. If the design has a fair amount of synchronous logic with outputs that tend to switch simultaneously, additional decoupling might be advisable. Octal flip-flop and buffers in bus-oriented circuits might also require more decoupling. Note that wire-wrapped circuits can require more decoupling than ground plane or multilayer PC boards.

TL/DD/10422-29

A recommended crystal oscillator circuit to be used with the HPC is shown below. See table for recommended component values. The recommended values given in the table below have yielded consistent results and are made to match a crystal with a 20 pF load capacitance, with some small allowance for layout capacitance.

A recommended layout for the oscillator network should be as close to the processor as physically possible, entirely within $1''$ distance. This is to reduce lead inductance from long PC traces, as well as interference from other components, and reduce trace capacitance. The layout should contain a large ground plane either on the top or bottom surface of the board to provide signal shielding, and a convenient location to ground both the HPC, and the case of the crystal.

It is very critical to have an extremely clean power supply for the HPC crystal oscillator. Ideally one would like a V_{CC} and ground plane that provide low inductance power lines to the chip. The power planes in the PC board should be decoupled with three decoupling capacitors as close to the chip as possible. A $1.0 \mu\text{F}$, a $0.1 \mu\text{F}$, and a $0.001 \mu\text{F}$ dipped mica or ceramic cap mounted as close to the HPC as is physically possible on the board, using the shortest leads, or surface mount components. This should provide a stable power supply, and noiseless ground plane which will vastly improve the performance of the crystal oscillator network.

HPC Oscillator Table

f_c (MHz)	R_{cc} (Ω)	C_1 (pF)	C_2 (pF)
2	50	82	100
4	50	62	75
6	50	50	56
8	50	47	50
10	50	39	50
12	0	39	39
14	0	33	39
16	0	33	39
18	0	33	33
20	0	33	33

Crystal Specifications:
 "AT" cut, parallel resonant crystals tuned to the desired frequency with the following specifications are recommended:

Series Resistance < 65Ω

Loading Capacitance: $C_L = 20 \text{ pF}$

HPC46400E CPU

The HPC46400E CPU has a 16-bit ALU and six 16-bit registers.

Arithmetic Logic Unit (ALU)

The ALU is 16 bits wide and can do 16-bit add, subtract and shift or logic AND, OR and exclusive OR in one timing cycle. The ALU can also output the carry bit to a 1-bit C register.

Accumulator (A) Register

The 16-bit A register is the source and destination register for most I/O, arithmetic, logic and data memory access operations.

Address (B and X) Registers

The 16-bit B and X registers can be used for indirect addressing. They can automatically count up or down to sequence through data memory.

Boundary (K) Register

The 16-bit K register is used to set limits in repetitive loops of code as register B sequences through data memory.

Stack Pointer (SP) Register

The 16-bit SP register is the stack pointer that addresses the stack. The SP register is incremented by two for each push or call and decremented by two for each pop or return. The stack can be placed anywhere in user memory and be as deep as the available memory permits.

Program (PC) Register

The 16-bit PC register addresses program memory.

Addressing Modes

ADDRESSING MODES—ACCUMULATOR AS DESTINATION

Register Indirect

This is the "normal" mode of addressing for the HPC46400E (instructions are single-byte). The operand is the memory addressed by the B register (or X register for some instructions).

Direct

The instruction contains an 8-bit or 16-bit address field that directly points to the memory for the operand.

Indirect

The instruction contains an 8-bit address field. The contents of the WORD addressed points to the memory for the operand.

Indexed

The instruction contains an 8-bit address field and an 8- or 16-bit displacement field. The contents of the WORD addressed is added to the displacement to get the address of the operand.

Immediate

The instruction contains an 8-bit or 16-bit immediate field that is used as the operand.

Register Indirect (Auto Increment and Decrement)

The operand is the memory addressed by the X register. This mode automatically increments or decrements the X register (by 1 for bytes and by 2 for words).

Register Indirect (Auto Increment and Decrement) with Conditional Skip

The operand is the memory addressed by the B register. This mode automatically increments or decrements the B register (by 1 for bytes and by 2 for words). The B register is then compared with the K register. A skip condition is generated if B goes past K.

ADDRESSING MODES—DIRECT MEMORY AS DESTINATION

Direct Memory to Direct Memory

The instruction contains two 8- or 16-bit address fields. One field directly points to the source operand and the other field directly points to the destination operand.

Immediate to Direct Memory

The instruction contains an 8- or 16-bit address field and an 8- or 16-bit immediate field. The immediate field is the operand and the direct field is the destination.

Double Register Indirect using the B and X Registers

Used only with Reset, Set and IF bit instructions; a specific bit within the 64 kbyte address range is addressed using the B and X registers. The address of a byte of memory is formed by adding the contents of the B register to the most significant 13 bits of the X register. The specific bit to be modified or tested within the byte of memory is selected using the least significant 3 bits of register X.

HPC Instruction Set Description

Mnemonic	Description	Action
ARITHMETIC INSTRUCTIONS		
ADD	Add	$MA + Meml \rightarrow MA$ carry $\rightarrow C$
ADDS	Add short imm8	$MA + imm8 \rightarrow MA$ carry $\rightarrow C$
ADC	Add with carry	$MA + Meml + C \rightarrow MA$ carry $\rightarrow C$
DADC	Decimal add with carry	$MA + Meml + C \rightarrow MA$ (Decimal) carry $\rightarrow C$
SUBC	Subtract with carry	$MA - Meml + C \rightarrow MA$ carry $\rightarrow C$
DSUBC	Decimal subtract w/carry	$MA - Meml + C \rightarrow MA$ (Decimal) carry $\rightarrow C$
MULT	Multiply (unsigned)	$MA * Meml \rightarrow MA \& X, 0 \rightarrow K, 0 \rightarrow C$
DIV	Divide (unsigned)	$MA / Meml \rightarrow MA, rem. \rightarrow X, 0 \rightarrow K, 0 \rightarrow C$
DIVD	Divide Double Word (unsigned)	$(x8 MA) / Meml \rightarrow MA, rem \rightarrow X, 0 \rightarrow K$ carry $\rightarrow C$
IFEQ	If equal	Compare MA & Meml, Do next if equal
IFGT	If greater than	Compare MA & Meml, Do next if MA \rightarrow Meml
AND	Logical and	$MA \text{ and } Meml \rightarrow MA$
OR	Logical or	$MA \text{ or } Meml \rightarrow MA$
XOR	Logical exclusive-or	$MA \text{ xor } Meml \rightarrow MA$
MEMORY MODIFY INSTRUCTIONS		
INC	Increment	$Mem + 1 \rightarrow Mem$
DECSZ	Decrement, skip if 0	$Mem - 1 \rightarrow Mem$, Skip next if Mem = 0
BIT INSTRUCTIONS		
SBIT	Set bit	$1 \rightarrow Mem.bit$ (bit is 0 to 7 immediate)
RBIT	Reset bit	$0 \rightarrow Mem.bit$
IFBIT	If bit	If Mem.bit is true, do next instr.
MEMORY TRANSFER INSTRUCTIONS		
LD	Load	$Meml \rightarrow MA$
ST	Load, incr/decr X	$Mem(X) \rightarrow A, X \pm 1 \text{ (or 2)} \rightarrow X$
X	Store to Memory	$MA \rightarrow Mem$
	Exchange	$A \leftrightarrow Mem; Mem \leftrightarrow Mem$
	Exchange, incr/decr X	$A \leftrightarrow Mem(X), X \pm 1 \text{ (or 2)} \rightarrow X$
PUSH	Push Memory to Stack	$W \rightarrow W(SP), SP + 2 \rightarrow SP$
POP	Pop Stack to Memory	$SP - 2 \rightarrow SP, W(SP) \rightarrow W$
LDS	Load A, incr/decr B, Skip on condition	$Mem(B) \rightarrow A, B \pm 1 \text{ (or 2)} \rightarrow B$, Skip next if B greater/less than K
XS	Exchange, incr/decr B, Skip on condition	$Mem(B) \leftrightarrow A, B \pm 1 \text{ (or 2)} \rightarrow B$, Skip next if B greater/less than K
REGISTER LOAD IMMEDIATE INSTRUCTIONS		
LD A	Load A immediate	$imm \rightarrow A$
LD B	Load B immediate	$imm \rightarrow B$
LD K	Load K immediate	$imm \rightarrow K$
LD X	Load X immediate	$imm \rightarrow X$
LD BK	Load B and K immediate	$imm \rightarrow B, imm \rightarrow K$
ACCUMULATOR AND C INSTRUCTIONS		
CLR A	Clear A	$0 \rightarrow A$
INC A	Increment A	$A + 1 \rightarrow A$
DEC A	Decrement A	$A - 1 \rightarrow A$
COMP A	Complement A	1's complement of A $\rightarrow A$
SWAP A	Swap nibbles of A	$A15:12 \leftarrow A11:8 \leftarrow A7:4 \leftrightarrow A3:0$
RRC A	Rotate A right thru C	$C \rightarrow A15 \rightarrow \dots \rightarrow A0 \rightarrow C$
RLC A	Rotate A left thru C	$C \leftarrow A15 \leftarrow \dots \leftarrow A0 \leftarrow C$
SHR A	Shift A right	$0 \rightarrow A15 \rightarrow \dots \rightarrow A0 \rightarrow C$
SHL A	Shift A left	$C \leftarrow A15 \leftarrow \dots \leftarrow A0 \leftarrow 0$
SC	Set C	$1 \rightarrow C$
RC	Reset C	$0 \rightarrow C$
IFC	IF C	Do next if C = 1
IFNC	IF not C	Do next if C = 0

HPC Instruction Set Description (Continued)

Mnemonic	Description	Action
TRANSFER OF CONTROL INSTRUCTIONS		
JSRP	Jump subroutine from table	PC → W(SP), SP+2 → SP W(table#) → PC
JSR	Jump subroutine relative	PC → W(SP), SP+2 → SP, PC+ # → PC (# is +1024 to -1023)
JSRL	Jump subroutine long	PC → W(SP), SP+2 → SP, PC+ # → PC
JP	Jump relative short	PC+ # → PC(# is +32 to -31)
JMP	Jump relative	PC+ # → PC(# is +256 to -255)
JMPL	Jump relative long	PC+ # → PC
JID	Jump indirect at PC + A	PC+A+1 → PC then Mem(PC)+PC → PC
JIDW		
NOP	No Operation	PC ← PC + 1
RET	Return	SP-2 → SP, W(SP) → PC
RETS	Return then skip next	SP-2 → SP, W(SP) → PC, & skip
RETI	Return from interrupt	SP-2 → SP, W(SP) → PC, interrupt re-enabled

Note: W is 16-bit word of memory
MA is Accumulator A or direct memory (8-bit or 16-bit)
Mem is 8-bit byte or 16-bit word of memory
MemI is 8-bit or 16-bit memory or 8-bit or 16-bit immediate data
imm is 8-bit or 16-bit immediate data

Memory Usage

For information on memory usage and instruction timing please refer to the HPC46400E User's Manual.

Code Efficiency

The HPC46400E has been designed to be extremely code-efficient. The HPC46400E looks very good in all the standard coding benchmarks; however, it is not realistic to rely only on benchmarks. Many large jobs have been programmed onto the HPC46400E, and the code savings over other popular microcontrollers has been considerable.

Reasons for this saving of code include the following:

SINGLE BYTE INSTRUCTIONS

The majority of instructions on the HPC46400E are single-byte. There are two especially code-saving instructions:

JP is a 1-byte jump. True, it can only jump within a range of plus or minus 32, but many loops and decisions are often within a small range of program memory. Most other micros need 2-byte instructions for any short jumps.

JSRP is a 1-byte call subroutine. The user makes a table of his 16 most frequently called subroutines and these calls will only take one byte. Most other micros require two and even three bytes to call a subroutine. The user does not have to decide which subroutine addresses to put into his table; the assembler can give him this information.

EFFICIENT SUBROUTINE CALLS

The 2-byte JSR instructions can call any subroutine within plus or minus 1k of program memory.

MULTIFUNCTION INSTRUCTIONS FOR DATA MOVEMENT AND PROGRAM LOOPING

The HPC46400E has single-byte instructions that perform multiple tasks. For example, the XS instruction will do the following:

1. Exchange A and memory pointed to by the B register
2. Increment or decrement the B register

3. Compare the B register to the K register
4. Generate a conditional skip if B has passed K

The value of this multipurpose instruction becomes evident when looping through sequential areas of memory and exiting when the loop is finished.

BIT MANIPULATION INSTRUCTIONS

Any bit of memory, I/O or registers can be set, reset or tested by the single byte bit instructions. The bits can be addressed directly or indirectly. Since all registers and I/O are mapped into the memory, it is very easy to manipulate specific bits to do efficient control.

DECIMAL ADD AND SUBTRACT

This instruction is needed to interface with the decimal user world.

It can handle both 16-bit words and 8-bit bytes.

The 16-bit capability saves code since many variables can be stored as one piece of data and the programmer does not have to break his data into two bytes. Many applications store most data in 4-digit variables. The HPC46400E supplies 8-bit byte capability for 2-digit variables and literal variables.

MULTIPLY AND DIVIDE INSTRUCTIONS

The HPC46400E has 16-bit multiply, 16-bit by 16-bit divide, and 32-bit by 16-bit divide instructions. This saves both code and time. Multiply and divide can use immediate data or data from memory. The ability to multiply and divide by immediate data saves code since this function is often needed for scaling, base conversion, computing indexes of arrays, etc.

Part Selection

The HPC family includes devices with many different options and configurations to meet various application needs. The number HPC46400E has been generally used throughout this datasheet to represent the whole family of parts. The following chart explains how to order various options available when ordering HPC family members.

Note: All options may not currently be available.

FIGURE 15. HPC Family Part Numbering Scheme

 HPC36400EV20—Industrial temp (-40°C to +85°C), PLCC

Development Support

HPC MICROCONTROLLER DEVELOPMENT SYSTEM

The HPC microcontroller development system is an in-system emulator (ISE) designed to support the entire family of HPC Microcontrollers. The complete package of hardware and software tools combined with a host system provides a powerful system for design, development and debug of HPC based designs. Software tools are available for IBM®, PC-AT® (MS-DOS, PC-DOS) and for UNIX® based multi-user Sun SPARCstation (SunOS™).

The stand alone unit comes complete with a power supply and external emulation POD. This unit can be connected to various host systems through an RS-232 link. The software package includes an ANSI compatible C-Compiler, Linker, Assembler and librarian package. Source symbolic debug capability is provided through a user friendly MS-windows 3.0 interface for IBM PC-AT environment and through a line debugger under Sunview for Sun SPARCstations.

The ISE provides fully transparent in-system emulation at speeds up to 20 MHz 1 waitstate. A 2K word (48-bit wide) trace buffer gives trace trigger and non intrusive monitoring of the system. External triggering is also available through an external logic interface socket on the POD. Comprehensive on-line help and diagnostics features reduce user's design and debug time. 8 hardware breakpoints (Address/range), 64 kbytes of user memory, and break on external events are some of the other features offered.

Hewlett Packard model HP64775 Emulator/Analyzer providing in-system emulation for up to 30 MHz 1 waitstate is also available. Contact your local sales office for technical details and support.

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications Group. Dial-A-Helper is an electronic bulletin board information system and additionally, provides the capability of remotely accessing the development system at a customer site.

INFORMATION SYSTEM

The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communications to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities can be found. The minimum requirement for accessing Dial-A-Helper is a Hayes compatible modem.

If the user has a PC with a communications package then files from the FILE SECTION can be down loaded to disk for later use.

Order P/N: MOLE-DIAL-A-HLP

Information System Package Contains:
Dial-A-Helper Users Manual
Public Domain Communications Software

FACTORY APPLICATIONS SUPPORT

Dial-A-Helper also provides immediate factory applications support. If a user is having difficulty in operating a development system, he can leave messages on our electronic bulletin board, which we will respond to.

Voice: (408) 721-5582
Modem: (408) 739-1162
Baud: 300 or 1200 baud
Set-Up: Length: 8-Bit
Parity: None
Stop Bit: 1
Operation: 24 Hrs, 7 Days

PRELIMINARY

HPC167064/467064 High-Performance microController with a 16k UV Erasable CMOS EPROM

General Description

The HPC167064 is a member of the HPC family of High Performance microControllers. Each member of the family has the same core CPU with a unique memory and I/O configuration to suit specific applications. The HPC167064 has a 16 kbyte, high-speed, UV-erasable, electrically programmable CMOS EPROM. This is ideally suited for applications where fast turnaround, pattern experimentation, and code confidentiality are important requirements. The HPC167064 can serve as a stand-alone emulator for either the HPC16064 or the HPC16083. Two configuration registers have been added for emulation of the different chips. The on-chip EPROM replaces the presently available user ROM space. The on-chip EPROM can be programmed via DATA I/O UNISITE, and HPC-MDS. There are security features added to the chip to implement READ, ENCRYPTED READ, and WRITE privileges for the on-chip EPROM. These defined privileges are intended to deter theft, alteration, or unintentional destruction of user code. Each part is fabricated in National's advanced microCMOS technology. This process combined with an advanced architecture provides fast, flexible I/O control, efficient data manipulation, and high speed computation.

The HPC devices are complete microcomputers on a single chip. All system timing, internal logic, EPROM, RAM, and I/O are provided on the chip to produce a cost effective solution for high performance applications. On-chip functions such as UART, up to eight 16-bit timers with 4 input capture registers, vectored interrupts, WATCHDOG™ logic and MICROWIRE/PLUS™ provide a high level of system integration. The ability to address up to 64k bytes of external memory enables the HPC to be used in powerful applications typically performed by microprocessors and expensive peripheral chips.

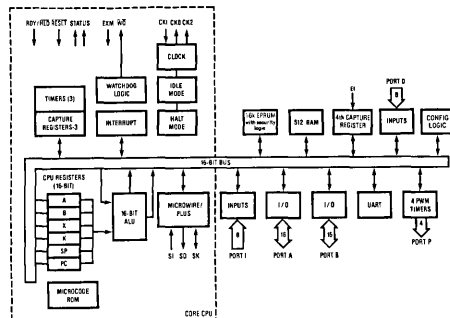

The microCMOS process results in very low current drain and enables the user to select the optimum speed/power

product for his system. The IDLE and HALT modes provide further current savings. The HPC167064 is available only in 68-pin LDCC package.

Features

- HPC family—core features:
 - 16-bit architecture, both byte and word operations
 - 16-bit data bus, ALU, and registers
 - 64 kbytes of direct memory addressing
 - FAST—200 ns for fastest instruction when using 20.0 MHz clock
 - High code efficiency—most instructions are single byte
 - 16 x 16 multiply and 32 x 16 divide
 - Eight vectored interrupt sources
 - Four 16-bit timer/counters with 4 synchronous outputs and WATCHDOG logic
 - MICROWIRE/PLUS serial I/O interface
 - CMOS—very low power with two power save modes: IDLE and HALT
- 16 kbytes high speed UV erasable: electrically programmable CMOS EPROM
- Stand-alone emulation of HPC16083 and HPC16064 family
- EPROM and configuration bytes programmable by DATA I/O UNISITE with Pinsite Module, MDS
- Four selectable levels of security to protect on-chip EPROM contents
- UART—full duplex, programmable baud rate
- Four additional 16-bit timer/counters with pulse width modulated outputs
- Four input capture registers
- 52 general purpose I/O lines (memory mapped)
- Commercial (0°C to +70°C), and military (-55°C to +125°C) temperature ranges

Block Diagram (HPC167064 with 16k EPROM shown)

TL/DD/111046-1

Absolute Maximum Ratings

If Military/Aerospace specified devices are required, please contact the National Semiconductor Sales Office/Distributors for availability and specifications.

Total Allowable Source or Sink Current	100 mA
Storage Temperature Range	-65°C to +150°C
Lead Temperature (Soldering, 10 sec.)	300°C

V_{CC} with Respect to GND -0.5V to 7.0V
All Other Pins ($V_{CC} + 0.5V$) to (GND - 0.5V)

Note: Absolute maximum ratings indicate limits beyond which damage to the device may occur. DC and AC electrical specifications are not ensured when operating the device at absolute maximum ratings.

DC Electrical Characteristics

$V_{CC} = 5.0V \pm 5\%$ unless otherwise specified, $T_A = -55^\circ C$ to $+125^\circ C$ for HPC167064 and $V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 0^\circ C$ to $70^\circ C$ for HPC467064

Symbol	Parameter	Test Conditions	Min	Max	Units
I_{CC1}	Supply Current	$V_{CC} = \max, f_{IN} = 20.0 \text{ MHz}$ (Note 1) $V_{CC} = \max, f_{IN} = 2.0 \text{ MHz}$ (Note 1)		70 40	mA mA
I_{CC2}	IDLE Mode Current	$V_{CC} = \max, f_{IN} = 20.0 \text{ MHz}$, (Note 1) $V_{CC} = \max, f_{IN} = 2.0 \text{ MHz}$, (Note 1)		4.5 1	mA mA
I_{CC3}	HALT Mode Current	$V_{CC} = \max, f_{IN} = 0 \text{ kHz}$, (Note 1) $V_{CC} = 2.5V, f_{IN} = 0 \text{ kHz}$, (Note 1)		400 100	μA μA

OUTPUT VOLTAGE LEVELS

V_{OH1} V_{OL1}	Logic High (CMOS) Logic Low (CMOS)	$I_{OH} = -10 \mu A$ (Note 2) $I_{OH} = 10 \mu A$ (Note 2)	$V_{CC} - 0.1$	0.1	V
V_{OH2} V_{OL2}	Port A/B Drive, CK2 (A0-A15, B10, B11, B12, B15)	$I_{OH} = -7 \text{ mA}$ $I_{OL} = 3 \text{ mA}$	2.4	0.4	V
V_{OH3} V_{OL3}	Other Port Pin Drive, \overline{WO} (open drain) (B0-B9, B13, B14, P0-P3)	$I_{OH} = -1.6 \text{ mA}$ (except \overline{WO}) $I_{OL} = 0.5 \text{ mA}$	2.4	0.4	V
V_{OH4} V_{OL4}	ST1 and ST2 Drive	$I_{OH} = -6 \text{ mA}$ $I_{OL} = 1.6 \text{ mA}$	2.4	0.4	V
V_{OH5} V_{OL5}	Port A/B Drive (A0-15, B10, B11, B12, B15) when used as External Address/Data Bus	$I_{OH} = -1 \text{ mA}$ $I_{OL} = 3 \text{ mA}$	2.4	0.4	V
V_{RAM}	RAM Keep-Alive Voltage	(Note 3)	2.5	V_{CC}	V
I_{OZ}	TRI-STATE® Leakage Current	$V_{IN} = 0$ and $V_{IN} = V_{CC}$		± 5	μA

Note 1: I_{CC1} , I_{CC2} , I_{CC3} measured with no external drive (I_{OH} and $I_{OL} = 0$, I_{IH} and $I_{IL} = 0$). I_{CC1} is measured with RESET = GND. I_{CC3} is measured with NMI = V_{CC} . CK1 driven to V_{IH1} and V_{IL1} with rise and fall times less than 10 ns.

Note 2: This is guaranteed by design and not tested.

Note 3: Test duration is 100 ms.

Note 4: The EPROM mode of operation for this device requires high voltage input on pins EXM/ V_{PP} , I3, I4, I5, I6 and I7. This will increase the input leakage current above the normal specification when driven to voltages greater than $V_{CC} + 0.3V$.

*See NORMAL RUNNING MODE.

*See NORMAL RUNNING MODE.

**This maximum frequency is attainable provided that this external baud clock has a duty cycle such that the high period includes two (2) falling edges of the CK2 clock.

Note: $C_L = 40$ pF.

Note 1: These AC Characteristics are guaranteed with external clock drive on CKI having 50% duty cycle and with less than 15 pF load on CKO with rise and fall times (t_{CKIR} and t_{CKIL}) on CKI input less than 2.5 ns.

Note 2: Do not design with this parameter unless CKI is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CKI or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{HLD} falling edge occurring at the latest time can be accepted during the present CPU cycle being executed. If \overline{HLD} falling edge occurs later, t_{HAE} may be as long as $(3t_C + 4 WS + 72t_C + 100)$ depending on the following CPU instruction cycles, its wait states and ready input.

Note 4: $WS = t_{WAIT} \times$ (number of pre-programmed wait states). Minimum and maximum values are calculated at maximum operating frequency, $t_C = 20.00$ MHz, with one wait state programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

Functional Modes of Operation

There are two primary functional modes of operation for the HPC167064.

- EPROM Mode
- Normal Running Mode

EPROM MODE

In the EPROM mode, the HPC167064 is configured to "approximately emulate" a standard NMC27C256 EPROM. Some dissimilarities do exist. The most significant one is that HPC167064 contains only 16 kbytes of programmable memory, rather than the 32 kbytes in 27C256. An HPC167064 in the EPROM mode can be programmed with a Data I/O machine or an HPC-MDS using a programming adapter board.

Given below is the list of functions that can be performed by the user in the EPROM mode.

- Programming

CAUTION: Exceeding 14V on pin 1 (V_{PP}) will damage the HPC167064.

Initially, and after each erasure, all bits of the HPC EPROM are in the "1" state. Data is introduced by selectively programming "0s" into the desired bit locations. Although only "0s" will be programmed, both "1s" and "0s" can be presented in the data word. The only way to change a "0" to a "1" is by ultraviolet light erasure.

- Program/verify EPROM registers

To read data (verify) during the programming process, V_{PP} must be at 13V. When reading data after the programming process, V_{PP} can be either 13V or at V_{CC} .

- Program/verify ECON registers

There are two configuration registers ECON6 and ECON7 to emulate different family members and also to enable/disable different features in the chip. These registers are not mapped in the EPROM user space. These bytes must be programmed through a pointer register ECONA.

To prevent unintentional programming, the ECON6, 7 registers must be programmed with the assistance of this pointer register. ECONA, and externally presented address, both identify the same ECON register may be programmed.

NORMAL RUNNING MODE

In this mode, the HPC167064 executes user software in the normal manner. By default, its architecture imitates that of the HPC16064. It may be configured to emulate the HPC16083. The addressable memory map will be exactly as for the HPC16083. The WATCHDOG function monitors addresses accordingly. Thus, the HPC167064 can be used as a stand-alone emulator for both HPC16064 and HPC16083.

Within this mode, the on-chip EPROM cell acts as read only memory. Each memory fetch is 16-bits wide. The HPC167064 operates to 20 MHz with 1 wait state for the on-chip memory.

The HPC167064 emulates all functional modes of operation for the HPC16064 and HPC16083, except as described here.

- The value of EXM is latched on the rising edge of RESET. Thus, the user may not switch from ROMed to ROMless operation or vice-versa, without another RESET pulse.
- The security logic can be used to control access to the on-chip EPROM. This feature is unique to the HPC167064. There is no corresponding mode of operation on the HPC16064 or the HPC16083.
- Specific inputs are allowed to be driven at high voltage (13V) to configure the device for programming. These high voltage inputs are unique to the HPC167064. The same inputs cannot be driven to high voltage on the HPC16064 and HPC16083 without damage to the part.
- The Port D input structure on this device is slightly different from the masked ROM HPC16083 and HPC16064. V_{IH2} min and V_{IL2} max are the same as for the masked ROM HPC16083 and HPC16064. There is a V_{IH2} max requirement for this device equal to $V_{CC} + 0.05V$. There is also a V_{IL2} min requirement for this device equal to $GND-0.05V$. The V_{IH2} max and V_{IL2} min requirement for the masked ROM devices is the Absolute Maximum Ratings of $V_{CC} + 0.5V$ and $GND-0.5V$ respectively.
- The D.C. Electrical Characteristics and A.C. Electrical Characteristics for the HPC167064, where $T_A = -55^{\circ}C$ to $+125^{\circ}C$, are guaranteed over a reduced operating voltage range of $V_{CC} \pm 5\%$. This is different from the masked ROM devices that it simulates which is $V_{CC} \pm 10\%$. These characteristics for the HPC467064, where $T_A = -0^{\circ}C$ to $+70^{\circ}C$, are guaranteed over the masked ROM operating voltage range which is $V_{CC} \pm 10\%$.
- In addition to the reduced operating voltage range for the HPC167064, the A.C. timing parameter t_{UDH} is required to be a minimum value of 25 ns. The masked ROM devices require a minimum t_{UDH} of 20 ns. This A.C. timing parameter for the HPC467064 is required to be the same as the masked ROM devices.

HPC167064 EPROM SECURITY

The HPC167064 includes security logic to provide READ and WRITE protection of the on-chip EPROM. These defined privileges are intended to deter theft, alteration, or unintentional destruction of user code. Two bits are used to define four levels of security on the HPC167064 to control access to on-chip EPROM.

Security Level 3

This is the default configuration of an erased HPC167064. READ and WRITE accesses to the on-chip EPROM or ECON registers may be accomplished without constraint in EPROM mode. READ accesses to the on-chip EPROM may be accomplished without constraint in NORMAL RUNNING mode.

Functional Modes of Operation (Continued)

Security Level 2

This security level prevents programming of the on-chip EPROM or the ECON registers thereby providing WRITE protection. Read accesses to the on-chip EPROM or ECON registers may be accomplished without constraint in EPROM mode. Read accesses to the on-chip EPROM may be accomplished without constraint in NORMAL RUNNING mode.

Security Level 1

This security level prevents programming of the on-chip EPROM or ECON registers—thereby providing registers write protection. Read accesses to the on-chip ECON-registers may be accomplished without constraint in EPROM mode. Read accesses to the on-chip EPROM will produce ENCRYPTED data in EPROM. READ accesses to the on-chip EPROM, during NORMAL RUNNING mode, are subject to **Runtime Memory Protection**. Under Runtime Memory Protection, only instruction opcodes stored within the on-chip EPROM are allowed to access the EPROM as operand. If any other instruction opcode attempts to use the contents of EPROM as an operand, it will receive the hex value "FF". The Runtime Memory Protection feature is designed to prevent hostile software, running from external memory or on-chip RAM, from reading secured EPROM data. Transfers of control into, or out of the on-chip EPROM (such as jump or branch) are not affected by Runtime Memory Protection. Interrupt vector fetches from EPROM proceed normally, and are not affected by Runtime Memory Protection.

Security Level 0

This security level prevents programming of the on-chip EPROM or ECON registers, thereby providing write protection. Read accesses to the on-chip ECON registers may be accomplished without constraint in EPROM mode. READ accesses to the on-chip EPROM are NOT ALLOWED in EPROM mode. Such accesses will return data value "FF" hex. Runtime Memory Protection is enforced as in security level 1.

These four levels of security help ensure that the user EPROM code is not tampered with in a test fixture and that code executing from RAM or external memory does not dump the user algorithm.

Erasure Characteristics

The erasure characteristics of the HPC167064 are such that erasure begins to occur when exposed to light with wavelengths shorter than approximately 4000 Angstroms (Å). It should be noted that sunlight and certain types of fluorescent lamps have wavelengths in the 3000Å–4000Å range.

After programming, opaque labels should be placed over the HPC167064's window to prevent unintentional erasure. Covering the window will also prevent temporary functional failure due to the generation of photo currents.

The recommended erasure procedure for the HPC167064 is exposure to short wave ultraviolet light which has a wavelength of 2537 Angstroms (Å). The integrated dose (i.e., UV intensity × exposure time) for erasure should be a minimum of 30W-sec/cm².

The HPC167064 should be placed within 1 inch of the lamp tubes during erasure. Some lamps have a filter on their tubes which should be removed before erasure. The erasure time table shows the minimum HPC167064 erasure time for various light intensities.

An erasure system should be calibrated periodically. The distance from lamp to unit should be maintained at one inch. The erasure time increases as the square of the distance. (If distance is doubled the erasure time increases by a factor of 4.) Lamps lose intensity as they age. When a lamp is changed, the distance has changed or the lamp has aged, the system should be checked to make certain full erasure is occurring.

Incomplete erasure will cause symptoms that can be misleading. Programmers, components, and even system designs have been erroneously suspected when incomplete erasure was the problem.

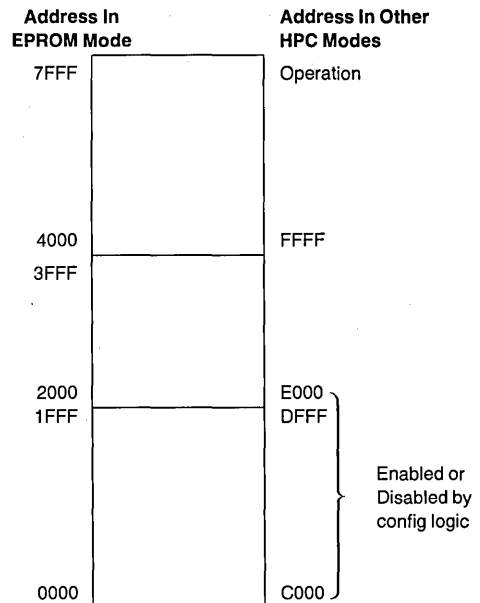

Minimum HPC167064 Erasure Time

Light Intensity (Micro-Watts/cm ²)	Erasure Time (Minutes)
15,000	36
10,000	50

Memory Map of the HPC167064

The HPC167064 has 256 bytes of on-chip user RAM and chip registers located at address 0000–01FF that is always enabled, and 256 bytes of on-chip RAM located at 0200–02FF that can be enabled or disabled. It has 8 kbytes of on-chip EPROM located at address 0E000–0FFFF that is always enabled and 8 kbytes of EPROM located at address 0C000–0DFFF that can be enabled or disabled.

The ECON6 contains two bits ROM0 and RAM0. When these bits are "1" (erased default), full 16 kbytes of ROM and 512 bytes of RAM are enabled. Programming a "0" to these bits disables the lower 8k for the EPROM and upper 256 bytes for the RAM. The ECON registers are only accessible to the user during EPROM mode.

Pin Descriptions

The HPC167064 is available only in 68-pin LDCC package.

I/O PORTS

Port A is a 16-bit bidirectional I/O port with a data direction register to enable each separate pin to be individually defined as an input or output. When accessing external memory, port A is used as the multiplexed address/data bus.

Port B is a 16-bit port with 12 bits of bidirectional I/O similar in structure to Port A. Pins B10, B11, B12 and B15 are general purpose outputs only in this mode. Port B may also be configured via a 16-bit function register BFUN to individually allow each pin to have an alternate function.

B0:	TDX	UART Data Output
B1:		
B2:	CKX	UART Clock (Input or Output)
B3:	T2IO	Timer2 I/O Pin
B4:	T3IO	Timer3 I/O Pin
B5:	SO	MICROWIRE/PLUS Output
B6:	SK	MICROWIRE/PLUS Clock (Input or Output)
B7:	$\overline{\text{FLDA}}$	Hold Acknowledge Output
B8:	TS0	Timer Synchronous Output
B9:	TS1	Timer Synchronous Output
B10:	UA0	Address 0 Input for UPI Mode
B11:	$\overline{\text{WRRDY}}$	Write Ready Output for UPI Mode
B12:		
B13:	TS2	Timer Synchronous Output
B14:	TS3	Timer Synchronous Output
B15:	$\overline{\text{RDRDY}}$	Read Ready Output for UPI Mode

When accessing external memory, four bits of port B are used as follows:

B10:	ALE	Address Latch Enable Output
B11:	$\overline{\text{WR}}$	Write Output
B12:	$\overline{\text{HBE}}$	High Byte Enable Output/Input (sampled at reset)
B15:	$\overline{\text{RD}}$	Read Output

Port I is an 8-bit input port that can be read as general purpose inputs and is also used for the following functions:

I0:		
I1:	NMI	Nonmaskable Interrupt Input
I2:	INT2	Maskable Interrupt/Input Capture/ $\overline{\text{URD}}$
I3:	INT3	Maskable Interrupt/Input Capture/ $\overline{\text{UWR}}$
I4:	INT4	Maskable Interrupt/Input Capture
I5:	SI	MICROWIRE/PLUS Data Input
I6:	RDX	UART Data Input
I7:		

Port D is an 8-bit input port that can be used as general purpose digital inputs.

Port P is a 4-bit output port that can be used as general purpose data, or selected to be controlled by timers 4 through 7 in order to generate frequency, duty cycle and pulse width modulated outputs.

POWER SUPPLY PINS

VCC1 and VCC2	Positive Power Supply
GND	Ground for On-Chip Logic
DGND	Ground for Output Buffers

Note: There are two electrically connected VCC pins on the chip, GND and DGND are electrically isolated. Both VCC pins and both ground pins must be used.

CLOCK PINS

CKI	The Chip System Clock Input
CKO	The Chip System Clock Output (inversion of CKI)

Pins CKI and CKO are usually connected across an external crystal.

CK2	Clock Output (CKI divided by 2)
-----	---------------------------------

OTHER PINS

$\overline{\text{WO}}$	This is an active low open drain output that signals an illegal situation has been detected by the WATCHDOG logic.
ST1	Bus Cycle Status Output: indicates first opcode fetch.
ST2	Bus Cycle Status Output: indicates machine states (skip, interrupt and first instruction cycle).
$\overline{\text{RESET}}$	is an active low input that forces the chip to re-start and sets the ports in a TRI-STATE mode.
RDY/ $\overline{\text{HLD}}$	has two uses, selected by a software bit. It's either an input to extend the bus cycle for slower memories, or a HOLD request input to put the bus in a high impedance state for DMA purposes.
NC	(no connection) do not connect anything to this pin.
EXM	Has two uses. External memory enable (active high) which disables internal EPROM and maps it to external memory, and is V _{PP} during EPROM mode.
EI	External interrupt with vector address FFF1:FFF0. (Rising/falling edge or high/low level sensitive). Alternately can be configured as 4th input capture.
$\overline{\text{EXUI}}$	External interrupt which is internally OR'ed with the UART interrupt with vector address FFF3:FFF2 (Active Low).

Ports A & B

The highly flexible A and B ports are similarly structured. The Port A (see *Figure 10*), consists of a data register and a direction register. Port B (see *Figures 11* thru *Figure 13*) has an alternate function register in addition to the data and direction registers. All the control registers are read/write registers.

The associated direction registers allow the port pins to be individually programmed as inputs or outputs. Port pins selected as inputs are placed in a TRI-STATE mode by resetting corresponding bits in the direction register.

A write operation to a port pin configured as an input causes the value to be written into the data register, a read operation returns the value of the pin. Writing to port pins configured as outputs causes the pins to have the same value, reading the pins returns the value of the data register.

Primary and secondary functions are multiplexed onto Port B through the alternate function register (BFUN). The secondary functions are enabled by setting the corresponding bits in the BFUN register.

Operating Modes

To offer the user a variety of I/O and expanded memory options, the HPC167064 has four operating modes. The various modes of operation are determined by the state of both the EXM pin and the EA bit in the PSW register. The state of the EXM pin determines whether on-chip EPROM will be accessed or external memory will be accessed within the address range of the on-chip EPROM. The on-chip EPROM range of the HPC167064 is C000 to FFFF (16 kbytes).

A logic "0" state on the EXM pin will cause the HPC device to address on-chip EPROM when the Program Counter (PC) contains addresses within the on-chip EPROM address range. A logic "1" state on the EXM pin will cause the HPC device to address memory that is external to the HPC when the PC contains on-chip EPROM addresses. The function of the EA bit is to determine the legal addressing range of the HPC device. A logic "0" state in the EA bit of the PSW register does two things—addresses are limited to the on-chip EPROM range and on-chip RAM and Register range, and the "illegal address detection" feature of the WATCH-

DOG logic is engaged. A logic "1" in the EA bit enables accesses to be made anywhere within the 64 kbytes address range and the "illegal address detection" feature of the WATCHDOG logic is disabled.

All HPC devices can be used with external memory. External memory may be any combination of RAM and EPROM. Both 8-bit and 16-bit external data bus modes are available. Upon entering an operating mode in which external memory is used, Port A becomes the Address/Data bus. Four pins of Port B become the control lines ALE, \overline{RD} , \overline{WR} and \overline{HBE} . The High Byte Enable pin (\overline{HBE}) is used in 16-bit mode to select high order memory bytes. The \overline{RD} and \overline{WR} signals are only generated if the selected address is off-chip. The 8-bit mode is selected by pulling \overline{HBE} high at reset. If \overline{HBE} is left floating or connected to a memory device chip select at reset, the 16-bit mode is entered. The following sections describe the operating modes of the HPC167064.

Note: The HPC devices use 16-bit words for stack memory. Therefore, when using the 8-bit mode, User's Stack must be in internal RAM.

HPC167064 Operating Modes

SINGLE CHIP NORMAL MODE

In this mode, the HPC167064 functions as a self-contained microcomputer (see *Figure 14*) with all memory (RAM and EPROM) on-chip. It can address internal memory only, consisting of 16 kbytes of EPROM (C000 to FFFF) and 512 bytes of on-chip RAM and Registers (0000 to 02FF). The "illegal address detection" feature of the WATCHDOG is enabled in the Single-Chip Normal mode and a WATCHDOG Output (\overline{WO}) will occur if an attempt is made to access addresses that are outside of the on-chip EPROM and RAM range of the device. Ports A and B are used for I/O functions and not for addressing external memory. The EXM pin and the EA bit of the PSW register must both be logic "0" to enter the Single-Chip Normal mode.

EXPANDED NORMAL MODE

The Expanded Normal mode of operation enables the HPC167064 to address external memory in addition to the on-chip ROM and RAM (see Table I). WATCHDOG illegal address detection is disabled and memory accesses may be made anywhere in the 64 kbyte address range without triggering an illegal address condition. The Expanded Normal mode is entered with the EXM pin pulled low (logic "0") and setting the EA bit in the PSW register to "1".

TABLE I. HPC167064 Operating Modes

Operating Mode	EXM Pin	EA Bit	Memory Configuration
Single-Chip Normal	0	0	C000–FFFF On-Chip
Expanded Normal	0	1	C000–FFFF On-Chip 0300–BFFF Off-Chip
Single-Chip ROMless	1	0	C000–FFFF Off-Chip
Expanded ROMless	1	1	0300–FFFF Off-Chip

SINGLE-CHIP ROMless MODE

In this mode, the on-chip EPROM of the HPC167064 is not used. The address space corresponding to the on-chip EPROM is mapped into external memory so 16k of external memory may be used with the HPC167064 (see Table I). The WATCHDOG circuitry detects illegal addresses (addresses not within the on-chip EPROM and RAM range). The Single-Chip ROMless mode is entered when the EXM pin is pulled high (logic "1") and the EA bit is logic "0".

EXPANDED ROM MODE

This mode of operation is similar to Single-Chip ROMless mode in that no on-chip ROM is used, however, a full 64 kbytes of external memory may be used. The "illegal address detection" feature of WATCHDOG is disabled. The EXM pin must be pulled high (logic "1") and the EA bit in the PSW register set to "1" to enter this mode.

Wait States

The internal EPROM can be accessed at the maximum operating frequency with one wait state. With 0 wait states, internal ROM accesses are limited to $\frac{2}{3} f_C$ max. The HPC167064 provides four software selectable Wait States that allow access to slower memories. The Wait States are selected by the state of two bits in the PSW register. Additionally, the RDY input may be used to extend the instruction cycle, allowing the user to interface with slow memories and peripherals.

FIGURE 15. Single-Chip Mode

TL/DD/11046-23

Power Save Modes

Two power saving modes are available on the HPC167064: HALT and IDLE. In the HALT mode, all processor activities are stopped. In the IDLE mode, the on-board oscillator and timer T0 are active but all other processor activities are stopped. In either mode, all on-board RAM, registers and I/O are unaffected.

HALT MODE

The HPC167064 is placed in the HALT mode under software control by setting bits in the PSW. All processor activities, including the clock and timers, are stopped. In the HALT mode, power requirements for the HPC167064 are minimal and the applied voltage (V_{CC}) may be decreased without altering the state of the machine. There are two ways of exiting the HALT mode: via the \overline{RESET} or the NMI. The \overline{RESET} input reinitializes the processor. Use of the NMI input will generate a vectored interrupt and resume operation from that point with no initialization. The HALT mode can be enabled or disabled by means of a control register HALT enable. To prevent accidental use of the HALT mode the HALT enable register can be modified only once.

IDLE MODE

The HPC167064 is placed in the IDLE mode through the PSW. In this mode, all processor activity, except the on-board oscillator and Timer T0, is stopped. As with the HALT mode, the processor is returned to full operation by the \overline{RESET} or NMI inputs, but without waiting for oscillator stabilization. A timer T0 overflow will also cause the HPC167064 to resume normal operation.

Note: If an NMI interrupt is received during the instruction which puts the device in Halt or Idle Mode, the device will enter that power saving mode. The interrupt will be held pending until the device exits that power saving mode. When exiting Idle mode via the T0 overflow, the NMI interrupt will be serviced when the device exits Idle. If another NMI interrupt is received during either Halt or Idle the processor will exit the power saving mode and vector to the interrupt address.

HPC167064 Interrupts

Complex interrupt handling is easily accomplished by the HPC167064's vectored interrupt scheme. There are eight possible interrupt sources as shown in Table II.

HPC167064 Interrupts (Continued)

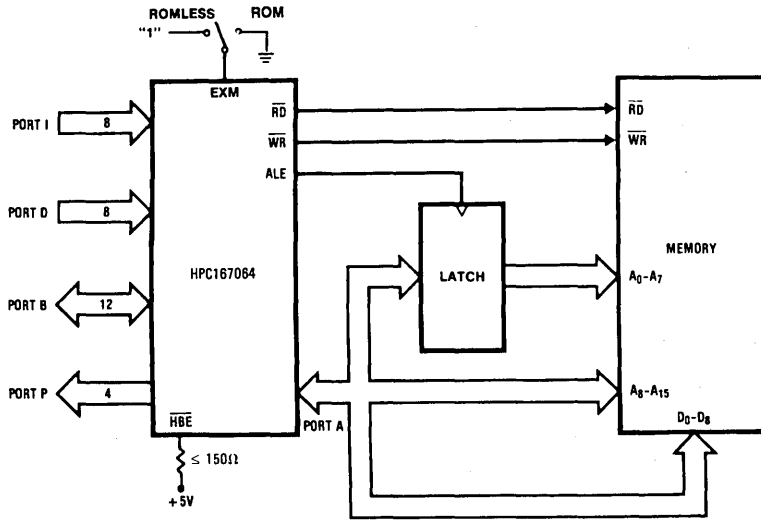

FIGURE 16. 8-Bit External Memory

TL/DD/11046-24

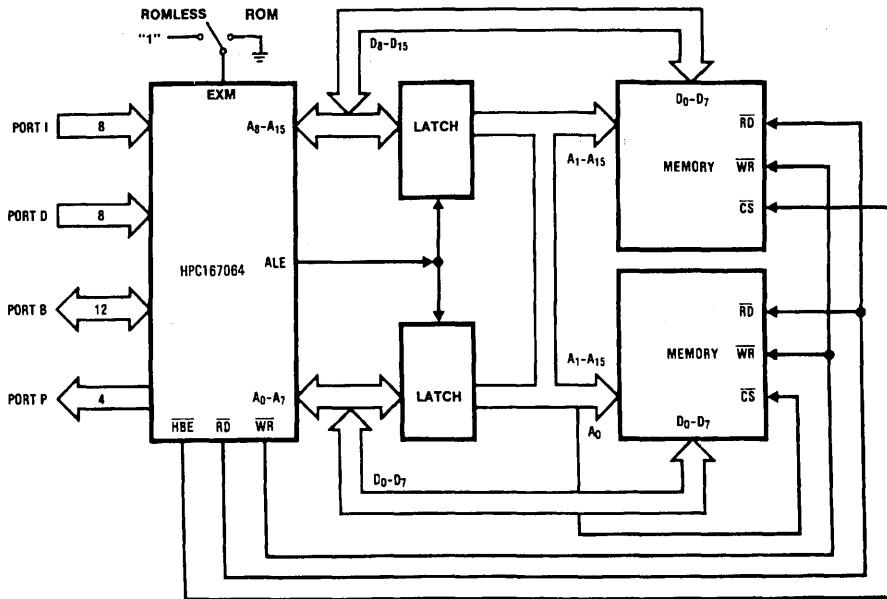

FIGURE 17. 16-Bit External Memory

TL/DD/11046-25

HPC167064 Interrupts (Continued)

TABLE II. Interrupts

Vector Address	Interrupt Source	Arbitration Ranking
FFFF:FFFE	RESET	0
FFFD:FFFC	Nonmaskable external on rising edge of I1 pin	1
FFFB:FFFA	External interrupt on I2 pin	2
FFF9:FFF8	External interrupt on I3 pin	3
FFF7:FFF6	External interrupt on I4 pin	4
FFF5:FFF4	Overflow on internal timers	5
FFF3:FFF2	Internal on the UART transmit/receive complete or external on EXUI	6
FFF1:FFF0	External interrupt on EI pin	7

Interrupt Arbitration

The HPC167064 contains arbitration logic to determine which interrupt will be serviced first if two or more interrupts occur simultaneously. The arbitration ranking is given in Table II. The interrupt on RESET has the highest rank and is serviced first.

Interrupt Processing

Interrupts are serviced after the current instruction is completed except for the RESET, which is serviced immediately. RESET and EXUI are level-LOW-sensitive interrupts and EI is programmable for edge-(RISING or FALLING) or level-(HIGH or LOW) sensitivity. All other interrupts are edge-sensitive. NMI is positive-edge sensitive. The external interrupts on I2, I3 and I4 can be software selected to be rising or falling edge. External interrupt (EXUI) is shared with UART interrupt. This interrupt is level-low sensitive. To select this interrupt disable the ERI and ETI UART interrupt bits in the ENUI register. To select the UART interrupt leave this pin floating or tie it high.

Interrupt Control Registers

The HPC167064 allows the various interrupt sources and conditions to be programmed. This is done through the various control registers. A brief description of the different control registers is given below.

INTERRUPT ENABLE REGISTER (ENIR)

RESET and the External Interrupt on I1 are non-maskable interrupts. The other interrupts can be individually enabled or disabled. Additionally, a Global Interrupt Enable Bit in the ENIR Register allows the Maskable interrupts to be collectively enabled or disabled. Thus, in order for a particular interrupt to request service, both the individual enable bit and the Global Interrupt bit (GIE) have to be set.

INTERRUPT PENDING REGISTER (IRPD)

The IRPD register contains a bit allocated for each interrupt vector. The occurrence of specified interrupt trigger conditions causes the appropriate bit to be set. There is no indication of the order in which the interrupts have been received. The bits are set independently of the fact that the interrupts may be disabled. IRPD is a Read/Write register. The bits corresponding to the maskable, external interrupts are normally cleared by the HPC167064 after servicing the interrupts.

For the interrupts from the on-board peripherals, the user has the responsibility of resetting the interrupt pending flags through software.

The NMI bit is read only and I2, I3, and I4 are designed as to only allow a zero to be written to the pending bit (writing a one has no affect). A LOAD IMMEDIATE instruction is to be the only instruction used to clear a bit or bits in the IRPD register. This allows a mask to be used, thus ensuring that the other pending bits are not affected.

INTERRUPT CONDITION REGISTER (IRCD)

Three bits of the register select the input polarity of the external interrupt on I2, I3, and I4.

Servicing the Interrupts

The interrupt, once acknowledged, pushes the program counter (PC) onto the stack thus incrementing the stack pointer (SP) twice. The Global Interrupt Enable bit (GIE) is copied into the CGIE bit of the PSW register; it is then reset, thus disabling further interrupts. The program counter is loaded with the contents of the memory at the vector address and the processor resumes operation at this point. At the end of the interrupt service routine, the user does a RETI instruction to pop the stack and re-enable interrupts if the CGIE bit is set, or RET to just pop the stack if the CGIE bit is clear, and then returns to the main program. The GIE bit can be set in the interrupt service routine to nest interrupts if desired. Figure 17 shows the Interrupt Enable Logic.

RESET

The RESET input initializes the processor and sets Ports A and B in the TRI-STATE condition and Port P in the LOW state. RESET is an active-low Schmitt trigger input. The processor vectors to FFFF:FFFE and resumes operation at the address contained at that memory location (which must correspond to an on board location). The Reset vector address must be between C000 and FFFF when emulating the HPC16064 and between E000 and FFFF when emulating the HPC16003.

Timer Overview

The HPC167064 contains a powerful set of flexible timers enabling the HPC167064 to perform extensive timer functions not usually associated with microcontrollers. The HPC167064 contains nine 16-bit timers. Timer T0 is a free-running timer, counting up at a fixed CKI/16

4-150

FIGURE 18. Block Diagram of Interrupt Logic

Timer Overview (Continued)

(Clock Input/16) rate. It is used for WATCHDOG logic, high speed event capture, and to exit from the IDLE mode. Consequently, it cannot be stopped or written to under software control. Timer T0 permits precise measurements by means of the capture registers I2CR, I3CR, and I4CR. A control bit in the register TMMODE configures timer T1 and its associated register R1 as capture registers I3CR and I2CR. The capture registers I2CR, I3CR, and I4CR respectively, record the value of timer T0 when specific events occur on the interrupt pins I2, I3, and I4. The control register IRCD programs the capture registers to trigger on either a rising edge or a falling edge of its respective input. The specified edge can also be programmed to generate an interrupt (see Figure 18).

The HPC167064 provides an additional 16-bit free running timer, T8, with associated input capture register EICR (External Interrupt Capture Register) and Configuration Register, EICON. EICON is used to select the mode and edge of the EI pin. EICR is a 16-bit capture register which records the value of T8 (which is identical to T0) when a specific event occurs on the EI pin.

The timers T2 and T3 have selectable clock rates. The clock input to these two timers may be selected from the following two sources: an external pin, or derived internally by

dividing the clock input. Timer T2 has additional capability of being clocked by the timer T3 underflow. This allows the user to cascade timers T3 and T2 into a 32-bit timer/counter. The control register DIVBY programs the clock input to timers T2 and T3 (see Figure 19).

The timers T1 through T7 in conjunction with their registers form Timer-Register pairs. The registers hold the pulse duration values. All the Timer-Register pairs can be read from or written to. Each timer can be started or stopped under software control. Once enabled, the timers count down, and upon underflow, the contents of its associated register are automatically loaded into the timer.

SYNCHRONOUS OUTPUTS

The flexible timer structure of the HPC167064 simplifies pulse generation and measurement. There are four synchronous timer outputs (TS0 through TS3) that work in conjunction with the timer T2. The synchronous timer outputs can be used either as regular outputs or individually programmed to toggle on timer T2 underflows (see Figure 19).

Timer/register pairs 4-7 form four identical units which can generate synchronous outputs on Port P (see Figure 20).

FIGURE 19. Timers T0, T1 and T8 with Four Input Capture Registers

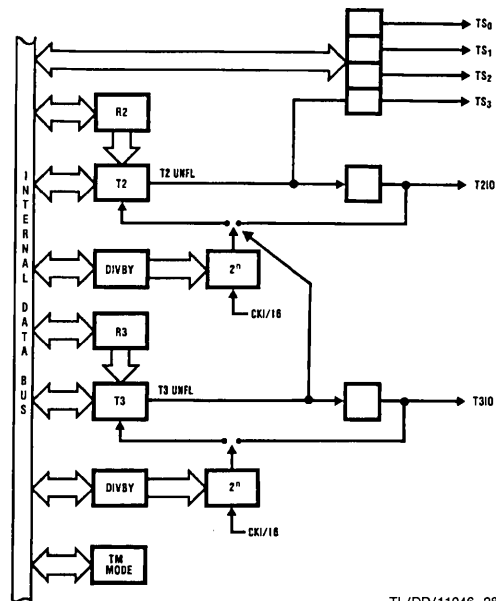

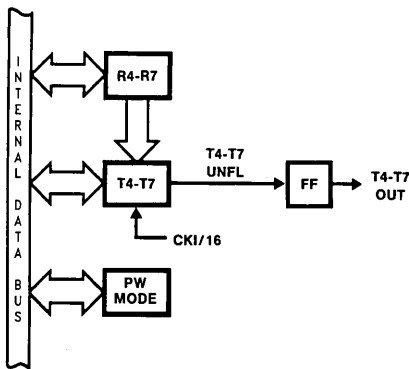

FIGURE 20. Timers T2-T3 Block

Timer Overview (Continued)

Maximum output frequency for any timer output can be obtained by setting timer/register pair to zero. This then will produce an output frequency equal to $\frac{1}{2}$ the frequency of the source used for clocking the timer.

Timer Registers

There are four control registers that program the timers. The divide by (DIVBY) register programs the clock input to timers T2 and T3. The timer mode register (TMMODE) contains control bits to start and stop timers T1 through T3. It also contains bits to latch, acknowledge and enable interrupts from timers T0 through T3. The control register PWMODE similarly programs the pulse width timers T4 through T7 by allowing them to be started, stopped, and to latch and enable interrupts on underflows. The PORTP register contains bits to preset the outputs and enable the synchronous timer output functions.

TL/DD/11046-29
FIGURE 21. Timers T4-T7 Block

Timer Applications

The use of Pulse Width Timers for the generation of various waveforms is easily accomplished by the HPC167064.

Frequencies can be generated by using the timer/register pairs. A square wave is generated when the register value is a constant. The duty cycle can be controlled simply by changing the register value.

Synchronous outputs based on Timer T2 can be generated on the 4 outputs TS0-TS3. Each output can be individually programmed to toggle on T2 underflow. Register R2 contains the time delay between events. Figure 22 is an example of synchronous pulse train generation.

TL/DD/11046-31
FIGURE 22. Square Wave Frequency Generation

WATCHDOG Logic

The WATCHDOG Logic monitors the operations taking place and signals upon the occurrence of any illegal activity.

TL/DD/11046-30
FIGURE 23. Synchronous Pulse Generation

The illegal conditions that trigger the WATCHDOG logic are potentially infinite loops and illegal addresses. Should the WATCHDOG register not be written to before Timer T0 overflows twice, or more often than once every 4096 counts, an infinite loop condition is assumed to have occurred. An illegal condition also occurs when the processor generates an illegal address when in the Single-Chip modes.* Any illegal condition forces the WATCHDOG Output (W \bar{O}) pin low. The W \bar{O} pin is an open drain output and can be connected to the RESET or NMI inputs or to the users external logic.

*Note: See Operating Modes for details.

MICROWIRE/PLUS

MICROWIRE/PLUS is used for synchronous serial data communications (see Figure 23). MICROWIRE/PLUS has an 8-bit parallel-loaded, serial shift register using SI as the input and SO as the output. SK is the clock for the serial shift register (SIO). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. A DONE flag indicates when the data shift is completed.

The MICROWIRE/PLUS capability enables it to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., A/D converters, display drivers, EEPROMs).

MICROWIRE/PLUS Operation

The HPC167064 can enter the MICROWIRE/PLUS mode as the master or a slave. A control bit in the IRCD register determines whether the HPC167064 is the master or slave. The shift clock is generated when the HPC167064 is configured as a master. An externally generated shift clock on the SK pin is used when the HPC167064 is configured as a slave. When the HPC167064 is a master, the DIVBY register programs the frequency of the SK clock. The DIVBY register allows the SK clock frequency to be programmed in 15 selectable steps from 64 Hz to 1 MHz with CKI at 16.0 MHz.

The contents of the SIO register may be accessed through any of the memory access instructions. Data waiting to be transmitted in the SIO register is clocked out on the falling edge of the SK clock. Serial data on the SI pin is clocked in on the rising edge of the SK clock.

MICROWIRE/PLUS Application

Figure 24 illustrates a MICROWIRE/PLUS arrangement for an automotive application. The microcontroller-based system could be used to interface to an instrument cluster and various parts of the automobile. The diagram shows two HPC167064 microcontrollers interconnected to other MICROWIRE peripherals. HPC167064 1 is set up as the master and initiates all data transfers. HPC167064 2 is set up as a slave answering to the master.

The master microcontroller interfaces the operator with the system and could also manage the instrument cluster in an automotive application. Information is visually presented to the operator by means of a LCD display controlled by the COP472 display driver. The data to be displayed is sent serially to the COP472 over the MICROWIRE/PLUS link. Data such as accumulated mileage could be stored and retrieved from the EEPROM COP494. The slave HPC167064 could be used as a fuel injection processor and generate timing signals required to operate the fuel valves. The master processor could be used to periodically send updated values to the slave via the MICROWIRE/PLUS link. To speed up the response, chip select logic is implemented by connecting an output from the master to the external interrupt input on the slave.

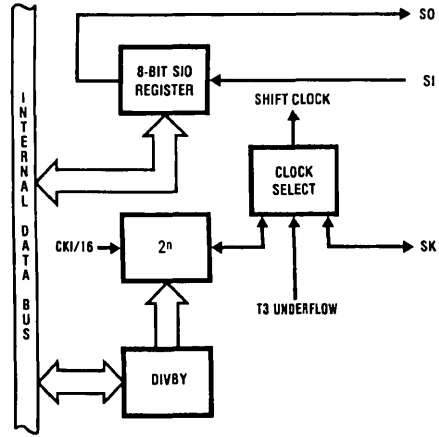

FIGURE 24. MICROWIRE/PLUS

TL/DD/11046-32

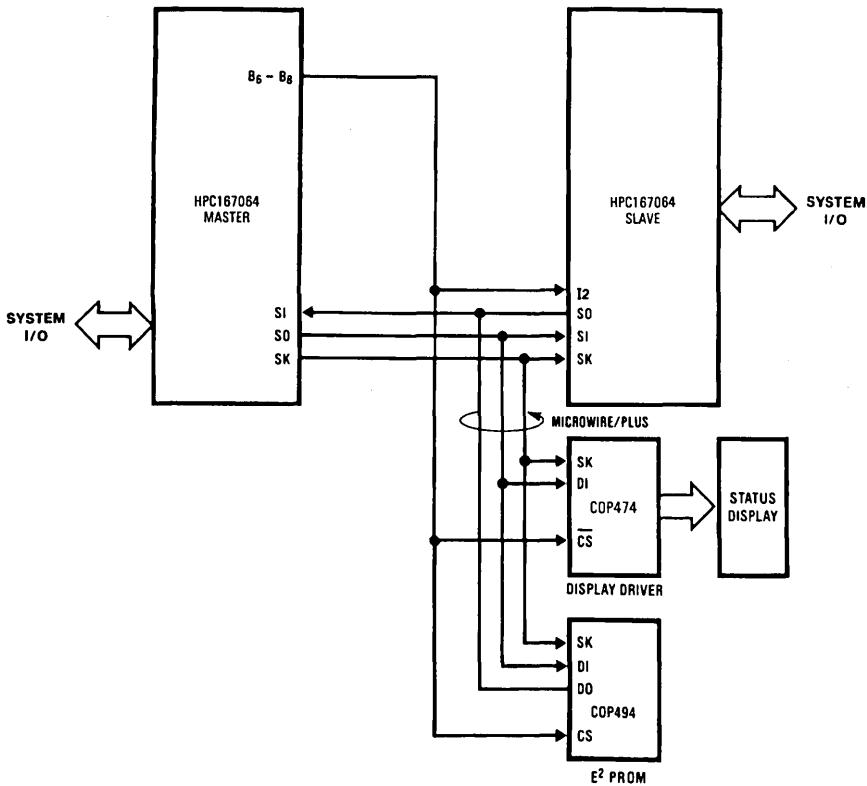

FIGURE 25. MICROWIRE/PLUS Application

TL/DD/11046-33

HPC167064 UART

The HPC167064 contains a software programmable UART. The UART (see *Figure 25*) consists of a transmit shift register, a receiver shift register and five addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR) and a UART interrupt and clock source register (ENUI). The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (8 or 9 bits) and the value of the ninth bit in transmission. The ENUR register flags framing and data overrun errors while the UART is receiving. Other functions of the ENUR register include saving the ninth bit received in the data frame and enabling or disabling the UART's Attention Mode of operation. The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits and enabling or disabling transmit and receive interrupts.

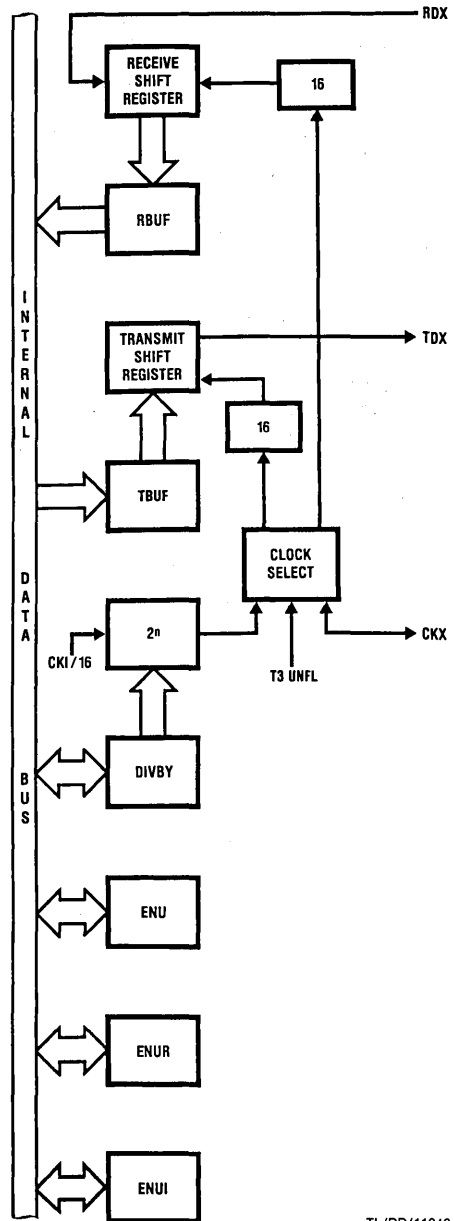

The baud rate clock for the Receiver and Transmitter can be selected for either an internal or external source using two bits in the ENUI register. The internal baud rate is programmed by the DIVBY register. The baud rate may be selected from a range of 8 Hz to 128 kHz in binary steps or T3 underflow. By selecting a 9.83 MHz crystal, all standard baud rates from 75 baud to 38.4 kBaud can be generated. The external baud clock source comes from the CKX pin. The Transmitter and Receiver can be run at different rates by selecting one to operate from the internal clock and the other from an external source.

The HPC167064 UART supports two data formats. The first format for data transmission consists of one start bit, eight data bits and one or two stop bits. The second data format for transmission consists of one start bit, nine data bits, and one or two stop bits. Receiving formats differ from transmission only in that the Receiver always requires only one stop bit in a data frame.

UART Wake-Up Mode

The HPC167064 UART features a Wake-Up Mode of operation. This mode of operation enables the HPC167064 to be networked with other processors. Typically in such environments, the messages consist of addresses and actual data. Addresses are specified by having the ninth bit in the data frame set to 1. Data in the message is specified by having the ninth bit in the data frame reset to 0.

The UART monitors the communication stream looking for addresses. When the data word with the ninth bit set is received, the UART signals the HPC167064 with an interrupt. The processor then examines the content of the receiver buffer to decide whether it has been addressed and whether to accept subsequent data.

TL/DD/11046-34

FIGURE 26. UART Block Diagram

Universal Peripheral Interface

The Universal Peripheral Interface (UPI) allows the HPC167064 to be used as an intelligent peripheral to another processor. The UPI could thus be used to tightly link two HPC167064's and set up systems with very high data exchange rates. Another area of application could be where a HPC167064 is programmed as an intelligent peripheral to a host system such as the Series 32000[®] microprocessor. *Figure 26* illustrates how a HPC167064 could be used as an intelligent peripheral for a Series 32000-based application.

The interface consists of a Data Bus (port A), a Read Strobe (\overline{URD}), a Write Strobe (\overline{UWR}), a Read Ready Line (\overline{RDRDY}), a Write Ready Line (\overline{WRRDY}) and one Address Input (UA0). The data bus can be either eight or sixteen bits wide.

The \overline{URD} and \overline{UWR} inputs may be used to interrupt the HPC167064. The \overline{RDRDY} and \overline{WRRDY} outputs may be used to interrupt the host processor.

The UPI contains an Input Buffer (IBUF), an Output Buffer (OBUF) and a Control Register (UPIC). In the UPI mode, Port A on the HPC167064 is the data bus. UPI can only be used if the HPC167064 is in the Single-Chip mode.

Shared Memory Support

Shared memory access provides a rapid technique to exchange data. It is effective when data is moved from a peripheral to memory or when data is moved between blocks of memory. A related area where shared memory access proves effective is in multiprocessing applications where two CPUs share a common memory block. The HPC167064 supports shared memory access with two pins. The pins are the $\overline{RDY}/\overline{HLD}$ input pin and the \overline{HLDA} output pin. The user can software select either the Hold or Ready function by the state of a control bit. The \overline{HLDA} output is multiplexed onto Port B.

The host uses DMA to interface with the HPC167064. The host initiates a data transfer by activating the \overline{HLD} input of the HPC167064. In response, the HPC167064 places its system bus in a TRI-STATE Mode, freeing it for use by the host. The host waits for the acknowledge signal (\overline{HLDA}) from the HPC167064 indicating that the system bus is free. On receiving the acknowledge, the host can rapidly transfer data into, or out of, the shared memory by using a conventional DMA controller. Upon completion of the message transfer, the host removes the HOLD request and the HPC167064 resumes normal operations.

To insure proper operation, the interface logic shown is recommended as the means for enabling and disabling the user's bus. *Figure 27* illustrates an application of the shared memory interface between the HPC167064 and a Series 32000 system.

Memory

The HPC167064 has been designed to offer flexibility in memory usage. A total address space of 64 kbytes can be addressed with 8 kbytes of EPROM and 512 bytes of RAM available on the chip itself. The EPROM may contain program instructions, constants or data. The EPROM and RAM share the same address space allowing instructions to be executed out of RAM.

Program memory addressing is accomplished by the 16-bit program counter on a byte basis. Memory can be addressed directly by instructions or indirectly through the B, X and SP registers. Memory can be addressed as words or bytes. Words are always addressed on even-byte boundaries. The HPC167064 uses memory-mapped organization to support registers, I/O and on-chip peripheral functions.

The HPC167064 memory address space extends to 64 kbytes and registers and I/O are mapped as shown in Table III and Table IV.

Design Considerations (Continued)

Designs using the HPC family of 16-bit high speed CMOS microcontrollers need to follow some general guidelines on usage and board layout.

Floating inputs are a frequently overlooked problem. CMOS inputs have extremely high impedance and, if left open, can float to any voltage. You should thus tie unused inputs to V_{CC} or ground, either through a resistor or directly. Unlike the inputs, unused output should be left floating to allow the output to switch without drawing any DC current.

To reduce voltage transients, keep the supply line's parasitic inductances as low as possible by reducing trace lengths, using wide traces, ground planes, and by decoupling the supply with bypass capacitors. In order to prevent additional voltage spiking, this local bypass capacitor must exhibit low inductive reactance. You should therefore use high frequency ceramic capacitors and place them very near the IC to minimize wiring inductance.

- Keep V_{CC} bus routing short. When using double sided or multilayer circuit boards, use ground plane techniques.
- Keep ground lines short, and on PC boards make them as wide as possible, even if trace width varies. Use separate ground traces to supply high current devices such as relay and transmission line drivers.
- In systems mixing linear and logic functions and where supply noise is critical to the analog components' performance, provide separate supply buses or even separate supplies.
- If you use local regulators, bypass their inputs with a tantalum capacitor of at least 1 μF and bypass their outputs with a 10 μF to 50 μF tantalum or aluminum electrolytic capacitor.
- If the system uses a centralized regulated power supply, use a 10 μF to 20F tantalum electrolytic capacitor or a 50 μF to 100 μF aluminum electrolytic capacitor to decouple the V_{CC} bus connected to the circuit board.
- Provide localized decoupling. For random logic, a rule of thumb dictates approximately 10 nF (spaced within 12 cm) per every two to five packages, and 100 nF for every 10 packages. You can group these capacitances, but it's more effective to distribute them among the ICs. If the design has a fair amount of synchronous logic with outputs that tend to switch simultaneously, additional decoupling might be advisable. Octal flip-flop and buffers in bus-oriented circuits might also require more decoupling. Note that wire-wrapped circuits can require more decoupling than ground plane or multilayer PC boards.

A recommended crystal oscillator circuit to be used with the HPC is shown in Figure 29. See table for recommended component values. The recommended values given in Table V have yielded consistent results and are made to match a crystal with a 20 pF load capacitance, with some small allowance for layout capacitance.

A recommended layout for the oscillator network should be as close to the processor as physically possible, entirely within 1" distance. This is to reduce lead inductance from long PC traces, as well as interference from other components, and reduce trace capacitance. The layout contains a large ground plane either on the top or bottom surface of the board to provide signal shielding, and a convenient location to ground both the HPC, and the case of the crystal.

It is very critical to have an extremely clean power supply for the HPC crystal oscillator. Ideally one would like a V_{CC} and ground plane that provide low inductance power lines to the chip. The power planes in the PC board should be decoupled with three decoupling capacitors as close to the chip as possible. A 1.0 μF , a 0.1F, and a 0.001F dipped mica or ceramic cap should be mounted as close to the HPC as is physically possible on the board, using the shortest leads, or surface mount components. This should provide a stable power supply, and noiseless ground plane which will vastly improve the performance of the crystal oscillator network.

TABLE V. HPC Oscillator

XTAL Frequency (MHz)	R_1 (Ω)
2	1500
4	1200
6	910
8	750
10	600
12	470
14	390
16	300
18	220
20	180

$R_F = 3.3 \text{ M}\Omega$
 $C_1 = 27 \text{ pF}$
 $C_2 = 33 \text{ pF}$

XTAL Specifications: The crystal used was an M-TRON Industries MP-1 Series XTAL. "AT" cut, parallel resonant.

$C_L = 20 \text{ pF}$

Series Resistance is
 25 Ω @ 25 MHz
 40 Ω @ 10 MHz
 600 Ω @ 2 MHz

TL/DD/11046-37

FIGURE 29. Recommended Crystal Circuit

HPC167064 CPU

The HPC167064 CPU has a 16-bit ALU and six 16-bit registers.

Arithmetic Logic Unit (ALU)

The ALU is 16 bits wide and can do 16-bit add, subtract and shift or logic AND, OR and exclusive OR in one timing cycle. The ALU can also output the carry bit to a 1-bit C register.

Accumulator (A) Register

The 16-bit A register is the source and destination register for most I/O, arithmetic, logic and data memory access operations.

Address (B and X) Registers

The 16-bit B and X registers can be used for indirect addressing. They can automatically count up or down to sequence through data memory.

Boundary (K) Register

The 16-bit K register is used to set limits in repetitive loops of code as register B sequences through data memory.

Stack Pointer (SP) Register

The 16-bit SP register is the pointer that addresses the stack. The SP register is incremented by two for each push or call and decremented by two for each pop or return. The stack can be placed anywhere in user memory and be as deep as the available memory permits.

Program (PC) Register

The 16-bit PC register addresses program memory.

Addressing Modes

ADDRESSING MODES—ACCUMULATOR AS DESTINATION

Register Indirect

This is the "normal" mode of addressing for the HPC167064 (instructions are single-byte). The operand is the memory addressed by the B register (or X register for some instructions).

Direct

The instruction contains an 8-bit or 16-bit address field that directly points to the memory for the operand.

Indirect

The instruction contains an 8-bit address field. The contents of the WORD addressed points to the memory for the operand.

Indexed

The instruction contains an 8-bit address field and an 8- or 16-bit displacement field. The contents of the WORD addressed is added to the displacement to get the address of the operand.

Immediate

The instruction contains an 8-bit or 16-bit immediate field that is used as the operand.

Register Indirect (Auto Increment and Decrement)

The operand is the memory addressed by the X register. This mode automatically increments or decrements the X register (by 1 for bytes and by 2 for words).

Register Indirect (Auto Increment and Decrement) with Conditional Skip

The operand is the memory addressed by the B register. This mode automatically increments or decrements the B register (by 1 for bytes and by 2 for words). The B register is then compared with the K register. A skip condition is generated if B goes past K.

ADDRESSING MODES—DIRECT MEMORY AS DESTINATION

Direct Memory to Direct Memory

The instruction contains two 8- or 16-bit address fields. One field directly points to the source operand and the other field directly points to the destination operand.

Immediate to Direct Memory

The instruction contains an 8- or 16-bit address field and an 8- or 16-bit immediate field. The immediate field is the operand and the direct field is the destination.

Double Register Indirect Using the B and X Registers

Used only with Reset, Set and IF bit instructions; a specific bit within the 64 kbyte address range is addressed using the B and X registers. The address of a byte of memory is formed by adding the contents of the B register to the most significant 13 bits of the X register. The specific bit to be modified or tested within the byte of memory is selected using the least significant 3 bits of register X.

HPC Instruction Set Description

Mnemonic	Description	Action
ARITHMETIC INSTRUCTIONS		
ADD	Add	MA + Mem1 → MA carry → C
ADC	Add with carry	MA + Mem1 + CMA carry → C
ADDS	Add short imm8	A + imm8 → A carry → C
DADC	Decimal add with carry	MA + Mem1 + C → MA (Decimal) carry → C
SUBC	Subtract with carry	MA - Mem1 + C → MA carry → C
DSUBC	Decimal subtract w/carry	MA - Mem1 + C → MA (Decimal) carry → C
MULT	Multiply (unsigned)	MA * Mem1 → MA & X, 0 → K, 0 → C
DIV	Divide (unsigned)	MA/Mem1 → MA, rem → X, 0 → K, 0 → C
DIVD	Divide Double Word (unsigned)	X & MA/Mem1 → MA, rem → X, 0 → K, carry → C
IFEQ	If equal	Compare MA & Mem1, Do next if equal
IFGT	If greater than	Compare MA & Mem1, Do next if MA > Mem1
AND	Logical AND	MA and Mem1 → MA
OR	Logical OR	MA or Mem1 → MA
XOR	Logical Exclusive-OR	MA xor Mem1 → MA
MEMORY MODIFY INSTRUCTIONS		
INC	Increment	Mem + 1 → Mem
DECSZ	Decrement, skip if 0	Mem - 1 → Mem, Skip next if Mem = 0

HPC Instruction Set Description (Continued)

Mnemonic	Description	Action
BIT INSTRUCTIONS		
SBIT	Set bit	1 → Mem.bit
RBIT	Reset bit	0 → Mem.bit
IFBIT	If bit	If Mem.bit is true, do next instr.
MEMORY TRANSFER INSTRUCTIONS		
LD	Load	Mem1 → MA
ST	Load, incr/decr X	Mem(X) → A, X ± 1 (or 2) → X
X	Store to Memory	A → Mem
	Exchange	A ↔ Mem
	Exchange, incr/decr X	A ↔ Mem(X), X ± 1 (or 2) → X
PUSH	Push Memory to Stack	W → W(SP), SP+2 → SP
POP	Pop Stack to Memory	SP-2 → SP, W(SP) → W
LDS	Load A, incr/decr B,	Mem(B) → A, B ± 1 (or 2) → B,
	Skip on condition	Skip next if B greater/less than K
XS	Exchange, incr/decr B,	Mem(B) ↔ A, B ± 1 (or 2) → B,
	Skip on condition	Skip next if B greater/less than K
REGISTER LOAD IMMEDIATE INSTRUCTIONS		
LD B	Load B immediate	imm → B
LD K	Load K immediate	imm → K
LD X	Load X immediate	imm → X
LD BK	Load B and K immediate	imm → B, imm → K
ACCUMULATOR AND C INSTRUCTIONS		
CLR A	Clear A	0 → A
INCA	Increment A	A + 1 → A
DECA	Decrement A	A - 1 → A
COMP A	Complement A	1's complement of A → A
SWAP A	Swap nibbles of A	A[15:12] ← A[11:8] ← A[7:4] ↔ A[3:0]
RRC A	Rotate A right thru C	C → A15 → ... → A0 → C
RLC A	Rotate A left thru C	C ← A15 ← ... ← A0 ← C
SHR A	Shift A right	0 → A15 → ... → A0 → C
SHL A	Shift A left	C ← A15 ← ... ← A0 ← 0
SC	Set C	1 → C
RC	Reset C	0 → C
IFC	IF C	Do next if C = 1
IFNC	IF not C	Do next if C = 0
TRANSFER OF CONTROL INSTRUCTIONS		
JSRP	Jump subroutine from table	PC → W(SP), SP+2 → SP W(table#) → PC
JSR	Jump subroutine relative	PC → W(SP), SP+2 → SP, PC+ # → PC (# is +1025 to -1023)
JSRL	Jump subroutine long	PC → W(SP), SP+2 → SP, PC+ # → PC
JP	Jump relative short	PC+ # → PC (# is +32 to -31)
JMP	Jump relative	PC+ # → PC (# is +257 to -255)
JMPL	Jump relative long	PC+ # → PC
JID	Jump indirect at PC + A	PC+ A + 1 → PC then Mem(PC) + PC → PC
JIDW		
NOP	No Operation	PC + 1 → PC
RET	Return	SP-2 → SP, W(SP) → PC
RETSK	Return then skip next	SP-2 → SP, W(SP) → PC, & skip
RETI	Return from interrupt	SP-2 → SP, W(SP) → PC, interrupt re-enabled

Note: W is 16-bit word of memory

MA is Accumulator A or direct memory (8-bit or 16-bit)

Mem is 8-bit byte or 16-bit word of memory

Mem1 is 8-bit or 16-bit memory or 8-bit or 16-bit immediate data

imm is 8-bit or 16-bit immediate data

imm8 is 8-bit immediate data only

Code Efficiency

One of the most important criteria of a single chip microcontroller is code efficiency. The more efficient the code, the more features that can be put on a chip. The memory size on a chip is fixed so if code is not efficient, features may have to be sacrificed or the programmer may have to buy a larger, more expensive version of the chip.

The HPC family has been designed to be extremely code-efficient. The HPC looks very good in all the standard coding benchmarks; however, it is not realistic to rely only on benchmarks. Many large jobs have been programmed onto the HPC, and the code savings over other popular microcontrollers has been considerable.

Reasons for this saving of code include the following:

SINGLE BYTE INSTRUCTIONS

The majority of instructions on the HPC167064 are single-byte. There are two especially code-saving instructions: JP is a 1-byte jump. True, it can only jump within a range of plus or minus 32, but many loops and decisions are often within a small range of program memory. Most other micros need 2-byte instructions for any short jumps.

JSRP is a 1-byte subroutine call. The user makes a table of the 16 most frequently called subroutines and these calls will only take one byte. Most other micros require two and even three bytes to call a subroutine. The user does not have to decide which subroutine addresses to put into the table; the assembler can give this information.

EFFICIENT SUBROUTINE CALLS

The 2-byte JSR instructions can call any subroutine within plus or minus 1k of program memory.

MULTIFUNCTION INSTRUCTIONS FOR DATA MOVEMENT AND PROGRAM LOOPING

The HPC167064 has single-byte instructions that perform multiple tasks. For example, the XS instruction will do the following:

1. Exchange A and memory pointed to by the B register
2. Increment or decrement the B register
3. Compare the B register to the K register
4. Generate a conditional skip if B has passed K

The value of this multipurpose instruction becomes evident when looping through sequential areas of memory and exiting when the loop is finished.

BIT MANIPULATION INSTRUCTIONS

Any bit of memory, I/O or registers can be set, reset or tested by the single byte bit instructions. The bits can be addressed directly or indirectly. Since all registers and I/O are mapped into the memory, it is very easy to manipulate specific bits to do efficient control.

DECIMAL ADD AND SUBTRACT

This instruction is needed to interface with the decimal user world.

It can handle both 16-bit words and 8-bit bytes.

The 16-bit capability saves code since many variables can be stored as one piece of data and the programmer does not have to break his data into two bytes. Many applications store most data in 4-digit variables. The HPC167064 supplies 8-bit byte capability for 2-digit variables and literal variables.

MULTIPLY AND DIVIDE INSTRUCTIONS

The HPC167064 has 16-bit multiply, 16-bit by 16-bit divide, and 32-bit by 16-bit divide instructions. This saves both code and time. Multiply and divide can use immediate data or data from memory. The ability to multiply and divide by immediate data saves code since this function is often needed for scaling, base conversion, computing indexes of arrays, etc.

Development Support

HPC MICROCONTROLLER DEVELOPMENT SYSTEM

The HPC microcontroller development system is an in-system emulator (ISE) designed to support the entire family of HPC Microcontrollers. The complete package of hardware and software tools combined with a host system provides a powerful system for design, development and debug of HPC based designs. Software tools are available for IBM® PC-AT® (MS-DOS, PC-DOS) and for UNIX® based multi-user Sun® SPARCstation (SunOSTM).

The stand alone units comes complete with a power supply and external emulation POD. This unit can be connected to various host systems through an RS-232 link. The software package includes an ANSI compatible C-Compiler, Linker, Assembler and librarian package. Source symbolic debug capability is provided through a user friendly MS-windows 3.0 interface.

The ISE provides fully transparent in-system emulation at speeds up to 20 MHz 1 waitstate. A 2k word (48-bit wide) trace buffer gives trace trigger and non intrusive monitoring of the system. External triggering is also available through an external logic interface socket on the POD. Direct EPROM programming can be done through the use of externally mounted EPROM socket. Form-Fit-Function emulator programming is supported by a programming board included with the system. Comprehensive on-line help and diagnostics features reduce user's design and debug time. 8 hardware breakpoints (Address/range), 64k bytes of user memory, and break on external events are some of the other features offered.

Hewlett Packard model HP64775 Emulator/Analyzer providing in-system emulation for up to 30 MHz 1 waitstate is also available. Contact your local sales office for technical details and support.

Development Support (Continued)

PROGRAMMING SUPPORT

The HPC167064 EPROM array can be programmed using the HPC ISE with the appropriate programming adaptor board, 7064-PRGM-LDCC. The procedure for doing this is documented in the HPC Emulator Programmer User's Manual that is shipped with every ISE. The programming adaptor board must be ordered separately. The EPROM array can also be programmed using a DATA I/O Unisite model with a pinsite module. No adaptor board is required with the DATA

I/O programmer. Programming of the configuration bytes and security bits is described in the HPC Family User's Manual.

HOW TO ORDER

To order a complete development package, select the section for the microcontroller to be developed and order the parts listed.

Development Support (Continued)

DIAL-A-HELPER

Dial-A-Helper is a service provided by the Microcontroller Applications group. Dial-A-Helper is an Electronic Bulletin Board Information system and, additionally, provides the capability of remotely accessing the development system at a customer site.

INFORMATION SYSTEM

The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communications to and from the Microcontroller Applications Group and a FILE SECTION which consists of several file areas where valuable application software and utilities can be found. The minimum requirement for accessing Dial-A-Helper is a Hayes compatible modem.

If the user has a PC with a communications package then files from the FILE SECTION can be downloaded to disk for later use.

Order P/N: MDS-DIAL-A-HLP

Information System Package Contains:
 Dial-A-Helper Users Manual
 Public Domain Communications Software

FACTORY APPLICATIONS SUPPORT

Dial-A-Helper also provides immediate factory applications support. If a user is having difficulty in operating a MDS, messages can be left on our electronic bulletin board, which we will respond to.

Voice: (408) 721-5582
 Modem: (408) 739-1162
 Baud: 300 or 1200 baud
 Set-Up: Length: 8-bit
 Parity: None
 Stop Bit: 1
 Operation: 24 hrs, 7 Days

TL/DD/11046-38

Part Selection

The HPC family includes devices with many different options and configurations to meet various application needs. The number HPC167064 has been generically used throughout this datasheet to represent the whole family of parts. The following chart explains how to order various options available when ordering HPC family members.

Note: All options may not currently be available.

TL/DD/11046-39

Examples:

HPC467064/EL20—16k EPROM, Commercial temperature (0°C to +70°C), LDCC

HPC167064/EL20—16k EPROM Military temperature (-55°C to +125°C), LDCC (to be used for automotive temperature range also)

Socket Selection

Suggested sockets and extractor tool:

Socket #	Amp	PLCC	#821574-1 6141749

HPC46100 High-Performance microController with DSP Capability

General Description

The HPC46100 is a member of the HPC™ family of High Performance microControllers. Each member of the family has a similar core CPU with unique memory, resources, and I/O configuration to suit specific applications. The HPC46100 is fabricated in National's advanced microCMOS technology. This process combined with an advanced architecture provides fast, flexible I/O control, efficient data manipulation, high speed computation, and low power consumption.

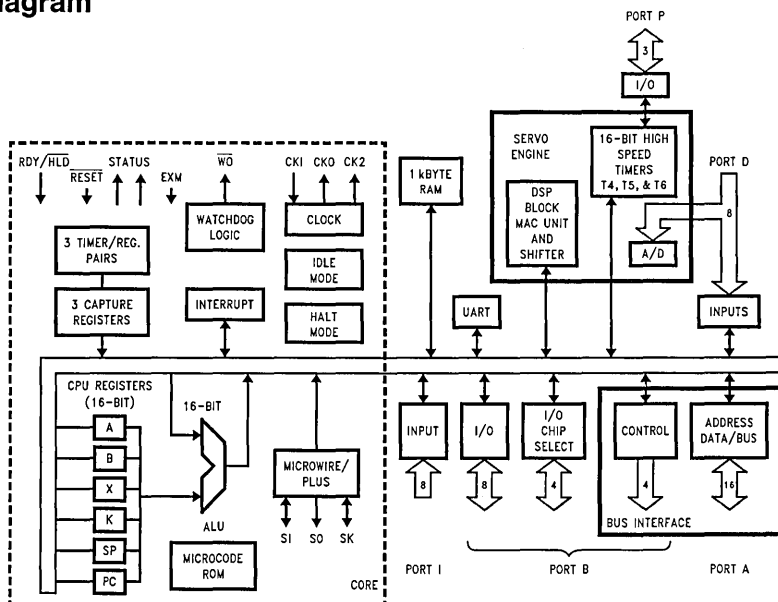

Throughput is enhanced by operating the HPC46100 at frequencies up to 40 MHz, by integrating a Multiply/Accumulate Unit (MAU) onto the chip, and by optimizing instructions to increase efficiency. These features increase performance in closed loop digital servo and filter applications.

The HPC devices are complete microcomputers on a single chip. All system timing, internal logic, RAM, and I/O are provided on the chip to produce a cost effective solution for high performance applications. On-chip functions such as an MAU unit, PWM outputs, Chip Select Signals, UART, up to seven 16-bit timers with input capture capability, WATCHDOG™ logic, vectored interrupts, and MICROWIRE/PLUS™ provide a high level of system integration. The ability to directly address up to 64 kbytes of memory enables the HPC to be used in powerful applications typically performed by microprocessors and peripheral chips.

Features

- Multiply/Accumulate Unit for fast signed multiply or multiply-accumulate
- High speed 16 bit timers with PWM outputs or input capture logic
- 4 Chip select output logic with programmable control
- 8-channel, 8-bit A/D Converter
- 1024 bytes of on-chip 0 wait state RAM
- FAST 100 ns for fastest instruction when using 40.0 MHz clock
- Very low power with two power save modes: IDLE and HALT
- UART full duplex, with a programmable baud rate generator and parity checking/detection
- MICROWIRE/PLUS serial I/O interface
- 8 vectored interrupt sources
- Signed overflow flag for add and subtract instructions
- 16 x 16 multiply and 32 x 16 divide
- 16-bit architecture with byte and word operations
- 64 kbytes of direct memory addressing
- 8- or 16-bit wide external memory
- Program instructions can be executed from RAM
- Up to 32 general purpose I/O lines that are memory mapped
- WATCHDOG logic

40 MHz (Continued)

AC Electrical Characteristics (Continued)

See Notes 1 and 4 and Figure 1 thru Figure 5. $V_{CC} = 5.0V \pm 10\%$ unless otherwise specified, $T_A = 25^\circ C$, one wait state.

Symbol	Parameter	Min	Max	Units
E SIGNAL TIMING PARAMETERS				
$t_{RWSE} = 0.25 t_C - 7$	\overline{WR} Falling Edge to E Rising Edge	5.5		ns
$t_{RWHE} = 0.5 t_C - 7$	E Falling Edge to \overline{WR} Rising Edge	18		ns
$t_{ASE} = t_C - 20$	Address Valid to E Rising Edge	30		ns
$t_{RDE} = WS - 20$	E Falling Edge to Data Input Valid	30		ns
SLOW PERIPHERAL TIMING PARAMETERS				
$t_{PLL} = t_C - 5$	PALE Pulse Width	45		ns
$t_{PST} = 0.75 t_C - 10$	Address Valid to PALE Falling Edge	27.5		ns
$t_{PVL} = 0.75 t_C - 15$	Address Hold from PALE Falling Edge	22.5		ns
$t_{PVP} = 0.75 t_C - 10$	PALE Falling Edge to \overline{RD} or \overline{WR} Falling Edge	27.5		ns
$t_{PCSA} = 0.25 t_C - 12.5$	Chip Select Setup to PALE Falling Edge	0		ns
$t_{PAS} = 1.5 t_C - 20$	Address Setup to \overline{RD} or \overline{WR} Falling Edge	55		ns
$t_{PCSS} = t_C - 15$	Chip Select Setup to \overline{RD} or \overline{WR} Falling Edge	35		ns
$t_{PCSH} = 0.5 t_C - 15$	Chip Select Hold from \overline{RD} or \overline{WR} Rising Edge	10		ns
$t_{PACC} = 5 t_C - 25$	Address Valid to Input Data Valid		225	ns
$t_{PRD} = 3.5 t_C - 25$	\overline{RD} Falling Edge to Data In Valid		150	ns
$t_{PDR} = t_C$ (max)	Data Hold after \overline{RD} Rising Edge	0	50	ns
$t_{PRW} = 3.5 t_C - 15$	\overline{RD} Strobe Width	160		ns
$t_{PSW} = 3.0 t_C - 20$	Data Setup before \overline{WR} Rising Edge	130		ns
$t_{PHW} = t_C - 20$	Data Hold after \overline{WR} Rising Edge	30		ns
$t_{PWW} = 3.5 t_C - 15$	\overline{WR} Strobe Width	160		ns

Note: $C_L = 40$ pF.

Note 1: These AC characteristics are guaranteed with external clock drive on CKI having 50% duty cycle and with less than 15 pF load on CKO with rise and fall times (t_{CKIR} and t_{CKIL}) on CKI input less than 2.5 ns.

Note 2: Do not design with these parameters unless CKI is driven with an active signal. When using a passive crystal circuit, its stability is not guaranteed if either CKI or CKO is connected to any external logic other than the passive components of the crystal circuit.

Note 3: t_{HAE} is spec'd for case with \overline{RD} falling edge occurring at the latest time it can be accepted during the present CPU cycle begin executed. If \overline{RD} falling edge occurs later, t_{HAE} as long as $(3 t_C + 4 WS + 72 t_C + 100)$ may occur depending on the following CPU instruction cycles, its wait states and ready input.

Note 4: WS (t_{WAIT}) x (number of preprogrammed wait states). Minimum and maximum values are calculated at maximum operating frequency, $t_C = 30$ MHz, with one wait state programmed.

Note 5: Due to emulation restrictions—actual limits will be better.

A/D Converter Specifications

$V_{CC} = 5V \pm 10\%$ ($V_{SS} - 0.050V$) \leq Any Input $\leq (V_{CC} + 0.050V)$, $f_{IN} = 24$ MHz

Parameter	Conditions	Min	Typ	Max	Units
Resolution				8	Bits
Reference Voltage Input	AGND = 0V	3		V_{CC}	V
Absolute Accuracy	$V_{REF} = V_{CC}$			± 1	LSB
Non-Linearity	$V_{REF} = V_{CC}$ Deviation from the Best Straight Line			$\pm 1/2$	LSB
Differential Non-Linearity	$V_{REF} = V_{CC}$			$\pm 1/2$	LSB
Input Reference Resistance		1.6		4.8	k Ω
Common Mode Input Range (Note 6)		AGND		V_{REF}	V
DC Common Mode Error				$\pm 1/4$	LSB
Off Channel Leakage Current			1		μ A
On Channel Leakage Current			1		μ A
A/D Clock Frequency (Note 7)		0.1		2.0	MHz
Conversion Time (Note 8)			13.0		A/D Clock Cycle

Note 6: For $V_{IN(-)} \geq V_{IN(+)}$ the digital output code will be 0000 0000. Two on-chip diodes are tied to each analog input. The diodes will forward conduct for analog input voltages below ground or above the V_{CC} supply. Be careful, during testing at low V_{CC} levels (4.5V), as high level analog inputs (5V) can cause this input diode to conduct—especially at elevated temperatures, and cause errors for analog inputs near full-scale. The spec allows 50 mV forward bias of either diode. This means that as long as the analog V_{IN} does not exceed the supply voltage by more than 50 mV, the output code will be correct. To achieve an absolute 0 V_{DC} to 5 V_{DC} input voltage range will therefore require a minimum supply voltage of 4.950 V_{DC} over temperature variations, initial tolerance and loading.

Note 7: See Prescaler description.

Note 8: Conversion Time includes sample and hold time. See following diagrams.

TL/DD/11289-33

Note: The trigger condition generated by the start conversion method selected by the SC bits requires one CK2 to propagate through before the trigger condition is known. Once the trigger condition is known, the sample and hold will start at the next rising edge of ADCLK. The diagram shows worst case.

General Description (Continued)

The HPC46100 has, as an on-chip peripheral, an 8-channel 8-bit Analog-to-Digital Converter. This A/D converter can operate in a single-ended mode where the analog input voltage is applied across one of the eight input channels (D0-D7) and AGND. The A/D converter can also operate in a differential mode where the analog input voltage is applied across two adjacent input channels. The A/D converter will convert up to eight channels in the single-ended mode and up to four channel pairs in the differential mode.

A group of three high speed timers provide processor independent PWM signal generation. These timers and their support logic provide independent control of PWM frequency and PWM duty cycle with a minimum resolution of 50 ns when running at 40 MHz.

The HPC46100 is upwards source code compatible with the HPC family except for Decimal Add and Subtract.

The HPC46100 is available in an 80-pin QFP package.

FIGURE 11. Slow Peripheral Bus Timing

I/O Ports

PORT A

Port A is a 16-bit multiplexed address/data bus used for accessing external program and data memory. Four associated bus control signals are available on port B. The Address Latch Enable (ALE) signal is used to provide timing to demultiplex the bus. Reading from and writing to external memory are signalled by \overline{RD} and \overline{WR} respectively. External memory can be addressed as either bytes or words with the decoding controlled by two lines. Bus High Byte Enable (\overline{HBE}) and Address/Data line 0 (A0).

PORT B

Port B is a 16-bit port with 12 bits of bidirectional I/O. B10, B11, B12 and B15 are the control bus signals for the address/data bus. Port B may also be configured via a function register BFUN to individually allow each bidirectional I/O pin to have an alternate function. The direction of port B is determined by the direction register (DIRB). This register is used to set up each pin to be individually defined as an input or output. A specific I/O bit is selected as a high impedance input by clearing the corresponding bit in the direction register. It is selected as an output by setting this bit. The data register (PORTB) is used to hold data to be output on the B port. A write operation to a port pin configured as an input causes the value to be written into the data register, a read operation returns the value of the pin. Writing to port pins configured as outputs causes the pins to have

the same value, reading the pins returns the value of the data register. *Figure 12 through Figure 14* show the structure of Port B.

Port B may also be configured via a 16-bit alternate function register BFUN, to individually allow each pin to have an alternate function. The alternate functions are enabled by setting the corresponding bits in the BFUN register. The alternate B port functions are as follows:

Pin	Alternate	Function
B0	TDX	UART Data Output
B1	E	E signal output
B2	CKX	UART Clock
B3	T2IO	Timer2 I/O Pin
B4	T3IO	Timer3 I/O Pin
B5	SO	MICROWIRE/PLUS Output (data)
B6	SK	MICROWIRE/PLUS Clock
B7	\overline{HLDA}	Hold Acknowledge Output
B8	TS0/CS0	Timer Synchronous or Chip Select Output
B9	TS1/CS1	Timer Synchronous or Chip Select Output
B10	ALE	Address/data bus Address Latch Enable
B11	\overline{WR}	Address/data bus Write Output
B12	\overline{HBE}	Address/data bus High Byte Enable
B13	TS2/CS2	Timer Synchronous or Chip Select Output
B14	TS3/CS3	Timer Synchronous or Chip Select Output
B15	\overline{RD}	Address/data bus Read Output

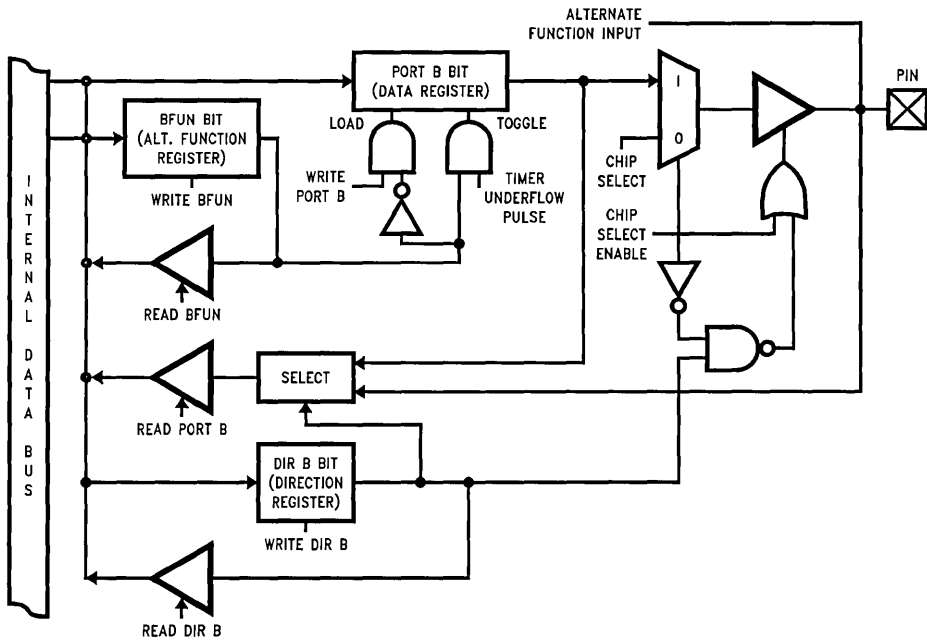

FIGURE 14. Structure of Port B Pins B8, B9, B13 and B14 (Timer Synchronous)

TL/DD/11289-16

I/O Ports (Continued)**PORT I**

Port I is an 8-bit input port that can be read as general purpose inputs and can also be used for the following functions:

Pin	Alternate	Function
I0	R5B	Timer T5 R5B Input
I1	NMI	Nonmaskable Interrupt Input
I2	INT2	Maskable Interrupt/Input Capture
I3	INT3	Maskable Interrupt/Input Capture
I4	INT4	Maskable Interrupt/Input Capture
I5	SI	MICROWIRE/PLUS Data Input
I6	RDX	UART Data Input
I7	R6B	Timer T6 R6B Input and A/D Trigger Input

PORT D

Port D is an 8-bit input port that can be used as general purpose digital inputs and as analog inputs for the A/D converter.

PORT P

Port P is a 3-bit input/output port that is used as general purpose outputs, or I/O that is controlled by timers T4, T5 and T6. These pins can be configured as Pulse Width Modulated Outputs (PWM), capture inputs or event counter inputs.

POWER SUPPLY PINS

Four pairs of power supply pins are provided to minimize cross talk between the analog, digital, and output driver sections of the chip.

Pin	Function
V _{CC}	Power for Digital Logic
GND	Ground for Digital Logic
DV _{CC}	Power for Output Drivers
DGND	Ground for Output Drivers
AV _{CC}	Power for Analog Logic
AV _{SS}	Ground for Analog Logic
V _{REF}	A/D Converter Reference Voltage Input
AGND	Ground Reference for Analog Logic

CLOCK PINS

Pin	Function
CKI	System Oscillator Input/External Clock Input
CKO	System Oscillator Output (Inversion of CKI)
CK2	Clock Output (CKI divided by 2)

OTHER PINS

Pin	Function
$\overline{\text{RESET}}$	System reset input, active low.
PALE	Slow peripheral address latch enable.
RDY/ $\overline{\text{HLD}}$	Has two uses, selected by a software bit. It's either a READY input to extend the bus cycle for slower memories, or HOLD request input to put the bus in a high impedance state for DMA purposes.
$\overline{\text{WO}}$	This is an active low open drain output that signals an illegal situation has been detected by the WATCHDOG logic.
ST1	Bus Cycle Status Output: indicates first opcode fetch.
ST2	Bus Cycle Status Output: indicates machine states (skip, interrupt and first instruction cycle).
EXM	External memory enable (active high) disables internal ROM and maps it to external memory.
$\overline{\text{EI}}$	Has two uses, it's either an active low level external interrupt with vector address FFF3:FFF2 which is shared with the UART, or Timer T4 R4B input.

Connection Diagram

TL/DD/11289-17

Operating Modes

The HPC46100 does not have any internal ROM, and has only one mode of operation, the Expanded ROMless Mode. The EXM pin must be pulled high (logic "1"). The EA bit in the PSW register of the HPC46100 is hard wired to a logic "1". The use of this bit is reserved. Currently, the HPC46100 is intended for use with external memory. The external memory may be any combination of ROM, RAM, or peripherals and may be configured with an 8-bit or 16-bit external address/data bus (see *Figure 16* and *Figure 17*). Up to 62k bytes of external memory may be accessed.

Wait States

The HPC46100 provides four selectable Wait States that allow access to slower memories. The Wait States are selectable by the state of two bits in the PSW register or by

two bits in the Chip Select Control registers. Additionally, the RDY input may be used to extend the instruction or memory access cycle, allowing the user to interface with slow memories and peripherals. There also is a slow peripheral bus mode when using the Chip Select logic.

Power Save Modes

Two power saving modes are available on the HPC46100: HALT and IDLE. In the HALT mode, all processor activities are stopped. In the IDLE mode, the internal oscillator and timer T0 are active but all other processor activities are stopped. In either mode, all internal RAM, registers and I/O are unaffected.

HALT MODE

The HPC46100 is placed in the HALT mode under software control by setting bits in the PSW. All processor activities,

Power Save Modes (Continued)

including the clock and timers, are stopped when the HALT mode is entered with the NMI input high. When the HALT mode is entered with the NMI input low, the high speed timers (T4, T5 and T6), remain active. In the HALT mode, power requirements for the HPC46100 are minimal and the applied voltage (V_{CC}) may be decreased without altering the state of the machine. There are two ways of exiting the HALT mode: via the \overline{RESET} or the NMI. The \overline{RESET} input re-initializes the processor. Use of the NMI input will generate a vectored interrupt and resume operation from that point with no initialization. The HALT mode can be enabled or disabled by means of a control register HALT enable. To prevent accidental use of the HALT mode the HALT enable register can be modified only once.

IDLE MODE

The HPC46100 is placed in the IDLE mode through the PSW. In this mode, all processor activity, except the internal oscillator, the high speed timers (T4, T5, and T6), and Timer T0, is stopped. As with the HALT mode, the processor is returned to full operation by the \overline{RESET} or NMI inputs, but without waiting for oscillator stabilization. A timer T0 overflow will also cause the HPC46100 to resume normal operation.

HPC46100 Interrupts

Complex interrupt handling is easily accomplished by the HPC46100's vectored interrupt scheme. There are eight possible interrupt sources as shown in Table I.

TABLE I. Interrupts

Vector Address	Interrupt Source	Arbitration Ranking
FFFF:FFFE	\overline{RESET}	0
FFFD:FFFC	Non-maskable external on rising edge of I1 pin	1
FFFB:FFFA	External interrupt on I2 pin	2
FFF9:FFF8	External interrupt on I3 pin	3
FFF7:FFF6	External interrupt on I4 pin	4
FFF5:FFF4	Overflow on internal timers	5
FFF3:FFF2	Internal by UART or external on \overline{EI} pin	6
FFF1:FFF0	A/D converter	7

INTERRUPT ARBITRATION

The HPC46100 contains arbitration logic to determine which interrupt will be serviced first if two or more interrupts occur simultaneously. The arbitration ranking is given in Table I. The interrupt on \overline{RESET} has the highest rank and is serviced first.

INTERRUPT PROCESSING

Interrupts are serviced after the current instruction is completed and except for the \overline{RESET} , which is serviced immediately. \overline{RESET} and \overline{EI} are level-LOW-sensitive interrupts. All other external interrupts are edge-sensitive. NMI is positive-edge sensitive. The external interrupts on I2, I3 and I4 can be software selected to be rising or falling edge.

INTERRUPT CONTROL REGISTERS

The HPC46100 allows the various interrupt sources and conditions to be programmed. This is done through the various control registers. A brief description of the different control registers is given below.

INTERRUPT ENABLE REGISTER (ENIR)

\overline{RESET} and the External Interrupt on I1 are non-maskable interrupts. The other interrupts can be individually enabled or disabled. Additionally, a Global Interrupt Enable Bit in the ENIR Register allows the Maskable interrupts to be collectively enabled or disabled. Thus, in order for a particular interrupt to request service, both the individual enable bit and the Global Interrupt bit (GIE) have to be set.

INTERRUPT PENDING REGISTER (IRPD)

The IRPD register contains a bit allocated for each interrupt vector excluding the \overline{EI} interrupt which has a dedicated register containing an interrupt enable and pending bit. The occurrence of specified interrupt trigger conditions causes the appropriate bit to be set. There is no indication of the order in which the interrupts have been received. The bits are set independently of the fact that the interrupts may be disabled. IRPD is a Read/Write register. The bits corresponding to the maskable, external interrupts are normally cleared by the HPC46100 after servicing the interrupts. For the interrupts from the on-board peripherals, the user has the responsibility of resetting the interrupt pending flags through software. The NMI bit is read only and I2, I3, and I4 are designed as to only allow a zero to be written to the pending bit (writing a one has no effect). A LOAD IMMEDIATE instruction is to be the only instruction used to clear a bit or bits in the IRPD register. This allows a mask to be used, thus ensuring that the other pending bits are not affected.

INTERRUPT CONDITION REGISTER (IRCD)

Three bits of the register select the input polarity of the external interrupt on I2, I3 and I4.

\overline{EI} INTERRUPT CONFIGURATION REGISTER (EICON)

The \overline{EI} pin is an active low level sensitive interrupt. Interrupts from the \overline{EI} pin are enabled by using the EICON register.

SERVICING THE INTERRUPTS

The Interrupt, once acknowledged, pushes the program counter (PC) onto the stack then incrementing the stack pointer (SP) by two. The Global Interrupt Enable bit (GIE) is copied into the CGIE bit of the PSW register; it is then reset, thus disabling further interrupts. The program counter is loaded with the contents of the memory at the vector address and the processor resumes operation at this point. At the end of the interrupt service routine, the user does a RETI instruction to pop the stack and re-enable interrupts if the CGIE bit is set, or RET to just pop the stack if the CGIE bit is clear, and then returns to the main program. The GIE bit can be set in the interrupt service routine to nest interrupts if desired. *Figure 15* shows the interrupt enable logic.

RESET

\overline{RESET} is an active-low Schmitt trigger input that initializes the processor and sets all pins in a TRI-STATE condition except for CK0, CK1, ST1, ST2, \overline{HBE} and \overline{WO} when held low. When rising edge is detected on \overline{RESET} , the processor vectors to FFFF:FFFE and resumes operation at the address contained at that memory location.

HPC46100 Interrupts (Continued)

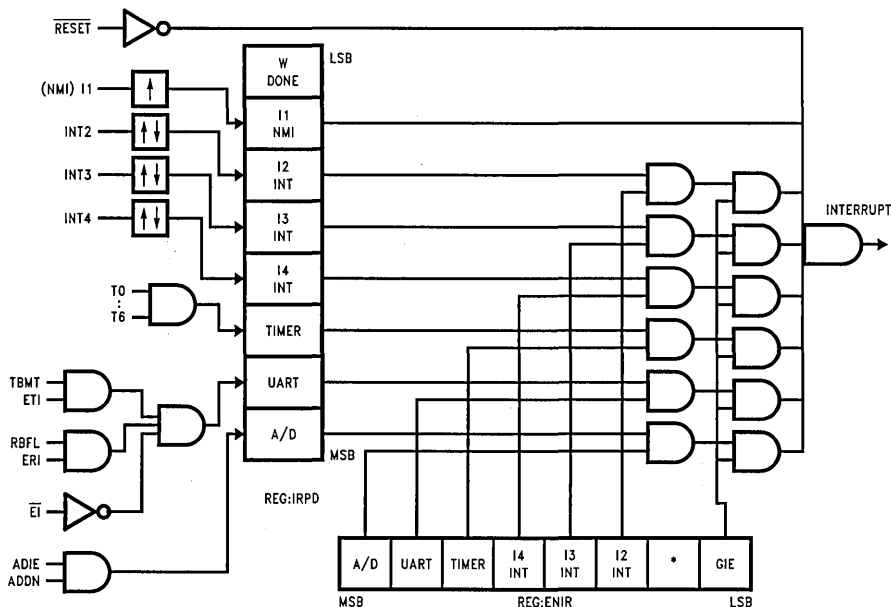

FIGURE 15. Interrupt Enable Logic

TL/DD/11289-18

Multiply/Accumulate Unit (MAU)

This is dedicated hardware that is supported by instructions which perform basic multiply-accumulate DSP steps for FIR and IIR filter calculations, an arithmetic right shift of the Math unit Result Register (MRR), and a signed multiply of two 16-bit values producing a 32-bit result.

The MACZ and MAC instructions support the MAU by fetching data and performing circular buffer management in parallel with the multiplication. The MACZ instruction is used initially, and it is followed by a string of additional MAC instructions, one instruction per filter tap (including the MACZ). The source values are taken as 16-bit values; there is not a form that operates on byte-wide inputs. The MACZ instruction clears the result register before completing the first multiply operation.

The MAC instruction is opcode 38 hex. The MACZ instruction is opcode 39 hex. Both instructions are one byte in length, and neither allows use of an Addressing Directive prefix.

The specific function performed is as follows:

- Clear MRR to zero (MACZ instruction only).
- Fetch 16-bit data pointed to by B, and issue it to the MAU as the first operand.
- Increment B by two (bytes), compare B with K: if $B > K$ then load B from A.
- Fetch 16-bit data pointed to by X, increment X by two (bytes).
- Issue data to the MAU to start multiply-accumulate operation. The MAU multiplies the two operands issued to it, and adds the 32-bit result to the current 32-bit contents of the MRR register.

On completion, the result goes to the MRR register. The MVP bit in the PSW is set to a "1" if a signed (2's complement) overflow occurred in the positive direction as a result of the accumulation substep (overflow from the multiplication substep is impossible). If the overflow occurred in the negative direction, the MVN bit is set instead. Neither of these bits is affected by the MAU if the other is already set.

By stringing together a sequence of MAC instructions, the HPC46100 can do a multiply-accumulate every 9 cycles (assuming a 1 wait state instruction fetch). At 40 MHz, this gives a 450 ns multiply-accumulate (including data fetching and circular buffer management). This can be reduced to 400 ns if executed from internal RAM.

Chip Select Signals

CHIP SELECT LOGIC

The chip select logic can produce up to four chip select signals without any off-chip logic. The chip select logic supports two bus timing modes. The first bus timing mode is native bus mode, which is the standard bus mode of all HPC family members. The second bus mode is the slow peripheral bus mode, which allows the HPC46100 to interface with slow peripherals without external chip select logic. There is an additional data strobe provided for auxiliary bus timing. This auxiliary strobe is called the E signal.

Each of chip select signals is controlled by a dedicated chip select control register (CSC0–CSC3). The control registers contain one bit to enable/disable the chip select signals, one bit to select the polarity of the chip select signal, two bits program the wait states of the data accesses, four bits that select the address range which the chip select signals are active in and one bit to enable or disable the E signal.

Chip Select Signals (Continued)

TL/DD/11289-19

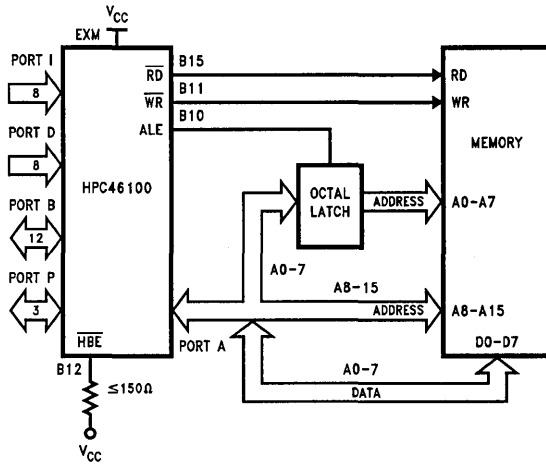

FIGURE 17. 8-Bit External Address/Data Bus

TL/DD/11289-20

Chip Select Signals (Continued)

The Chip Select Address Range Selection (SEL) defines the address range the chip select is valid over. For Chip Select 0 (CSC0), the address range starts at location 0800 hex and extends to S₀FFF hex, where S₀ is the 4-bit contents of the SEL field. For both Chip Select 1 (CSC1) and Chip Select 2 (CSC2) the SEL field defines a single 4 kbyte range: S₁000 through S₁FFF for CSC1, and S₂000 through S₂FFF for CSC2, where S₁ and S₂ are their respective SEL field contents. These ranges can be used to control peripherals by using the "Slow Peripheral" bus timing mode. Chip Select 3 (CSC3) defines a range beginning at S₃000 hex, and continuing through FFFF hex. This range will typically define the off-chip ROM space. See Figure 18.

Shaded Ranges Present
No Chip Select, and
Global Bus Features
are Selected

FIGURE 18. Chip Select Address Ranges

Chip Select 0 and Chip Select 3 can be programmed independently to operate with 1, 2 or 4 wait states. Chip Select 1 and 2 can be programmed independently to operate in native bus mode with 1, 2 or 4 wait states or slow peripheral bus mode.

Timer Overview

The HPC46100 contains seven 16-bit timers, four core timers and three high speed timers. Timers T0–T3 are the standard core timers and are fully compatible with the core timers on other HPC family members. See Figure 19 and Figure 20.

FIGURE 19. Timers T0–T1 Block

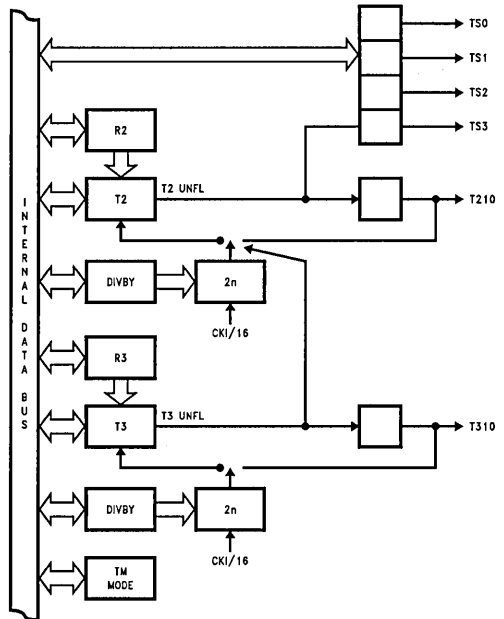

FIGURE 20. Timers T2–T3 Block

Timer Overview (Continued)

CORE TIMERS

Timer T0 is a free-running timer, counting up at a fixed CKI/16 (Clock Input/16) rate. It is used for Watchdog logic, high speed event capture, and to exit from the IDLE mode. Consequently, it cannot be stopped or written to under software control. Timer T0 permits precise measurements by means of the capture registers I2CR, I3CR, and I4CR. Registers I2CR and I3CR have the alternate function of being R1 and T1 respectively. The function of these registers (I2CR/R1 and I3CR/T1) are mutually exclusive and under the control of software. The capture registers I2CR, I3CR, and I4CR respectively, record the value of timer T0 when specific events occur on the interrupt pins I2, I3, and I4. The control register IRCD programs the capture registers to trigger on either a rising edge or a falling edge of its respective input. The specified edge can also be programmed to generate an interrupt.

The timers T2 and T3 have a clock rate which is selectable. The clock input to these two timers may be selected from the following two sources: an external pin, or derived internally by dividing the clock input. Timer T2 has additional capability of being clocked by the timer T3 underflow. This allows the user to cascade timers T3 and T2 into a 32-bit timer/counter.

The timers T1 through T3 in conjunction with their registers form Timer-Register pairs. All the Timer-Register pairs can be read from or written to. Each timer can be started or stopped under software control. Once enabled, the timers count down, and upon underflow, the contents of its associated register are automatically loaded into the timer.

Synchronous Outputs

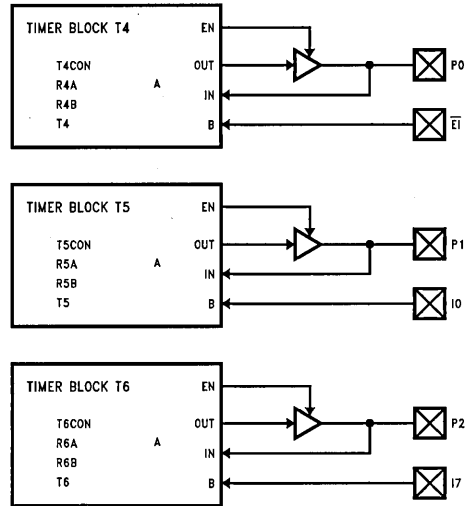

There are four synchronous timer outputs (TS0 through TS3) that work in conjunction with the timer T2. The synchronous timer outputs can be used either as regular outputs or individually programmed to toggle on timer T2 underflow.

Note: These outputs are shared with the chip select outputs. The use of these two functions are mutually exclusive.

TIMERS T4, T5 AND T6

The HPC46100 has a set of three powerful timers/counters, T4, T5 and T6. Since the three timers, T4, T5 and T6 are identical, all comments are equally applicable to any of the three timer blocks.

These timers are designed to allow the device to easily perform all timer functions with minimal software overhead. All timers are synchronized on the first overflow of timer T0. Each timer has four 16-bit registers dedicated to it, a control register (TnCON), timer register (Tn), and two auto-load/capture registers (RnA, RnB). *Figure 21* shows a block diagram of the three high speed timers.

TL/DD/11289-23

FIGURE 21. High Speed Timers Block

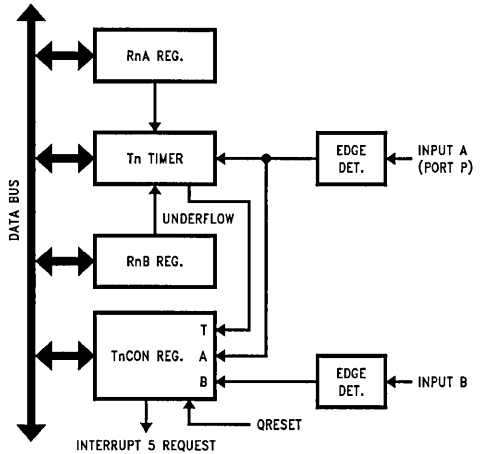

TIMER CONTROL REGISTERS

There are three timer control registers (T4CON, T5CON and T6CON). These control registers have bits which set the clock input rate, mode of operation and interrupt control structure. Each timer control register has interrupt pending and interrupt acknowledge bits for Tn, RnA and RnB, and a global interrupt pending bit for that specific timer. There are bits to enable/disable the interrupts from Tn, RnA and RnB. The clock input rate can be selected to be CKI/2, CKI/4, CKI/8 or CKI/16. The Four modes of operation are: External Event Counter mode, Input Capture mode, Processor Independent PWM mode and externally triggered PWM mode.

MODE 0. EXTERNAL EVENT COUNTER MODE

This mode is the default after RESET. In this mode the timer register Tn is decremented each time there is an active edge on the A input. The active edge is determined by the value of a bit in the control register. Upon every underflow of the timer register (Tn), the timer (Tn) is alternately reloaded with the contents of the supporting registers RnA and RnB. The first underflow of the timer after entry into this mode will cause the timer to reload from register RnA. All following underflows will alternate which reload is used beginning with RnB. Every underflow from the timer will set a Tn global interrupt pending bit in the control register. The selected edge on Input A and Input B will also set corresponding pending bits in the control register. *Figure 22* shows a block diagram of the high speed timers in Mode 0.

Timer Overview (Continued)

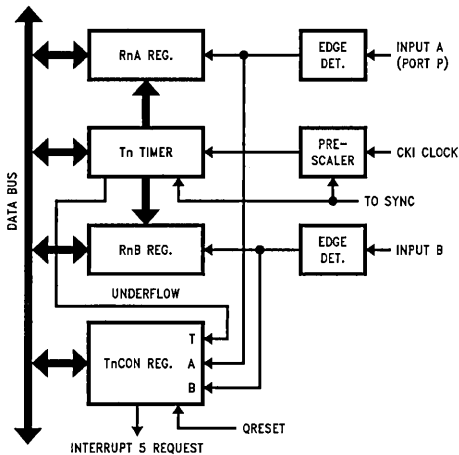

TL/DD/11289-24

FIGURE 22. External Event Counter

MODE 1. DUAL INPUT CAPTURE MODE

The device can precisely measure external frequencies or time external events by placing the timer in the input capture mode. In this mode, the timer T_n is constantly running at a fixed rate as selected in the timer control register. The two registers, R_nA and R_nB , act as capture registers. Each register is loaded with the contents of the timer register T_n when an active edge on it's associated pin is detected. The active edge is determined by the value of two bits in the control register. The active edge for each input pin can be specified independently, and can be programmed to generate an interrupt. The interrupt can be generated on an input from the A or B input along with an underflow of the timer register (T_n). Figure 23 shows a block diagram of the timer in Input Capture mode.

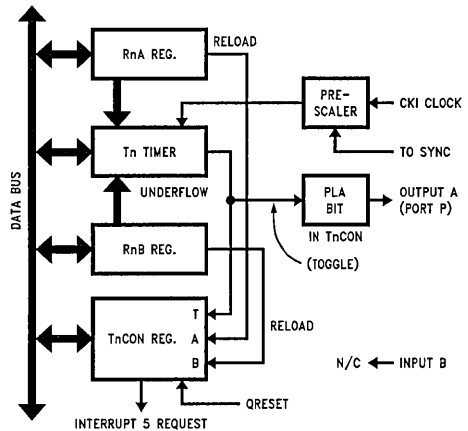

TL/DD/11289-25

FIGURE 23. Dual Input Capture

MODE 2. PROCESSOR INDEPENDENT PWM MODE

As the name suggests, this mode allows the device to generate a PWM signal with very minimal user intervention. The user only has to define the parameters of the PWM signal (ON time and OFF time). Once begun, the timer block will continuously generate the PWM signal completely independent of the microcontroller. The user software services the timer block only when the PWM parameters require updating. In this mode the timer T_n counts down at a fixed rate as programmed in the control register. Upon every underflow the timer is alternately reloaded with the contents of its supporting registers, R_nA and R_nB . The very first underflow of the timer after entry into this mode causes the timer to reload from the register R_nA . Subsequent underflows cause the timer to be reloaded from the registers alternately beginning with the register R_nB . Figure 24 shows a block diagram of the timer in PWM mode.

TL/DD/11289-26

FIGURE 24. PWM

The underflow can be programmed to toggle the A output pin (Port P). The underflow can also be programmed to generate interrupts. These interrupts can occur on a reload from R_nA or R_nB . This gives the user the flexibility of interrupting once per PWM period on either the rising or falling edge of the PWM output. Alternatively, the user may choose to interrupt on both edges of the PWM output.

MODE 3. EXTERNALLY TRIGGERED PWM/PORT OUTPUT

In this mode the timer is stopped and the corresponding port P pin can be programmed as a general purpose output pin. The timer block can be programmed to remain halted using its A pin for use as a general purpose output, or it can be programmed to exit mode 3 and enter mode 2 (Processor Independent PWM) when a rising edge is detected on the B input.

The external triggering of this feature provides the capability of generating a delayed pulse triggered by an external event as follows: From the rising edge of the B input the timer enters PWM mode. When the timer register underflows the output toggles and the value of R_nA is loaded to the timer. The next underflow will cause the R_nB register to load into

Timer Overview (Continued)

the timer and operation will continue as in the PWM mode. Alternately, an interrupt from the RnB load can be used to branch to a routine that would set the timer into mode 3 waiting for the trigger for another pulse. *Figure 25* shows a block diagram of the timer in this mode.

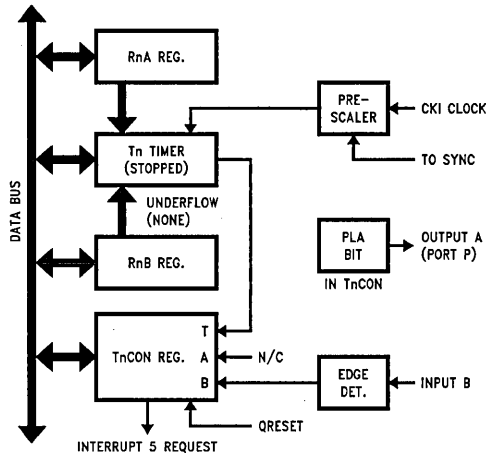

FIGURE 25. Port Output/Externally Triggered PWM

TL/DD/11289-27

WATCHDOG LOGIC

The WATCHDOG Logic monitors the operations taking place and signals upon the occurrence of any illegal activity. The illegal conditions that trigger the WATCHDOG logic are potentially infinite loops. Should the WATCHDOG register not be written to before Timer T0 overflows twice, or more often than once every 4096 counts, an infinite loop condition is assumed to have occurred. Any illegal condition forces the WATCHDOG Output ($\overline{W0}$) pin low. The $\overline{W0}$ pin is an open drain output and can be connected to the RESET or NMI inputs or to the users external logic.

MICROWIRE/PLUS

MICROWIRE/PLUS is used for synchronous serial data communications and has an 8-bit parallel-loaded, serial shift register using SI as the input and SO as the output. SK is the clock for the serial shift register (SIO). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. A DONE flag indicates when the data shift is completed. The MICROWIRE/PLUS capability enables it to interface with any of National Semiconductor's MICROWIRE peripherals (i.e., A/D converters, display drivers, EEPROMs).

MICROWIRE/PLUS OPERATION

The HPC46100 can enter the MICROWIRE/PLUS mode as the master or a slave. A control bit in the IRCD register determines whether the HPC46100 is the master or slave. The shift clock is generated when the HPC46100 is configured as a master. An externally generated shift clock on the SK pin is used when the HPC46100 is configured as a slave.

When the HPC46100 is a master, the DIVBY register programs the frequency of the SK clock. The DIVBY register allows the SK clock frequency to be programmed in 15 selectable steps from 64 Hz to 1 MHz with CKI at 16.0 MHz. The contents of the SIO register may be accessed through any of the memory access instructions. Data waiting to be transmitted in the SIO register is clocked out on the falling edge of the SK clock. Serial data on the SI pin is clocked in on the rising edge of the SK clock.

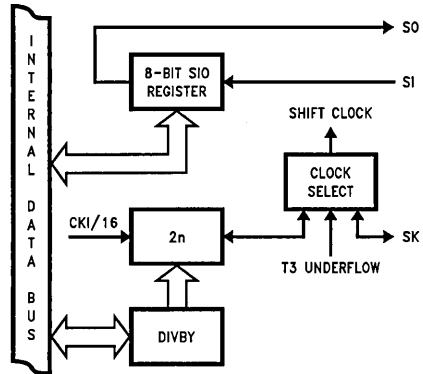

FIGURE 26. MICROWIRE/PLUS

TL/DD/11289-28

HPC46100 UART

The HPC46100 contains a software programmable UART. The UART (see *Figure 27*) consists of a transmit shift register, a receiver shift register and five addressable registers, as follows: a transmit buffer register (TBUF), a receiver buffer register (RBUF), a UART control and status register (ENU), a UART receive control and status register (ENUR) and a UART interrupt and clock source register (ENUI). The ENU register contains flags for transmit and receive functions; this register also determines the length of the data frame (7, 8 or 9 bits) and the value of the ninth bit in transmission. The ENUR register flags framing, parity, and data overrun errors while the UART is receiving. Other functions of the ENUR register include saving the ninth bit received in the data frame, reporting receiving and transmitting status, and enabling or disabling the UART's Attention Mode of operation.

The determination of an internal or external clock source is done by the ENUI register, as well as selecting the number of stop bits ($7/8$, 1, $1\frac{1}{8}$ or 2 stop bits), selecting between the synchronous or asynchronous mode and enabling or disabling transmit and receive interrupts. The clock inputs to the Transmitter and Receiver sections of the UART can be individually selected to come from either an off-chip source on the CKX pin or one of the two on-chip sources. The Divide-By (DIVBY) Register provides upward compatibility from earlier HPC family members, and the most flexible and accurate on-chip clocking is provided by the Baud Rate Generator (BRG).

HPC46100 UART (Continued)

FIGURE 27. UART Block Diagram

The Baud Rate Generator is controlled by the register pair PSR and BAUD. The Prescaler factor is selected by the upper 5 bits of the PSR register (the PRESCALE field), in units of the CK2 clock from 1 to 16 in $\frac{1}{2}$ step increments. The lower 3 bits of the PSR register, in conjunction with the 8 bits of the baud register, form the 11-bit BAUDRATE field, which defines a baud rate divisor ranging from 1 to 2048, in units of the prescaled clock selected by the PRESCALE field.

In Asynchronous Mode, the resulting baud rate is $\frac{1}{16}$ of the clocking rate selected through the BRG circuit. The maximum baud rate generated using the BRG is 625 kbaud.

In the Synchronous Mode data is transmitted on the rising edge and received on the falling edge of the external clock. Although the data is transmitted and received synchronously, it is still contained within an asynchronous frame; i.e., a start bit, parity bit (if selected) and stop bit(s) are still present.

UART ATTENTION MODE

The HPC46100 UART features an Attention Mode of operation. This mode of operation enables the HPC46100 to be networked with other processors. Typically in such environments, the messages consist of addresses and actual data.

Addresses are specified by having the ninth bit in the data frame set to 1. Data in the message is specified by having the ninth bit in the data frame reset to 0. The UART monitors the communication stream looking for addresses. When the data word with the ninth bit set is received, the UART signals the HPC46100 with an interrupt. The processor then examines the content of the receiver buffer to decide whether it has been addressed and whether to accept subsequent data.

A/D Converter

The HPC46100 has an on-board eight-channel 8-bit Analog to Digital converter. Conversion is performed using a successive approximation technique. The A/D converter cell can operate in single-ended mode where the input voltage is applied across one of the eight input channels (D0–D7) and AGND or in differential mode where the input voltage is applied across two adjacent input channels. The A/D converter will convert up to eight channels in single-ended mode and up to four channel-pairs in differential mode.

OPERATING MODES

The operating modes of the converter are selected by 4 bits called ADMODE (ADCR2.4–7) see Table II. Associated with the eight input channels in single-ended mode are eight result registers, one for each channel. The A/D converter can be programmed by software to convert on any specific channel storing the result in the result register associated with that channel. It can also be programmed to stop after one conversion or to convert continuously. If a brief history of the signal on any specific input channel is required, the converter can be programmed to convert on that channel and store the consecutive results in each of the result registers before stopping. As a final configuration in single-ended mode, the converter can be programmed to convert the signal on each input channel and store the result in its associated result register continuously.

Associated with each even-odd pair of input channels in differential mode of operation are four result register-pairs. The A/D converter performs two conversions on the selected pair of input channels. One conversion is performed assuming the positive connection is made to the even channel and the negative connection is made to the following odd channel. This result is stored in the result register associated with the even channel. Another conversion is performed assuming the positive connection is made to the odd channel and the negative connection is made to the preceding even channel. This result is stored in the result register associated with the odd channel. This technique does not require that the programmer know the polarity of the input signal. If the even channel result register is non-zero (meaning the odd channel result register is zero), then the input signal is positive with respect to the odd channel. If the odd channel result register is non-zero (meaning the even channel result register is zero), then the input signal is positive with respect to the even channel.

A/D Converter (Continued)

TABLE II. Operating Modes

Mode 0	single-ended, single channel, single result register, one-shot (default value on power-up)
Mode 1	single-ended, single channel, single result register, continuous
Mode 2	single-ended, single channel, multiple result registers, stop after 8
Mode 3	single-ended, multiple channel, multiple result register, continuous
Mode 4	differential, single channel-pair, single result register-pair, one-shot
Mode 5	differential, single channel-pair, single result register-pair, continuous
Mode 6	differential, single channel-pair, multiple result register-pairs, stop after 4 pairs
Mode 7	differential, multiple channel-pair, multiple result register-pairs, continuous
Mode 8	single-ended, single channel, single result register, one-shot (default value on power-up), quiet address/data bus
Mode C	differential, single channel-pair, single result register-pair, one-shot, quiet address/data bus

The same operating modes for single-ended operation also apply when the inputs are taken from channel-pairs in differential mode. The programmer can configure the A/D to convert on any selected channel-pair and store the result in its associated result register-pair then stop. The A/D can also be programmed to do this continuously. Conversion can also be done on any channel-pair storing the result into four result register-pairs for a history of the differential input. Finally, all input channel-pairs can be converted continuously.

The final mode of operation suppresses the external address/data bus activity during the single conversion modes. These quiet modes of operation utilize the RDY function of the HPC Core to insert wait states in the instruction being executed in order to limit digital noise in the environment due to external bus activity when addressing external memory.

CONTROL

The conversion clock supplied to the A/D converter can be selected by three bits in ADCR1. These bits are used as a prescaler on CKI, and can provide a clock rate from CKI/4 to CKI/32. These bits can be used to ensure that the A/D is clocked as fast as possible when different external crystal frequencies are used. Controlling the starting of conversion cycles in each of the operating modes can be done by four different methods. The method is selected by two bits called SC (ADCR3.0–1). Conversion cycles can be initiated through software by resetting a bit in a control register, through hardware by an underflow of Timer T2, or externally by a rising or falling edge of a signal input on I7.

INTERRUPTS

The A/D converter can interrupt the HPC when it completes a conversion cycle if one of the non-continuous modes has been selected. If one of the cycle modes was selected, then the converter will request an interrupt after eight conversions. If one of the one-shot modes was selected, then the converter will request an interrupt after every conversion. When this interrupt is generated, the HPC vectors to the A/D converter interrupt vector location at address FFF0.

Analog Input and Source Resistance Considerations

Figure 28 shows the A/D pin model for the HC46100 in single ended mode. The differential mode has similar A/D pin model. The leads to the analog inputs should be kept as short as possible. Both noise and digital clock coupling to an A/D input can cause conversion errors. The clock lead should be kept away from the analog input line to reduce coupling. The A/D channel input pins do not have any internal output driver circuitry connected to them because this circuitry would load the analog input signals due to output buffer leakage current.

TL/DD/11289-34

*The analog switch is closed only during the sample time.

FIGURE 28. Port D Input Structure

A/D Converter (Continued)

Source impedances greater than 1 kΩ on the analog input lines will adversely affect internal RC charging time during input sampling. As shown in Figure 28, the analog switch to the DAC array is closed only during the 2 A/D cycle sample time. Large source impedances on the analog inputs may result in the DAC array not being charged to the correct voltage levels, causing scale errors.

If large source resistance is necessary, the recommended solution is to slow down the A/D clock speed in proportion to the source resistance. The A/D converter may be operated at the maximum speed for R_S less than 1 kΩ. For R_S greater than 1 kΩ, A/D clock speed needs to be reduced. For example, with R_S = 2 kΩ, the A/D converter may be operated at half the maximum speed. A/D converter clock speed may be slowed down by either increasing the A/D prescaler divide-by or decreasing the CK1 clock frequency. The A/D clock speed may be reduced to its minimum frequency of 100 kHz.

Shared Memory Support

Shared memory access provides a rapid technique to exchange data. It is effective when data is moved from a peripheral to memory or when data is moved between blocks of memory. A related area where shared memory access proves effective is in multiprocessing applications where two CPUs share a common memory block (see Figure 29). The HPC46100 supports shared memory access with two pins. The pins are the RDY/HLD input pin and the HLDA output pin. The user can software select either the Hold or Ready function by the state of a control bit. The HLDA output is multiplexed onto port B.

The host uses DMA to interface with the HPC46100. The host initiates a data transfer by activating the HLD input of the HPC46100. In response, the HPC46100 places its system bus in a TRI-STATE Mode, freeing it for use by the host.

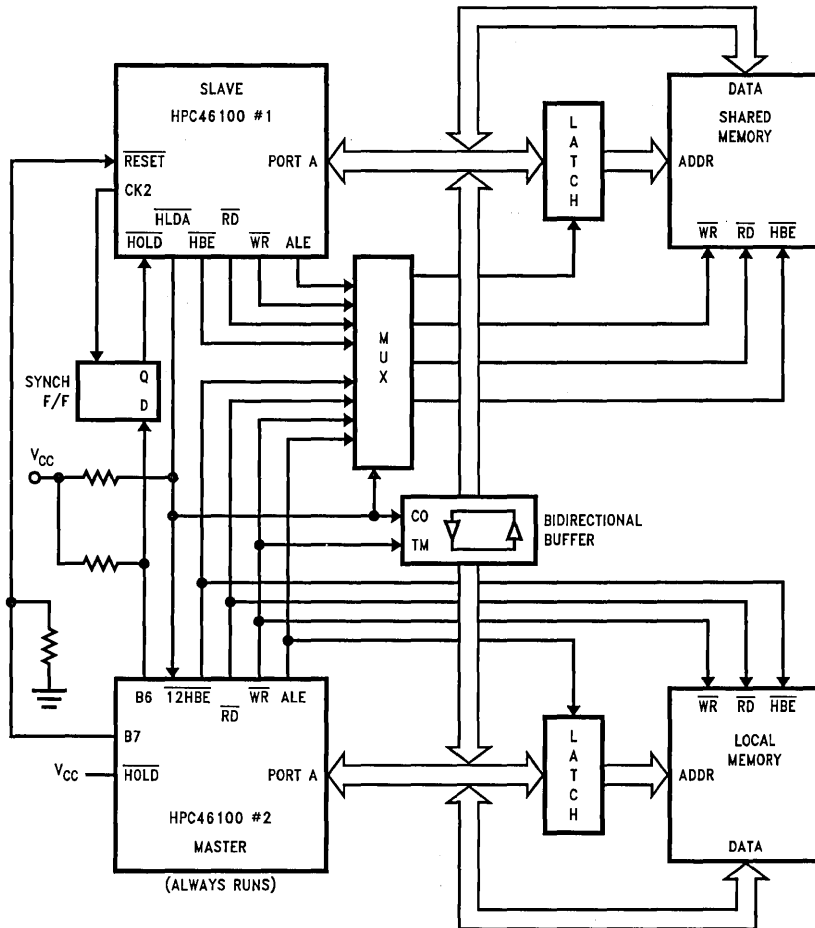

FIGURE 29. Shared Memory Application, Using $\overline{\text{HOLD}}$

TL/DD/11289-31

Shared Memory Support (Continued)

The host waits for the acknowledge signal (HLDA) from the HPC46100 indicating that the system bus is free. On receiving the acknowledge, the host can rapidly transfer data into, or out of, the shared memory by using a conventional DMA controller. Upon completion of the message transfer, the host removes the HOLD request and the HPC46100 resumes normal operations.

Memory

The HPC46100 has been designed to offer flexibility in memory usage. A total address space of 64 kbytes can be

directly addressed including 1024 bytes of RAM available on the chip itself.

Program memory addressing is accomplished by the 16-bit program counter on a byte basis. Memory can be addressed directly by instructions or indirectly through registers or any memory word in the first 256 bytes of memory (On-Chip Basepage RAM). Memory can be addressed as words or bytes. Words are always addressed on even-byte boundaries. The HPC46100 uses memory-mapped organization to support registers, I/O and on-chip peripheral functions. The HPC46100 memory address space extends to 64 kbytes and registers and I/O are mapped as shown in Table III.

Design Considerations

Designs using the HPC family of 16-bit high speed CMOS microcontrollers need to follow some general guidelines on usage and board layout.

Floating inputs are a frequently overlooked problem. CMOS inputs have extremely high impedance and, if left open, can float to any voltage. You should thus tie unused inputs to V_{CC} or ground, either through a resistor or directly. Unlike the inputs, unused outputs should be left floating to allow the output to switch without drawing any DC current.

To reduce voltage transients, keep the supply line's parasitic inductances as low as possible by reducing trace lengths, using wide traces, ground planes, and by decoupling the supply with bypass capacitors. In order to prevent additional voltage spiking, this local bypass capacitor must exhibit low inductive reactance. You should therefore use high frequency ceramic capacitors and place them very near the IC to minimize wiring inductance.

- Keep V_{CC} bus routing short. When using double sided or multilayer circuit boards, use ground plane techniques.
- Keep ground lines short, and on PC boards make them as wide as possible, even if trace width varies. Use separate ground traces to supply high current devices such as relay and transmission line drivers.
- In systems mixing linear and logic functions and where supply noise is critical to the analog components' performance, provide separate supply buses or even separate supplies.
- If you use local regulators, bypass their inputs with a tantalum capacitor of at least $1\ \mu\text{F}$ and bypass their outputs with a $10\ \mu\text{F}$ to $50\ \mu\text{F}$ tantalum or aluminum electrolytic capacitor.
- If the system uses a centralized regulated power supply, use a $10\ \mu\text{F}$ to $20\ \mu\text{F}$ tantalum electrolytic capacitor or a $50\ \mu\text{F}$ to $100\ \mu\text{F}$ aluminum electrolytic capacitor to decouple the V_{CC} bus connected to the circuit board.
- Provide localized decoupling. For random logic, a rule of thumb dictates approximately $10\ \text{nF}$ (spaced within $12\ \text{cm}$) per every two to five packages, and $100\ \text{nF}$ for every 10 packages. You can group these capacitances, but it's more effective to distribute them among the ICs. If the design has a fair amount of synchronous logic with outputs that tend to switch simultaneously, additional decoupling might be advisable. Octal flip-flop and buffers in bus-oriented circuits might also require more decoupling. Note that wire-wrapped circuits can require more decoupling than ground plane or multilayer PC boards.

A recommended crystal oscillator circuit to be used with the HPC is shown in *Figure 30*. See table for recommended component values. The recommended values given in the table have yielded consistent results and are made to match a crystal with a $18\ \text{pF}$ load capacitance, with some small allowance for layout capacitance.

A recommended layout for the oscillator network should be as close to the processor as physically possible, entirely within "1" distance. This is to reduce lead inductance from long PC traces, as well as interference from other components, and reduce trace capacitance. The layout contains a large ground plane either on the top or bottom surface of the board to provide signal shielding, and a convenient location to ground both the HPC, and the case of the crystal. It is

very critical to have an extremely clean power supply for the HPC crystal oscillator. Ideally one would like a V_{CC} and ground plane that provide low inductance power lines to the chip. The power planes in the PC board should be decoupled with three decoupling capacitors as close to the chip as possible. A $1.0\ \mu\text{F}$, a $0.1\ \mu\text{F}$, and a $0.001\ \mu\text{F}$ dipped mica or ceramic cap mounted as close to the HPC as is physically possible on the board using the shortest leads, or surface mount components. This should provide a stable power supply, and noiseless ground plane which will vastly improve the performance of the crystal oscillator network.

HPC46100 CPU

The HPC46100 CPU has a 16-bit ALU and six 16-bit registers.

ARITHMETIC LOGIC UNIT (ALU)

The ALU is 16 bits wide and can do 16-bit add, subtract and shift or logic AND, OR and exclusive OR in one timing cycle.

The ALU has two carry bits; one for signed overflow (V bit) and one for unsigned overflow (C bit).

ACCUMULATOR (A) REGISTER

The 16-bit A register is the source and destination register for most I/O, arithmetic, logic and data memory access operations.

ADDRESS (B AND X) REGISTERS

The 16-bit B and X registers can be used for indirect addressing. They can automatically count up or down to sequence through data memory.

BOUNDARY (K) REGISTER

The 16-bit K register is used to set limits in repetitive loops of code as register B sequences through data memory. The K register can also be used as a pointer register.

STACK POINTER (SP) REGISTER

The 16-bit SP register is the pointer that addresses the stack. The SP register is incremented by two for each push or call and decremented by two for each pop or return. The stack can be placed anywhere in user memory and be as deep as the available memory permits. The SP register can also be used as a pointer register.

PROGRAM (PC) REGISTER

The 16-bit PC register addresses program memory.

MAU RESULT REGISTER (MRR)

The 32-bit MAU Result Register holds the results from MAC (Multiply/Accumulate) instructions. In addition, it receives the result of the MULS (Multiply Signed) instruction, and can be shifted in place by the ASHR (Arithmetic Shift Right) operation.

Addressing Modes

ADDRESSING MODES WITH THE ACCUMULATOR AS DESTINATION

Register Indirect

The operand is the memory addressed by the A, B, X or K register. This mode of addressing for the HPC46100 produces single byte instructions when using the B or X register (depending on the instruction).

Direct

The instruction contains an 8-bit or 16-bit address field that directly points to the memory for the operand.

Indirect

The instruction contains an 8-bit address field. The contents of the WORD addressed points to the memory for the operand.

Indexed

The instruction contains an 8-bit address field and an 8- or 16-bit displacement field. The contents of the WORD addressed is added to the displacement to get the address of the operand.

Immediate

The instruction contains an 8-bit or 16-bit immediate field that is used as the operand.

Register Indirect (Auto Increment and Decrement)

The operand is the memory addressed by the X register. This mode automatically increments or decrements the X register (by 1 for bytes and by 2 for words).

Register Indirect Auto Increment and Decrement with Conditional Skip

The operand is the memory addressed by the B register. This mode automatically increments or decrements the B register (by 1 for bytes and by 2 for words). The B register is then compared with the K register. A skip condition is generated if B goes past K.

ADDRESSING MODES WITH DIRECT MEMORY AS DESTINATION

Direct Memory to Direct Memory

The instruction contains two 8- or 16-bit address fields. One field directly points to the source operand and the other field directly points to the destination operand.

Immediate to Direct Memory

The instruction contains an 8- or 16-bit address field and an 8- or 16-bit immediate field. The immediate field is the operand and the direct field is the destination.

Double Register Indirect Using the B and X Registers

Used only with Reset, Set, IF and IF NOT bit instructions; a specific bit within the 64 kbyte address range is addressed using the B and X registers. The address of a byte of memory is formed by adding the contents of the B register to the most significant 13 bits of the X register. The specific bit to be modified or tested within the byte of memory is selected using the least significant 3 bits of register X.

Code Efficiency

One of the most important criteria of a single chip microcontroller is code efficiency. The more efficient the code, the more features that can be put on a chip. The memory size on a chip is fixed so if code is not efficient, features may have to be sacrificed or the programmer may have to buy a larger, more expensive version of the chip.

The HPC46100 has been designed to be extremely code-efficient. The HPC46100 looks very good in all the standard coding benchmarks; however, it is not realistic to rely only on benchmarks. Many large jobs have been programmed onto the HPC46100, and the code savings over other popular microcontrollers has been considerable. Reasons for this saving of code include the following:

SINGLE BYTE INSTRUCTIONS

The majority of instructions on the HPC46100 are single-byte. There are two especially code-saving instructions: JP is a 1-byte jump. True, it can only jump within a range of plus or minus 32, but many loops and decisions are often within a small range of program memory.

JSRP is a 1-byte call subroutine. The user makes a table of his 16 most frequently called subroutines and these calls will only take one byte. Most other micros require two and even three bytes to call a subroutine. The user does not have to decide which subroutine addresses to put into his table; the assembler can give him this information.

Code Efficiency (Continued)

EFFICIENT SUBROUTINE CALLS

The 2-byte JSR instructions can call any subroutine within plus or minus 1k of program memory.

MULTIFUNCTION INSTRUCTION FOR DATA MOVEMENT AND PROGRAM LOOPING

The HPC46100 has single-byte instructions that perform multiple tasks. For example, the XS instruction will do the following.

1. Exchange A and memory pointed to by the B register
2. Increment or decrement the B register
3. Compare the B register to the K register
4. Generate a conditional skip if B has passed K

The value of this multipurpose instruction becomes evident when looping through sequential areas of memory and exiting when the loop is finished.

BIT MANIPULATION INSTRUCTIONS

Any bit of memory, I/O or registers can be set, reset or tested by the single byte bit instructions. The bits can be addressed directly or indirectly. Since all registers and I/O are mapped into the memory, it is very easy to manipulate specific bits to do efficient control.

MULTIPLY AND DIVIDE INSTRUCTIONS

The HPC46100 has 16-bit multiply, 16-bit by 16-bit divide, and 32-bit by 16-bit divide instructions. This saves both code and time. Multiply and divide can use immediate data or data from memory. The ability to multiply and divide by immediate data saves code since this function is often needed for scaling, base conversion, computing indexes of arrays, etc.

HPC Instruction Set Description

Mnemonic	Description	Action
ARITHMETIC INSTRUCTIONS		
ADD	Add	$MA + Mem1 \rightarrow MA$, carry $\rightarrow C$
ADC	Add with carry	$MA + Mem1 + C \rightarrow MA$, carry $\rightarrow C$
SUB	Subtract without carry	$MA - Mem1 \rightarrow MA$
SUBC	Subtract with carry	$MA - Mem1 + C \rightarrow MA$, carry $\rightarrow C$
MULT	Multiply (unsigned)	$MA * Mem1 \rightarrow MA \& X$, 0 $\rightarrow K$, 0 $\rightarrow C$
DIV	Divide (unsigned)	$MA / Mem1 \rightarrow MA$, rem. $\rightarrow X$, 0 $\rightarrow K$, 0 $\rightarrow C$
DIVD	Divide Double Word (unsigned)	$X \& MA / Mem1 \rightarrow X$, 0K, Carry $\rightarrow C$
IFEQ	If equal	Compare MA & Mem1, Do next if equal
IFGT	If greater than	Compare MA & Mem1, Do next if $MA > Mem1$
IFGE	If greater than or equal	Compare MA & Mem1, Do next if $MA =$ or $> Mem1$
IFGESS	If greater than or equal signed	Signed compare MA & Mem1, Do next if $MA =$ or $> Mem1$
IFGTS	If greater than signed	Signed compare MA & Mem1, Do next if $MA > Mem1$
AND	Logical and	$MA \text{ and } Mem1 \rightarrow MA$
OR	Logical or	$MA \text{ or } Mem1 \rightarrow MA$
XOR	Logical exclusive-or	$MA \text{ xor } Mem1 \rightarrow MA$
MACZ	Multiply-accumulate From Zero signed word	0 $\rightarrow MRR$, $[B+] * [X+] + MRR \rightarrow MRR$ OVERFLOW $\rightarrow MVP$ or MVN , IF $B > K$ THEN $A \rightarrow B$
MAC	Multiple-accumulate signed word	$[B+] * [X+] + MRR \rightarrow MRR$, OVERFLOW $\rightarrow MVP$ or MVN , IF $B > K$ then $A \rightarrow B$
MULS	Multiply, signed	$MA * Mem1 \rightarrow MRR$
ASHR	Arithmetic right	$MRR / 2^{imm} \rightarrow MRR$, or $MRR / 2^A \rightarrow MRR$
MEMORY MODIFY INSTRUCTIONS		
INC	Increment	$Mem + 1 \rightarrow Mem$
DECSZ	Decrement, skip if 0	$Mem - 1 \rightarrow Mem$, Skip next if $Mem = 0$
BIT INSTRUCTIONS		
SBIT	Set bit	1 $\rightarrow Mem.bit$
RBIT	Reset bit	0 $\rightarrow Mem.bit$
IFBIT	If bit	If $Mem.bit$ is = 1, do next instruction
IFNBIT	If not bit	If $Mem.bit$ is = 0, do next instruction

HPC MICROWIRE/PLUS™ Master-Slave Handshaking Protocol

National Semiconductor
Application Note 474
Richard Lazovick

INTRODUCTION

This applications note describes how to use National Semiconductor's MICROWIRE/PLUS to communicate between two members of the HPC family of microcontrollers, and will discuss the implications of adding other MICROWIRE™ peripherals. MICROWIRE/PLUS (μWIRE) may be effectively used to communicate between chips, such as in Small Area Networks (SANs). Possible applications range from setting up a communications network within an automobile to home security systems. Among the standard MICROWIRE peripherals available are display drivers (LCD, VF, LED), memories (RAM, EEPROM), A/D converters, and frequency generators/timers. Each MICROWIRE peripheral requires its own handshaking protocol, however the HPC's MICROWIRE is flexible enough to work with any peripheral and allows you to define your own handshaking protocol when having two HPC family members communicate.

MICROWIRE

MICROWIRE/PLUS is an extension of National Semiconductor's MICROWIRE communications interface. It allows

high speed two way serial communications between a master processor and one or more slave processors or peripherals. MICROWIRE/PLUS uses only three wires plus chip selects, therefore it saves on intricate bus routing and does not waste 8-bit ports. *Figure 1* shows the block diagram of a sample application using two HPC family members and an 8-bit A/D peripheral to monitor and control certain environmental conditions within a system.

MICROWIRE/PLUS has an 8-bit parallel-loaded, serial shift register (SIO) using SI as the serial input and SO as the serial output. The contents of the SIO register may be accessed through any of the memory access instructions. SK is the clock for the SIO register (see *Figure 2*). The SK clock signal can be provided by an internal or external source. The internal clock rate is programmable by the DIVBY register. Data to be transmitted from the SIO register is shifted out on the falling edge of the SK clock. Serial data on the SI pin is latched in on the rising edge of the SK clock (see *Figure 3 μWIRE Timing*).

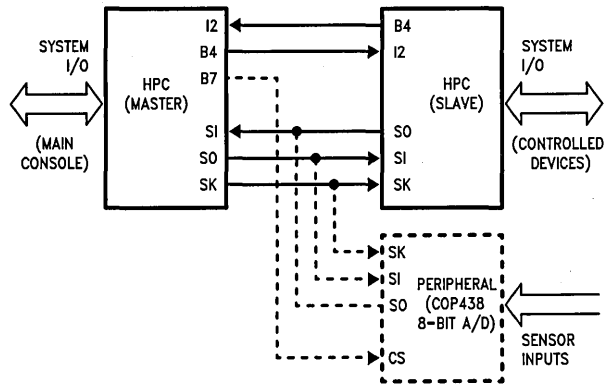

FIGURE 1. HPC μWIRE Block Diagram
(Environmental Control System)

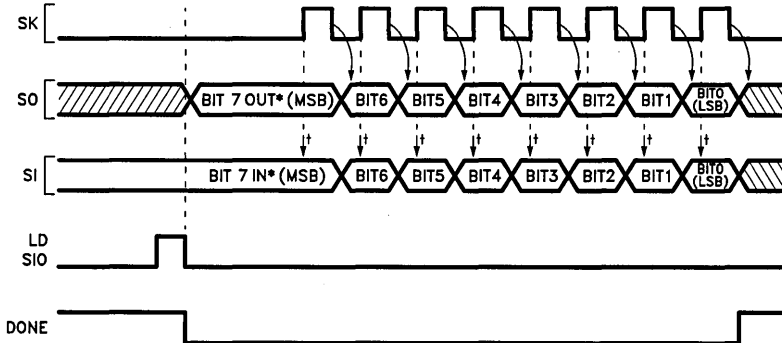

TL/DD/9140-1

TL/DD/9140-2

Note: The most significant bit is shifted out first. The SO pin reflects the contents of the MSB in the SIO register.

FIGURE 2. MICROWIRE/PLUS Block Diagram

TL/DD/9140-3

Note: The first bit of every eight bits in the SIO register being shifted out will have a longer duration than the other bits. This results from the hardware implementation used for MICROWIRE.

* This bit becomes valid immediately when the transmitting device loads its SIO register.

† Arrows indicate points at which SI is sampled.

FIGURE 3. μ WIRE Timing

A μ WDONE flag in the IRPD (Interrupt Pending) register indicates when the data shift is completed.

The HPC can enter the MICROWIRE/PLUS mode as a master or a slave. The μ WMODE control bit in the IRCD (Interrupt Condition) register determines whether the HPC is a master or slave. The shift clock is generated internally when the HPC is configured as a master. An externally generated shift clock on the SK pin is used when the HPC is configured as a slave. When the HPC is a master, the DIVBY register allows the SK clock frequency to be programmed in 14 selectable steps from 122 Hz to 1 MHz when CKI is 16 MHz (see Table I).

HOW TO USE MICROWIRE/PLUS

To use MICROWIRE, start by setting up the B port appropriately for the MICROWIRE functions. The SO and SK functions are multiplexed onto Port B pins B5 and B6 respectively. For the master, set bits 5 and 6 in the DIRB register (direction register for Port B) to set SO and SK as outputs. For the slave, set bit 5 and reset bit 6 in the DIRB register to set SO as an output and SK as an input. The BFUN register (Port B function register) is used to set SO and SK as alternate functions in the master and only SO as an alternate function in the slave. The MICROWIRE/PLUS mode can be enabled or disabled any time under program control. This is done through the BFUN register. Placing a "1" in the corresponding bit location causes the alternate function to be activated, a "0" causes the alternate function to be disabled. It is good practice to initialize the output pins by setting PORTB (Port B data register) to a known state.

The SI function is multiplexed onto Port I pin I5. This pin is always an input and the SI function is automatically selected when in the MICROWIRE mode. Setting the μ WMODE control bit, bit 1, in the IRCD register will enable the part to be a

master, resetting the bit will make it a slave. For the master, the DIVBY register has to be initialized to set the appropriate SK frequency (see Table I.). For example if the crystal frequency is 16 MHz and an SK frequency of 1 MHz is desired, load the least significant nibble of the DIVBY register with 2 (16 MHz/16 = 1 MHz).

For a summary of the register and pin configurations for the master and slave modes see Table II.

TABLE I. HPC μ WIRE DIVBY Register

μ WIRE SK Divisor				
MSB			LSB	CLOCK
0	0	0	0	not allowed
0	0	0	1	not recommended*
0	0	1	0	CKI/16

1	1	1	0	CKI/65536
1	1	1	1	CKI/131072

*This option uses timer T3 output, but does not generate a square wave. (See HPC users manual for more details.)

TABLE II. μ WIRE Register and Pin Conditions for Master and Slave Operation

Operation	μ WMODE bit	BFUN B5	BFUN B6	DIRB B5	DIRB B6	PIN B5	PIN B6	PIN I5
MICROWIRE Master	1	1	1	1	1	SO	INT. SK	SI
MICROWIRE Master	1	1	1	0	1	TRI-STATE®	INT. SK	SI
MICROWIRE Slave	0	1	0	1	0	SO	EXT. SK	SI
MICROWIRE Slave	0	1	0	0	0	TRI-STATE	EXT. SK	SI

DEFINING THE MASTER/SLAVE HANDSHAKING PROTOCOL

There are a few things to keep in mind when defining a handshaking protocol for the HPC:

- 1) Only the master can generate SK clocks.
- 2) As 8 bits are shifted into the SIO register, the 8 bits already in there are shifted out.
- 3) After 8 bits are shifted into (or out of) the SIO register the MICROWIRE done (μ WIRE DONE) flag gets set.
- 4) ANY access to the SIO register in the master that performs a write operation causes the contents of SIO to be shifted out.
- 5) No data will be shifted into or out of the slave's SIO register if its μ WIRE DONE flag is set.
- 6) Any write to the SIO register in the master or slave resets its μ WIRE DONE flag.

Keeping the above six points in mind, let's look at one possible handshaking protocol between a master HPC and a slave HPC. Number two above tells us we can send and receive data at the same time, however since only the master initiates data transfer we want to be sure the slave is ready before we get started with the exchange. Since the master initiates the transfer process there is no need for the master's MICROWIRE routine to be interrupt driven (though it can be if it is desired to have the slave initiate data transfers also). On the other hand, since the slave will be off doing other tasks it is most effective to have its MICROWIRE routine be interrupt driven.

A FEW THINGS TO NOTE ABOUT THE PROGRAMS

The following programs refer to the system configuration shown in *Figure 1*. This example code does a simple data transfer. The master reads in data on Port D, sends it via MICROWIRE to the slave, and reads it back. They both start by initializing the chip mode and number of wait states

(PSW), disabling interrupts, setting the DIVBY register as necessary, initializing Port B, and enabling the appropriate MICROWIRE mode (IRCD). Then the slave continues with its main code (a wait loop) until interrupted. When the master decides it's ready to send MICROWIRE data, it signals the slave by setting the slave interrupt pin on Port B, then it waits for the slave to respond.

Meanwhile, the slave goes into action. It clears the μ WDONE flag and loads the SIO register (X A, SIO), then notifies the master that it is ready to continue. Once the master realizes the slave is ready to continue, it removes the interrupt signal to the slave (RESET PORTB.SLAVI), reads in the data to be sent (LD A, PORTD), and starts transmitting it (X A, SIO). At the same time the master reads in the data received at the last data exchange with the slave. Then the master loops until it is done transferring data and loops again until the slave is finished with its interrupt routine. In a real program the master would be off executing code and not having to wait in these loops. Once the transmission is complete the slave reads in the new data (LD A, SIO), lets the master know it is done with its interrupt routine (RESET PORTB.MASTR), and re-enables interrupts as it returns to the main routine (RETI).

In the master's code there is only one access to the SIO register and that access is an exchange. Remember point #4, we can take advantage of the exchange instruction (X A, SIO), which is a read-modify-write instruction. Therefore, with one instruction, we can read the data from the previous transfer into the accumulator, and write the data to be transferred into the SIO register. If this method is not practical, then separate read and write instructions must be used.

When accessing the SIO register be sure the μ WIRE DONE flag is set so you know the data is not changing. At other times we have to be sure the flag is reset or no data will ever be transferred (shifted in or out). Notice that the "X A, SIO" was used to reset the μ WIRE DONE flag as well as load the register with the data to be sent.

ADDING PERIPHERALS OR ANOTHER SLAVE

Adding another slave HPC or a peripheral to the above Microwire configuration can add more power to your design with minimal extra cost and design time. In *Figure 1*, an extra peripheral is shown in dotted outline form. The hardware and software modifications are straightforward, however there are a few considerations to keep in mind:

- Tri-state the SO pin on the slave HPC by resetting B5 in the DIRB register when the slave is not 'chip-selected' by the master.
- When adding more HPC slaves, the master's and slave's routines remain the same. Only different B port pins for chip select and I or B port pins for slave acknowledgement need to be used.
- For peripherals the principals of operation are still the same and so are the initialization procedures, however some of the code will have to be modified to accommodate the specific handshaking required by the peripheral. (Note: some of the peripherals require 16 or more consecutive bits without interruption of the SK clock. To provide continuous SK clocks, set up the accumulator with next byte of data to send, loop until μ WDONE is set, then exchange the contents of the accumulator and the SIO register (X A, SIO). The above steps will provide nearly continuous SK clocks—the slower the SK clock is set for, the more continuous they will appear.)

APPLICATIONS

Now that you are more familiar with MICROWIRE/PLUS, where can you get experience using it?

- It can be used in a security system where the on-site master lets the periphery slaves know which security codes they can now let in, while at the same time the slaves monitor fire alarms and smoke detectors.
- It can be used in automotive brakes to allow all the wheels to communicate with each other. The wheels can trade information on road conditions and a master can monitor all four wheels to coordinate them and check for malfunctions.
- It can be used in a robot arm to allow each joint to make the decision as to how it will help the entire arm reach its final position. This application is one example of how MICROWIRE/PLUS can be used for system task partitioning.
- It can be used in a MUX-WIRING system.

When using MICROWIRE to communicate between two chips on the same board, a high data rate can be used. When communicating over longer distances, slower speeds should be used.

SUMMARY

MICROWIRE/PLUS can be a very powerful tool that can easily add power to a microcontroller based system. It is easy to use and does not require much hardware to implement. To add a new feature to your current design, choose a peripheral and add a small amount of code. To start using MICROWIRE, define the handshake protocol best suited for your application keeping in mind the six points given above in the 'Defining the Master/Slave Handshaking Protocol' section. Then initialize the appropriate registers: BFUN, DIRB, PORTB, DIVBY, and IRCD. The MICROWIRE circuitry will then run independent of the CPU except to exchange data between the SIO register and the CPU, and to initiate the data exchange between the master and slaves. With a CPU clock of 16 MHz, MICROWIRE/PLUS may achieve a maximum data rate of 1 MHz. MICROWIRE can be used to add display controllers, A/D's, memories, timers, and even other microcontrollers to an HPC microcontroller based design. Remember MICROWIRE/PLUS is not a trivial piece of very fine wire, it is a high speed two way serial communications interface!

Interfacing Analog Audio Bandwidth Signals to the HPC

National Semiconductor
Application Note 484
Ashok Krishnamurthy

INTRODUCTION

This report describes a method of interfacing analog audio bandwidth signals to the National Semiconductor HPC microcontroller. The analog signal is converted to a digital value using the National Semiconductor TP3054 codec/filter combo. The digital value is then transferred to the HPC using the MICROWIRE/PLUSTM synchronous serial interface. The digital output sample computed by the HPC is also transferred to the TP3054 using the MICROWIRE/PLUS interface. The TP3054 then converts this digital value to an analog signal.

ADVANTAGES OF USING A CODEC

There are a number of advantages in using a codec for A/D and D/A conversion of analog signals.

1. The codec/filter combos such as the TP3054 integrate a number of functions on a single chip. Thus the TP3054 includes the analog anti-aliasing filters, the Sample-and-Hold circuitry and the A/D and D/A converters for analog signal interfacing.
2. The μ -law coding effectively codes a 14-bit conversion accuracy in 8 bits. This allows the interface to the HPC to be greatly simplified.

DISADVANTAGES IN USING A CODEC

While the use of a codec is appropriate for audio (in particular speech) processing applications, it has a number of disadvantages in other cases.

1. The sampling rate is fixed at 8 kHz. If lower or higher sampling rates are desired, the codec cannot be used. Note that the real-time signal processing that the HPC can perform at a 8 kHz sampling rate is limited.
2. The resolution is fixed, and is about 14 bits/sample.
3. Digital filtering algorithms require that the samples used in the processing be linear coded PCM. Thus the 8-bit μ -law PCM values output by the codec need to be converted to linear coded PCM. Correspondingly, the output of the digital filter, which is in linear coded PCM needs to be converted to 8-bit μ -law PCM before outputting to the codec. This requires additional processing per sample.

DESCRIPTION OF THE INTERFACE

The circuit schematic of the interface is shown in *Figure 1*. Note that the schematic does not show complete details of the HPC. Only the HPC pins that are relevant to this interface are shown. A wire-wrapped version of the circuit has been constructed on a NSC HPC 16040 Chip Carrier Board.

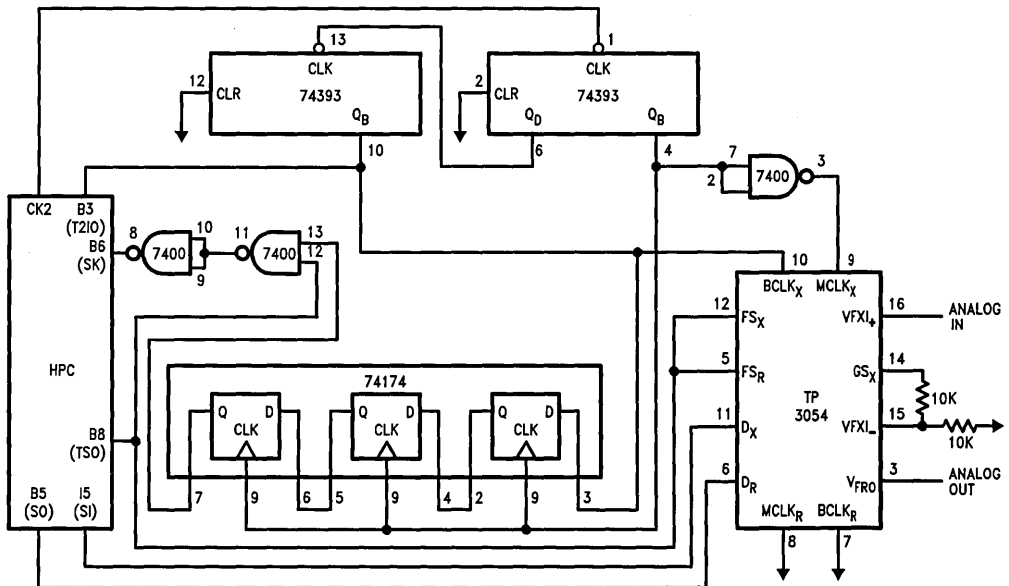

FIGURE 1. Circuit Schematic

TL/DD/9246-1

Note that this report does not go into the details about the use of the TP3054 codec chip or programming the HPC. It also does not discuss the μ -law to linear and linear to μ -law code conversion in detail. For more information on these issues, please consult the references listed at the end.

1. **Codec Signalling Considerations.** The TP3054 can operate in either synchronous or asynchronous modes. Further, in each of these modes, it uses short or long frame sync operation. The circuit shown in *Figure 1* runs the codec in synchronous mode with long-frame-sync operation.

The codec requires 4 clock sources for proper operation in the synchronous mode. These are MCLK-x, BCLK-x, FS-x and FS-r. MCLK-x is a master clock and is used to clock the switched-capacitor filters. BCLK-x is the bit shift clock, and FS-x and FS-r are the frame sync clocks. These clocks need to be synchronous.

These clocks are obtained in the circuit as follows. MCLK-x is obtained by dividing the HPC CK2 clock output by 4. If the HPC is using a 16 MHz crystal, this results in MCLK-x being 2 MHz.

BCLK-x is obtained by dividing CK2 by 64. This gives an effective value for BCLK-x of 125 kHz. Note that MCLK-x is inverted before being fed to the codec. This is done to synchronize MCLK-x and BCLK-x on their leading edges.

FS-x and FS-r are the same clocks in the circuit. They are obtained by dividing BCLK-x by 16 using the timer T2 on the HPC. BCLK-x is used as the external clock input on pin T2IO of the HPC and FS-x (FS-r) is obtained from the timer synchronous output TS0. Note that the delay inherent in the HPC between the underflow of a timer and the toggling of the corresponding output allows FS-x and BCLK-x to be leading edge synchronized (more accurately, the delay is within the codec's acceptable limits.) Note that in order to accomplish these functions, the HPC pins need to be properly configured. This is not described here. Please refer to the appropriate HPC documentation and consult the sample program included with this report.

2. **MICROWIRE/PLUS Interface Considerations.** MICRO-WIRE/PLUS is a National Semiconductor defined 8-bit serial synchronous communication interface. It is designed to allow easy interfacing of NSC microcontrollers and peripheral chips. The HPC microcontroller has a MICROWIRE/PLUS interface; however the TP3054 codec does not. Thus some external "glue logic" is necessary to allow the HPC and the TP3054 to be interfaced.

The HPC MICROWIRE/PLUS interface is operated in Slave mode for this application. This means that the shift clock needed to latch-in/shift-out data from the Micro-wire SIO register is provided externally on the SK pin. Micro-wire latches in data on the leading edge of the SK clock and shifts out data on the trailing edge of SK. Also SK needs to be a burst clock for proper operation.

FIGURE 2. Timing Waveforms

TL/DD/9246-2

The codec shifts out data on the D-x pin on the first 8 leading edges of BCLK-x after a FS-x leading edge. Also, it latches in data on the D-r pin on the first 8 trailing edges of BCLK-x after a FS-r leading edge. Note that FS-x and FS-r are the same in this application. Refer to the timing diagram in *Figure 2*.

Thus, it is seen that there is a timing difference in the way the codec and the Micro-wire interfaces work. However, as seen in *Figure 2*, if the shift clock, SK, to the Microwire interface is delayed with respect to BCLK-x, the two interfaces should work compatibly. This delay is accomplished by clocking BCLK-x through a shift register using MCLK-x as the clock source. This can be seen in the circuit schematic in *Figure 1*. (The author thanks Mr. Richard Lazovick for this suggestion.)

μ -LAW TO LINEAR/LINEAR TO μ -LAW CONVERSION

It was explained earlier that the codec outputs digital values that are expanded using the MU-255 PCM standard. However, for linear digital filtering applications, the input needs to be in linear PCM format. Similarly, it is necessary to provide the conversion from linear PCM to MU-255 PCM before output to the codec. The HPC accomplishes this in software.

1. μ -law to linear conversion. The codec output is actually the complement of the μ -law value. Thus, this first needs to be complemented to obtain the true μ -law value. The simplest way to obtain the corresponding linear value is through table look-up. The output of the table is the 16-bit 2's complement linear value. The sample program included with this report utilizes this technique. A macro that constructs this table is also provided.
2. Linear to μ -law conversion. An algorithm to convert a 13-bit positive linear number to 7-bit μ -law is described in *Figure 3*. The algorithm is based on the description in the book by Bellamy listed in the reference. The most significant 8th bit for the μ -law code is obtained from the sign of the input linear code.
1. Get 13-bit positive input value.
2. Add to it the bias value of 31-decimal.
3. The compressed μ -law word is then obtained as follows:

Biased Linear Value												
Bits												
12	11	10	9	8	7	6	5	4	3	2	1	0
0	0	0	0	0	0	0	1	Q3	Q2	Q1	Q0	a

1	1	0	Q3	Q2	Q1	Q0
1	1	1	Q3	Q2	Q1	Q0

FIGURE 3. 13-Bit Linear to 8-Bit μ -Law Conversion

POSSIBLE APPLICATIONS

The codec/HPC interface described above can be used in a number of speech processing applications. One application, ADPCM coding of speech, is presently under development. Other applications include: a voiced/unvoiced/silence classifier, a voice pitch tracker, speech detection circuitry etc. Note that the main limitation here (at least for real-time applications) is the amount of effective computation that can be done by the HPC between samples.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communication package and a PC, the code detailed in this App Note can be down loaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162
Voice (408) 721-5582

Digital Filtering Using the HPC

National Semiconductor
Application Note 485
Ashok Krishnamurthy

INTRODUCTION

This report discusses the implementation of Infinite Impulse Response (IIR) digital filters using the National Semiconductor HPC microcontroller. A general program, that can be used to implement cascaded second order sections, up to a maximum of 8 sections, is also included. The program may have to be modified for specific A/D and D/A interfaces.

This report is not intended to be a tutorial on Digital Filter Design methods or their implementation details. Such information can be found in references 1 and 2 below. The general discussion included here closely follows that in reference 3.

DIGITAL FILTERING

The general IIR filter with input $x(n)$ and output $y(n)$ can be described by a transfer function of the form

$$H(z) = \frac{Y(z)}{X(z)} = \frac{a(0) + a(1)z^{-1} + \dots + a(m)z^{-m}}{1 + b(1)z^{-1} + \dots + b(p)z^{-p}}$$

To minimize the effects of coefficient truncation, high order filters are usually implemented as a cascade of second order sections. (Another possible choice is parallel realization—see references below).

In cascade realizations, the numerator and denominator polynomials in the above are factored into second order terms, and the filter is realized as a cascade of such second order sections. This is shown in *Figure 1*. A typical second order section has a transfer function of the form

$$H(z) = \frac{A_0 + A_1 \times z^{-1} + A_2 \times z^{-2}}{1 + B_1 \times z^{-1} + B_2 \times z^{-2}}$$

A second order section such as the above can be realized in a number of ways; the one of concern here is the so-called 1-D form (see Reference 3). The second order 1-D form is shown in *Figure 2*. Based on this figure, we can obtain the following equations:

$$m(k) = x(k) - B_1 \times m(k-1) - B_2 \times m(k-2)$$

$$y(k) = A_0 \times m(k) + A_1 \times m(k-1) + A_2 \times m(k-2)$$

Define $T_1 = -B_1 \times m(k-1) - B_2 \times m(k-2)$,

$$T_2 = A_1 \times m(k-1) + A_2 \times m(k-2)$$

FIGURE 1. Cascade Realization of a Digital Filter

TL/DD/9247-2

FIGURE 2. One Second Order Section

Since T_1 and T_2 depend on signal values at time $k-1$ and $k-2$, we can precompute and store these quantities in the time interval from $k-1$ to k . Then, when $x(k)$ becomes available at time k , $y(k)$ and $m(k)$ can be quickly computed using

$$m(k) = x(k) + T_1,$$

$$y(k) = A_0 \times m(k) + T_2$$

If there are a number of stages, then these computations should be repeated for each stage. Based on these discussions, the operation of a digital filter can be described using the flowchart in *Figure 3*.

USING THE FILTER PROGRAM

Appendix A contains the listing of the program FILTER that can be used to implement cascaded IIR filters as described above. The program as shown uses a codec interfaced to the HPC using MICROWIRE/PLUSTM to do the A/D and D/A conversion. The program can be used with other A/D and D/A converters by suitably modifying the following sub-routines: INPUT, OUTPUT and INIT. Only the portions of INIT that deal with the codec interface need to be modified.

TL/DD/9247-1

The filter coefficients and the number of cascaded stages need to be supplied to the program. This is done as follows:

1. *Specification of filter order.* Define a word address called ROMNST and store the number of cascaded stages in that word. The program is presently set up for 4 cascaded stages.

2. *Specification of filter coefficients.* Each second order stage needs the specification of 5 coefficients, A0, A1, A2, B1 and B2. If the number of stages is m, let the coefficients be

A0-1, A1-1, A2-1, B1-1, B2-1 for stage 1,

A0-2, A1-2, A2-2, B1-2, B2-2 for stage 2,

.

.

A0-m, A1-m, A2-m, B1-m, B2-m for stage m.

TL/DD/9247-3

FIGURE 3. Flowchart for the Computations in a Second Order Module (Based on Reference 3)

Define 5 word addresses called ROMA0, ROMA1, ROMA2, ROMB1, ROMB2 and store these coefficients at these addresses as follows:

ROMA0: WORD A0-1, A0-2, A0-3, ... A0-m

ROMA1: WORD A1-1, A1-2, A1-3, ... A1-m

ROMA2: WORD A2-1, A2-2, A2-3, ... A2-m

ROMB1: WORD B1-1, B1-2, B1-3, ... B1-m

ROMB2: WORD B2-1, B2-2, B2-3, ... B2-m.

Note that the coefficients are signed and need to be in 2's complement representation. Also, the stored coefficients need to be half their actual value. This is because of the way that the program does 2's complement multiplication using the subroutine SMULT.

The FILTER program copies all the coefficients to on-chip RAM for faster execution. Also temporary storage for $m(k)$, $m(k-1)$, $m(k-2)$, T1 and T2 is obtained from on-chip RAM. This, along with the storage of various addresses used by the program consumes the entire 192 bytes of user base page RAM.

Note that the filter program does not check for overflow during the various additions. This is because the HPC does not have a signed addition/subtraction overflow flag, and it was felt that the simulation of this feature in software would add excessive overhead. It is therefore the user's responsibility to ensure that the filter coefficients are properly scaled so that the overflow will not occur.

16 x 16 2's COMPLEMENT MULTIPLICATION

One of the basic operations in digital filtering is that of signed multiplication. Since the HPC supports unsigned multiplication only, a method to perform 2's complement multiply using the unsigned multiply is needed.

Let A and B be 2's complement 16 bit integers. Consider the following cases.

1. $A \geq 0, B \geq 0$. In this case the unsigned multiply result is $A \times B$, which is also the 2's complement multiply result. Thus no further processing is needed.
2. $A \geq 0, B < 0$. In this case the unsigned multiply result is $(2^{16}) \times A - A \times |B|$. However the desired result is $(2^{32}) - A \times |B|$. Thus we need to add $(2^{32}) - (2^{16}) \times A$ to the unsigned multiply result to obtain the correct value.
3. $A < 0, B \geq 0$. This case is similar to the previous one. $(2^{32}) - (2^{16}) \times B$ should be added to the unsigned multiply result to get the correct answer.
4. $A < 0, B < 0$. The unsigned multiply result in this case is $(2^{32}) - (2^{16}) \times (|A| + |B|) + |A| \times |B|$. The desired result in this case is $|A| \times |B|$. To get the correct answer, add $(2^{16}) \times (|A| + |B|)$ to the unsigned multiply result.

Based on the above discussion, an algorithm for 2's complement multiplication, where the result is a 32 bit 2's complement integer is shown in Figure 4.

1. Let A and B be the two 2's complement integers to be multiplied.
2. Compute $C = A \times B$, the unsigned product of A and B. Let the upper half of C be C-hi and its lower half C-lo.
3. If A is negative, then add $(2^{16}) - B$ to C-hi. This can be easily done using the SET C, SUBC instructions of the HPC. Let the result be C-hi1.
4. If B is negative, then add $(2^{16}) - A$ to C-hi1. Again it is easily done using the SET C, SUBC instructions. Let the result be C-hi2.
5. The 2's complement product of A and B is C-hi2. C-lo.

FIGURE 4. Algorithm for 2's Complement Multiplication.

MULTIPLICATION BY FILTER COEFFICIENTS

The coefficients that arise in most IIR filter designs are numbers that are usually in the range from $-2 < \text{coeff} < 2$. The coefficients, in most instances can be scaled to be in this range. The action of digital filtering involves successive multiplications. If we want no loss in accuracy due to multiplication, the word length needed to store successive partial products increases rapidly—clearly an impractical choice. Thus the results of the multiplication at the various stages need to be truncated to 16 bits before proceeding to the next stage. The program FILTER does this as follows: The filter state variables are regarded as integers, while the filter coefficients are regarded as fixed point fractions with the binary point to the immediate right of the sign bit. After the multiplication, the result is shifted so that the integer part of the product is in one word, and the fractional part in another. The integer part is then returned as the result of the multiplication, i.e. the product is truncated to 16 bits. This is per-

formed by the subroutine SMULT. Since the filter coefficients are regarded as fixed point fractions, only coefficients in the range $-1 < \text{coeff} < 1$ can be represented. However, as discussed earlier, the coefficients are usually in the $-2 < \text{coeff} < 2$ range. This is handled by storing half the coefficient value, and SMULT performs a multiplication by 2 (Shift left) to compensate for it. This is why the coefficient values need to be half their value—a fact mentioned earlier.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be downloaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

A Floating Point Package for the HPC

National Semiconductor
Application Note 486
Ashok Krishnamurthy

INTRODUCTION

This report describes the implementation of a Single Precision Floating Point Arithmetic package for the National Semiconductor HPC microcontroller. The package is based upon the IEEE Standard for Binary Floating-Point Arithmetic (ANSI/IEEE Std 754-1985). However, the package is not a conforming implementation of the standard. The differences between the HPC implementation and the standard are described later in this report.

The following single precision (SP) operations have been implemented in the package.

- (1) **FADD.** Addition of two SP floating point (FLP) numbers.
- (2) **FSUB.** Subtraction of two SP FLP numbers.
- (3) **FMULT.** Multiplication of two SP FLP numbers.
- (4) **FDIV.** Division of two SP FLP numbers.
- (5) **ATOF.** Convert an ASCII string representing a decimal FLP number to a binary SP FLP number.
- (6) **FTOA.** Convert a binary SP FLP number to a decimal FLP number and output the decimal FLP number as an ASCII string.

The report is organized as follows. The next section discusses the representation of FLP numbers. Then, the differences between the HPC implementation and the IEEE/ANSI standard are described. This is followed by a description of the algorithms used in the computations. Appendix A is a User's Manual for the package, Appendix B describes the test data for the package and Appendix C is a listing of the code.

Note that this report assumes that the reader is familiar with the IEEE/ANSI Binary Floating-Point Standard. Please refer to this document for an explanation of the terms used here.

REPRESENTATION OF FLOATING POINT NUMBERS

The specification of a binary floating point number involves two parts: a mantissa and an exponent. The mantissa is a signed fixed point number and the exponent is a signed integer. The IEEE/ANSI standard specifies that a SP FLP number shall be represented in 32 bits as shown in *Figure 1*.

FIGURE 1

The significance of each of these fields is as follows:

1. **S**—this 1-bit field is the sign of the mantissa. $S = 0$ means that the number is positive, while $S = 1$ means that it is negative.
2. **E**—this is the 8-bit exponent field. The exponent is represented as a biased value with a bias of 127-decimal.
3. **F**—this is the 23-bit mantissa field. For normalized FLP numbers (see below), a MSB of 1 is assumed and not represented. Thus, for normalized numbers, the value of the mantissa is 1.F. This provides an effective precision of 24 bits for the mantissa.

Normalized FLP number: A binary FLP number is said to be normalized if the value of the MSB of the mantissa is 1. Normalization is important and useful because it provides maximum precision in the representation of the number. If we deal with normalized numbers only (as the HPC imple-

mentation does) then since the MSB of the mantissa is always 1, it need not be explicitly represented. This is as specified in the IEEE/ANSI standard.

Given the values of S , E and F , the value of the SP FLP number is obtained as follows.

If $0 < E < 255$, then the FLP number is $(-1)^S \cdot 1.F \cdot 2^{(E-127)}$.

If $E = 0$, then the value of the FLP number is 0.

If $E = 255$, then the FLP number is not a valid number (NaN).

The above format for binary SP FLP numbers provides for the representation of numbers in the range $-3.4 \cdot 10^{38}$ to $-1.75 \cdot 10^{-38}$, 0, and $1.75 \cdot 10^{-38}$ to $3.4 \cdot 10^{38}$. The accuracy is between 7 and 8 decimal digits.

DIFFERENCES BETWEEN THE IMPLEMENTATION AND THE IEEE/ANSI STANDARD

The IEEE/ANSI standard specifies a comprehensive list of operations and representations for FLP numbers. Since an implementation that fully conforms to this standard would lead to an excessive amount of overhead, a number of the features in the standard were dropped. This section describes the differences between the implemented package and the standard.

1. Omission of -0 . The IEEE/ANSI standard requires that both $+$ and $-$ zero be represented, and arithmetic carried out using both. The implementation does not represent -0 . Only $+0$ is represented and arithmetic is carried out with $+0$ only.
2. Omission of Infinity Arithmetic. The IEEE/ANSI standard provides for the representation of plus and minus Infinity, and requires that valid arithmetic operations be carried out on Infinity. The HPC implementation does not support this.
3. Omission of Quiet NaN. The IEEE/ANSI standard provides for both quiet and signalling NaNs. The HPC implementation provides for signalling NaNs only. A signalling NaN can be produced as the result of overflow during an arithmetic operation. If the NaN is passed as input to further floating point routines, then these routines will produce another NaN as output. The routines will also set the Invalid Operation flag, and call the user floating point error trap routine at address FPTRAP.
4. Omission of denormalized numbers. Denormalized numbers are FLP numbers with a biased exponent, E of zero and a non zero mantissa F . Such denormalized numbers are useful in providing gradual underflow to zero. Denormalized numbers are not represented or used in the HPC implementation. Instead, if the result of a computation cannot be represented as a normalized number within the allowable exponent range, then an underflow is signaled, the result is set to zero, and the user floating point error trap routine at address FPTRAP is called.
5. Omission of the Inexact Result exception. The IEEE/ANSI standard requires that an Inexact Result exception be signaled when the rounded result of an operation is not exact, or it overflows without an overflow trap. This feature is not provided in the HPC implementation.

6. **Biased Rounding to Nearest.** The IEEE/ANSI standard requires that rounding to nearest be provided as the default rounding mode. Further, the rounding is required to be unbiased. The HPC implementation provides biased rounding to nearest only. An example will help clarify this. Suppose the result of an operation is .b1b2b3XXX and needs to be rounded to 3 binary digits. Then if XXX is 0YY, the round to nearest result is .b1b2b3. If XXX is 1YY, with at least one of the Y's being 1, then the result is .b1b2b3 + 0.001. Finally if XXX is 100, it is a tie situation. In such a case, the IEEE/ANSI standard requires that the rounded result be such that its LSB is 0. The HPC implementation, on the other hand, will round the result in such a case to .b1b2b3 + 0.001.

DESCRIPTION OF ALGORITHMS

1. **General Considerations.** The HPC implementation of the SP floating point package consists of a series of subroutines. The subroutines have been designed to be compatible with the CCHPC C Cross Compiler. They have, however, not been tested with the CCHPC Cross Compiler.

The Arithmetic subroutines that compute F1 op F2 (where op is +, -, * or /) expect that F1 and F2 are input in the IEEE format. Each of F1 and F2 consists of two 16-bit words organized as follows.

F_n-HI: S EXP 7 MS bits of F

F_n-LO: 16 LS bits of F

In the above, S is the sign of the mantissa, EXP is the biased exponent, and F is the mantissa.

On input it is assumed that F1-HI is in register K, F1-LO is in the accumulator A, and F2-HI and F2-LO are on the stack just below the return address i.e., F2-HI is at W(SP-4) and F2-LO is at W(SP-6). The result, C, is also returned in IEEE format with C-HI in register K and C-LO in the accumulator A.

The two Format Conversion routines, ATOF and FTOA expect that on entry, register B contains the address of the start of the ASCII byte string representing the decimal FLP number. ATOF reads the byte string starting from this address. Note that the string must be terminated with a null byte. The binary floating point number is returned in registers K and A. FTOA, on the other hand, writes the decimal FLP string starting from the address in register B on entry. A terminating null byte is also output. Also, FTOA expects that the binary FLP number to be converted is in registers K and A on entry.

Most of the storage required by the subroutines is obtained from the stack. Two additional words of storage in the base page are also used. The first is W(0), and is referenced in the subroutines as W(TMP1). The second word of storage can be anywhere in the base page and is used to store the sticky flags used to signal floating point exceptions. This is referenced in the subroutines as W(FPERWD). Thus any user program that uses the floating point package needs to have the symbols TMP1 and FPERWD defined appropriately.

2. **Exception Handling.** The following types of exception can occur during the course of a computation.

- (i) **Invalid Operand.** This exception occurs if one of the input operands is a NaN.
- (ii) **Exponent Overflow.** This occurs if the result of a computation is such that its exponent has a biased value of 255 or more.

(iii) **Exponent Underflow.** This occurs if the result of a computation is such that its exponent is 0 or less.

(iv) **Divide-by-zero.** This exception occurs if the FDIV routine is called with F2 being zero.

The package signals exceptions in two ways. First a word at address FPERWD is maintained that records the history of these exception conditions. Bits 0-3 of this word are used for this purpose.

Bit 0—Set on Exponent Overflow.

Bit 1—Set on Exponent Underflow.

Bit 2—Set on Illegal Operand.

Bit 3—Set on Divide-by-zero.

These bits are never cleared by the floating point package, and can be examined by the user software to determine the exception conditions that occurred during the course of a computation. It is the responsibility of the user software to initialize this word before calling any of the floating point routines.

The second method that the package uses to signal exceptions is to call a user floating point exception handler subroutine whenever an exception occurs. The corresponding exception bit in FPERWD is set before calling the handler. The starting address of the handler should be defined by the symbol FPTRAP.

3. **Unpacked Floating Point Format.** The IEEE/ANSI standard floating point format described earlier is very cumbersome to deal with during computation. This is primarily because of the splitting of the mantissa between the two words. The subroutines in the package unpack the input FLP numbers into an internal representation, do the computations using this representation, and finally pack the result into the IEEE format before return to the calling program. The unpacking is done by the subroutine FUNPAK and the packing by the subroutine FPAK. The unpacked format consists of 3 words and is organized as follows.

F_n-EXP.F_n-SIGN 8 bits biased sign (extended to exponent 8 bits)

F_n-HI MS 16 bits of mantissa (implicit 1 is present as MSB)

F_n-LO LS 8 bits of Eight mantissa Zeros

Since all computations are carried out in this format, note that the result is actually known to 32 bits. This 32-bit mantissa is rounded to 24 bits before being packed to the IEEE format.

4. **Algorithm Description.** All the arithmetic algorithms first check for the easy cases when either F1 or F2 is zero or a NaN. The result in these cases is immediately available. The description of the algorithms below is for those cases when neither F1 nor F2 is zero or a NaN. Also, in order to keep the algorithm description simple, the check for underflow/overflow at the various stages is not shown. The documentation in the program, the descriptions given below, and the theory as described in the references should allow these programs to be easily maintained.

(i) **FADD.**

The processing steps are as follows:

1. Compare F1-EXP and F2-EXP. Let the difference be D. Shift right the mantissa (F_n-HI.F_n-LO, n = 1 or 2) of the FLP number with the smaller exponent D times. Let the numbers after this step be F1-EXP.F1-SIGN, F1-HI, F1-LO and F2-EXP.F2-SIGN,

F2-HI and F2-LO. This step equalizes the two exponents.

2. Take the XOR of F1-SIGN and F2-SIGN. If this is 0, then go to step 4, else go to step 3.
3. Do a true subtract of F2-LO from F1-LO. (A true subtract is when the SUBC instruction is preceded by a SET C instruction.) Then do a 1's complement subtract of F2-HI from F1-HI. If the last subtract resulted in C = 1, then go to step 3.2, else go to step 3.1.
 - 3.1. Get here means that F2 is larger than F1, and the computed result is negative. Take the 2's complement of the result to make it positive. Set the sign of the result to be the sign of F2. Go to step 3.3.
 - 3.2. Get here means F1 is larger than F2, and the result of the mantissa subtract is positive. Set the sign of the result to be the sign of F1. Go to step 3.3.
 - 3.3. The result after a subtract need not be normalized. Shift left the result mantissa until its MSB is 1. Decrement the exponent of the result by 1 for each such left shift. Go to step 5.
4. Add F2-LO to F1-LO. Next add with any carry from the previous add, F2-HI to F1-HI. If this last add results in C = 1, then go to step 4.1, else go to step 5.
 - 4.1. Rotate Right with carry C-HI. Next load C-LO in and rotate it right with carry. Increase the exponent of the result, C by 1. Go to step 5.
5. Round the result. Go to step 6.
6. Pack the result and return.

(ii) FSUB.

The processing steps are as follows:

1. Copy F2 to the stack and change its sign. Go to step 2.
2. Call FADD.
3. Remove the copy of -F2 from the stack and return.

(iii) FMULT.

The processing steps are as follows.

1. Add F1-EXP and F2-EXP to get C1-EXP. Subtract from C1-EXP 127-decimal which is the IEEE bias, to get C-EXP. Go to step 2.
2. Take the XOR of F1-SIGN and F2-SIGN to get C-SIGN. Go to step 3.
3. Compute F1-HI*F2-HI. Let the upper half of the product be C1-HI and the lower half C1-LO. Go to step 4.
4. Compute F1-HI*F2-LO. Let the upper half of this product be C2-HI. Add C2-HI to C1-LO to give C11-LO. If this last add results in C = 1, then increment C1-HI. Go to step 5.
5. Compute F1-LO*F2-HI. Let the upper half of this product be C3-HI. Add C3-HI to C11-LO to get C12-LO. If this last add results in C = 1, then increment C1-HI. Go to step 6.
6. Mantissa normalization. If the MSB of C1-HI is 1, then increment C-EXP, else shift left C1-HI.C12-LO. Go to step 7.
7. Round C1-HI.C12-LO to get C-HI.C-LO. Go to step 8.

8. Pack C-EXP.C-SIGN, C-HI and C-LO and return as the answer.

(iv) FDIV.

The processing steps are as follows:

1. Compare F1-HI and F2-HI. If F2-HI is greater than F1-HI then go to Step 3, else go to step 2.
2. Shift right F1-HI.F1-LO. Increase F1-EXP by 1.
3. Subtract F2-EXP from F1-EXP. Add to the result 127-decimal to get C1-EXP. Go to step 4.
4. Take the XOR of F1-SIGN and F2-SIGN to get C-SIGN. Go to step 5.
5. Compute F1-HI*F2-LO. Let the result be M1-HI.M1-LO. Go to step 6.
6. Divide M1-HI.M1-LO by F2-HI. Let the quotient be M2-HI. Go to step 7.
7. Do a true subtract of M2-HI from F1-LO. Let the result be M3-LO. If C = 1 as a result of this subtract, then go to step 8, else decrement F1-HI and go to step 8.
8. Divide F1-HI.M3-LO by F2-HI. Let the quotient be C1-HI and the remainder R1. Go to step 9.
9. Divide R1 .0000 by F2-HI. Let the quotient be C1-LO. Go to step 10.
10. If the MSB of C1-HI is 1 then go to step 11, else shift left C1-HI.C1-LO, decrease C1-EXP by 1 and go to step 11.
11. Round C1-HI.C1-LO to get C-HI.C-LO. go to step 12.
12. Pack C1-EXP.C-SIGN, C-HI and C-LO and return as the result.

(v) ATOF.

The processing steps in this case are as follows.

1. Set M-SIGN, the mantissa sign to 0.
Set M10-EXP, the implicit decimal exponent to 0.
Set HI-INT to 0.
Set LO-INT to 0.
Go to step 2.
2. Get a character from the input string. Let the character be C.
If C is a '+', then go to the start of step 2.
If C is a '-', then set M-SIGN to FF and go to start of step 2.
If C is a '.', then go to step 5.
If C is none of the above, then go to step 3.
3. Subtract 30 from C to get its integer value. Let this be I. Check and see if (HI-INT.LO-INT)*10 + 9 can fit in 32 bits. If it can, then go to step 3.1, else go to step 3.2.
 - 3.1. Multiply HI-INT.LO-INT by 10 and add I to the product. Store this sum back in HI-INT.LO-INT. Go to step 4.
 - 3.2. Increase M10-EXP by 1 and go to step 4.
4. Get a character from the input string. Let the character be C.
If C is a '.', then go to step 5.
If C is a 'E', then go to step 7.
If C is the space character, then go to the start of step 4.
If C is none of the above, then go to step 3.

5. Get a character from the input string. Let the character be C.
If C is a 'E', then go to step 7.
If C is the space character, then go to the start of step 5.
If C is none of the above, then go to step 6.
6. Subtract 30 from C to get its integer value. Let this be I. Check and see if $(HI-INT.LO-INT)*10 + 9$ can fit in 32 bits. If it can, then go to step 6.1, else go to step 5.
 - 6.1. Multiply HI-INT.LO-INT by 10 and add I to the product. Store this sum back in HI-INT.LO-INT. Decrement M10-EXP by 1. Go to step 5.
7. Set SEXP, the exponent sign to be 0. Go to step 8.
8. Get a character from the input string. Let the character be C.
If C is a '+', then go to start of step 8.
If C is a '-', then set SEXP to be FF and go to the start of step 8.
If C is none of the above, then go to step 9.
9. Set M20-EXP, the explicit decimal exponent to 0. Go to step 10.
10. Subtract 30 from C to get its integer value. Let this be I. Multiply M20-EXP by 10 and add I to the product. Store this sum back in M20-EXP. Go to step 11.
11. Get a character from the input string. Let this be C. If C is the null character, then go to step 12, else go to step 10.
12. Add M10-EXP and M20-EXP (with the proper sign as determined by SEXP) to get the 10's exponent M-EXP. Save in M-EXP the magnitude of the sum and in SEXP the sign of the sum. Go to step 13.
13. Check and see if HI-INT.LO-INT is 0. If it is, then set the resulting floating point number, C, to zero and return. If it is not then go to step 14.
14. Normalize HI-INT.LO-INT by left shifts such that the MSB is 1. Let the number of left shifts needed to do this be L. Set B1-EXP to 32-decimal - L. Go to step 15.
15. If SEXP is 0, then set P-HI.P-LO to the binary representation of 0.625, else set P-HI.P-LO to the binary representation of 0.8. Go to step 16.
16. Multiply HI-INT.LO-INT by P-HI.P-LO M-EXP times. After each multiplication, normalize the partial product if needed by left shifting. Accumulate the number of left shifts needed in B2-EXP. Let the final product be C-HI.C-LO. Go to step 17.
17. Subtract B2-EXP from B1-EXP. Let the result be B-EXP. Go to step 18.
18. If SEXP is 0, then multiply M-EXP by 4, else multiply M-EXP by -3. Let the result be B3-EXP. Go to step 19.
19. Add B-EXP and B3-EXP. Let the result be C1-EXP. Add 126 to C1-EXP to restore the IEEE bias, getting C-EXP. Go to step 20.
20. Round C-HI.C-LO. Go to step 21.
21. Pack C-EXP.M-SIGN, C-HI and C-LO and return.

(vi) FTOA.

The processing steps are as follows.

1. Unpack the input FLP number. Let the unpacked number be represented by C-EXP.C-SIGN, C-HI and C-LO. Go to step 2.
2. Subtract 126-decimal from C-EXP to remove the IEEE bias. Let the result be C1-EXP. Go to step 3.
3. Multiply C1-EXP by the binary representation of $\log_2(2)$. Let the product be U-HI.U-LO. Go to step 4.
4. Subtract 8 from U-HI.U-LO. Let the magnitude of the integer part of the result be V and its sign VSIGN. Go to step 5.
5. If VSIGN is 0, then set P-HI.P-LO to the binary representation of 0.8, else set P-HI.P-LO to the binary representation of 0.625. Go to step 6.
6. Multiply C-HI.C-LO by P-HI.P-LO V times. Normalize the partial product after each multiplication, if needed, by left shifting. Accumulate any left shifts needed in B1-EXP. Let the final product be HI-INT.LO-INT. Go to step 7.
7. Subtract B1-EXP from C1-EXP. Let the result be B2-EXP. Go to step 8.
8. If VSIGN is 0, then multiply V by -3, else multiply it by 4. Let the result be B3-EXP. Go to step 9.
9. Add B2-EXP and B3-EXP. Let the result be B4-EXP. Go to step 10.
10. If B4-EXP is more than 32-decimal, then increase V and go to step 6, else go to step 11.
11. If B4-EXP is less than 28-decimal, then decrease V and go to step 6, else go to step 12.
12. Subtract B4-EXP from 32. Let the result be B5-EXP. Go to step 13.
13. Shift HI-INT.LO-INT right B5-EXP number of times. Go to step 14.
14. Add 16-decimal to the address of the start of the decimal string. Output a null byte there. Go to step 15.
15. Divide V by 10-decimal. Let the quotient be Q and the remainder R. Add 30 to R and output it to the decimal string. Next add 30 to Q and output it to the decimal string. Go to step 16.
16. If VSIGN is 0, then output '+' to the output string, else output '-' to the output string. Go to step 17.
17. Output 'E' to the output string. Output '.' to the output string. Go to step 18.
18. Divide C-HI.C-LO by 10-decimal 10 times. Let the remainder in each division be R. Add 30 to each R and output it to the output string. Go to step 19.
19. If C-SIGN is 0, then output the space character to the output string, else output '-' to the output string. Then return to the calling program.

APPENDIX A**A USER'S MANUAL FOR THE HPC
FLOATING POINT PACKAGE**

The Single Precision Floating Point Package for the HPC implements the following functions.

ARITHMETIC FUNCTIONS

1. FADD—Add two floating point numbers.
2. FSUB—Subtract two floating point numbers.
3. FMULT—Multiply two floating point numbers.
4. FDIV—Divide two floating point numbers.

FORMAT CONVERSION FUNCTIONS

5. ATOF—Convert an ASCII string representing a decimal floating point number to a single precision floating point number.
6. FTOA—Convert a single precision floating point number to an ASCII string that represents the decimal floating point value of the number.

The entire package is in the form of a collection of subroutines and is contained in the following files.

1. FERR.MAC
2. FNACHK.MAC
3. FZCHK.MAC
4. FUNPAK.MAC
5. FPAK.MAC
6. FPTRAP.MAC
7. ROUND.MAC
8. BFMUL.MAC
9. ISIOK.MAC
10. MUL10.MAC
11. ATOF.MAC
12. FTOA.MAC
13. FADD.MAC
14. FMULT.MAC
15. FDIV.MAC

The first 7 files are general utility routines that are used by all the Arithmetic and Format Conversion subroutines. The next 3 files, BFMUL.MAC, ISIOK.MAC and MUL10.MAC are used only by the Format Conversion subroutines, ATOF and FTOA. Depending on the functions being used in the user program, only the necessary files need be included.

INTERFACE WITH USER PROGRAMS

1. All the Arithmetic routines expect the input to be in the IEEE Single Precision format. This format requires 2 words for the storage of each floating point number. If the required arithmetic operation is FlopF2, where op is +, -, *, or /, then the routines expect that F1 is available in registers K and A on entry, with the high half in K. Also, the two words of F2 are expected to be on the stack. If SP is the stack pointer on entry into one of the Arithmetic function subroutines, then the high word of F2 should be at W(SP-4) and the low word at W(SP-6). The result of the Arithmetic operation is returned in IEEE format in registers K and A, with the high word in K.

2. The Format Conversion subroutine ATOF expects that on entry, B contains the address of the ASCII string representing the decimal floating point number. This string must be of the form

Siiii.fffffEsNND

where

S is an optional sign for the mantissa. Thus S can be '+', '-' or not present at all.

iiii is the optional integer part of the mantissa. If it is present, it can be of any length, must contain only the characters '0' through '9' and must not contain any embedded blanks.

. is the optional decimal point. It need not be present if the number has no fractional part.

fffff is the optional fractional part of the mantissa. fffff is it is present must consist of a sequence of digits '0' through '9'. It can be of any length. Note that either iiiii, the integer part or .fffff the fractional part must be present.

E is the required exponent start symbol.

s is the optional sign of the exponent. If it is present, it must be '+' or '-'.

NN is the exponent and consists of at most two decimal digits. It is required to be present.

D is the null byte <00> and must be present to terminate the string.

The floating point number represented by the above string is returned by ATOF in IEEE format in registers K and A.

3. The format conversion routine FTOA expects the floating point number input to be in registers K and A in the IEEE format. Register B is expected to contain the starting address of a 17 byte portion of memory where the output string will be stored.
4. Three global symbols need to be defined in the user program before assembling the user program and any included floating point package files. These symbols are:
 - (i) TMP1 which must be set to 0. The package uses W(TMP1) for temporary storage.
 - (ii) FPERWD which must be set to an address in the base page. The package signals floating point exceptions using W(FPERWD). This is described below.
 - (iii) FPTRAP which must be set to the address of the start of a user floating point exception handler. Again this is described below.

FLOATING POINT EXCEPTS

The package maintains a history of floating point exceptions in the 4 least significant bits of the word W(FPERWD). The value of the symbol FPERWD should be defined by the user program, and should be an address in the base page. This word should also be cleared by the user program before calling any floating point routine. The word is never cleared by the floating point package, and the user program can examine this word to determine the type of exceptions that may have occurred during the course of a computation.

The following 4 types of error can occur in the course of a floating point computation.

1. **Invalid Operand.** This happens if one of the input numbers for an Arithmetic routine or the input for FTOA is not a valid floating point number. An invalid floating point number (or NaN) can be created either by an overflow in a previous computation step, or if the ASCII decimal floating point number input to ATOF is too large to be represented in the IEEE format. The result, if one of the inputs is a NaN is always set to a NaN.
2. **Overflow.** This happens if the result of a computation is too large to be represented within the exponent range available. Overflow can occur in any of the arithmetic routines or ATOF. On overflow, the result is set to a representation called NaN. An NaN is considered an illegal operand in all successive steps.
3. **Underflow.** This occurs if the result of a computation is too small to be represented with the precision and expo-

nent range available. On underflow, the result is set to zero.

4. **Divide-by-zero.** This error occurs if F2 is zero when computing $F1/F2$. The result is set to an NaN.

Each of the above errors results in a bit being set in W(FPERWD). This is done as follows:

Bit 0—Set on Overflow.

Bit 1—Set on Underflow.

Bit 2—Set on Illegal Operand.

Bit 3—Set on Divide-by-zero.

One further action is taken when a floating point exception occurs. After the result has been set to the appropriate value, and the corresponding bit in W(FPERWD) set, the package does a subroutine call to address FPTRAP. The user can provide any exception handler at this address. The file FPTRAP.MAC contains the simplest possible user exception handler. It does nothing, but merely returns back to the calling program.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be down loaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162
Voice (408) 721-5582

A Radix 2 FFT Program for the HPC

National Semiconductor
Application Note 487
Ashok Krishnamurthy

INTRODUCTION

This report describes the implementation of a radix-2, Decimation-in-time FFT algorithm on the HPC. The program, as presently set up can do FFTs of length 2, 4, 8, 16, 32, 64, 128 and 256. The program can be easily modified to work with higher FFT lengths by increasing the Twiddle Factor table.

FFT FUNDAMENTALS

If $x(n)$, $n = 0, 1, \dots, N-1$ are N samples of a time domain signal, its Discrete Fourier Transform (DFT) is defined as

$$X(k) = \sum_{n=0}^{N-1} x(n) W^{nk}, \quad k = 0, 1, \dots, N-1$$

where $W = e^{-j2\pi/N}$

The straight evaluation of the above equation requires on the order of N^2 complex multiplies. The FFT is nothing but a fast algorithm to compute the DFT that uses only on the order of $N \log(N)$ complex multiplies. Many different FFT algorithms exist (please see references 1, 2 and 3). The algorithm implemented for the HPC is the most common type of FFT — a radix-2, Decimation-in-time algorithm. This class of algorithms requires that the number of input samples, N , be a power of 2. This is usually not a problem, since the input data can be zero padded to achieve this. The development of this algorithm is described in references 1 and 2; the discussion here is brief and based on reference 1.

Separating the DFT summation above into the even-numbered points and odd-numbered points of $x(n)$, we can rewrite the above sum as:

$$X(k) = \sum_{n \text{ even}} x(n) W^{nk} + \sum_{n \text{ odd}} x(n) W^{nk}$$

Using $n = 2r$ for n even and $n = 2r + 1$ for n odd, we can further rewrite the above as:

$$X(k) = \sum_{r=0}^{N/2-1} x(2r) W^{2rk} + W^k \sum_{r=0}^{N/2-1} x(2r+1) W^{2rk}$$

If $G(k)$ is the $N/2$ point DFT of $x(2r)$ and $H(k)$ is the $N/2$ point DFT of $x(2r+1)$, the above equation can be written as:

$$X(k) = G(k) + W^k H(k)$$

This equation shows that a N point DFT can be written as the sum of two $N/2$ point DFTs. The $N/2$ point DFTs can be computed as the sum two $N/4$ point DFTs and so on until we are left with two point DFTs. The two point DFTs can be trivially evaluated by direct computation.

Figure 1, taken from reference 1, shows the decomposition for the case $N = 8$. With reference to this figure, we can note the following points.

1. If N is the number of points in the original sequence, where $N = 2^L$, then there are L stages in the DFT decomposition.

2. The basic computation unit is the so-called Butterfly, shown in Figure 2. Each stage involves the computation of $N/2$ butterflies.
3. The results from the computation in one stage are fed to the next stage after multiplication by some power of W . These powers of W are the so-called Twiddle Factors. Note that each power of W is really a complex number that can be represented by its real and imaginary parts. The real part of W^k is $\cos(2\pi k/N)$ and the imaginary part is $-\sin(2\pi k/N)$.
4. The number of distinct Twiddle Factors used in the first stage is 1, in the second stage is 2 etc., until the L^{th} stage that involves $2^{L-1} = N/2$ twiddle factors. Each twiddle factor in the first stage is involved in $N/2$ Butterflies, in the second stage with $N/4$ butterflies etc., until in the L^{th} stage each twiddle factor is involved with $N/(2^L) = 1$ butterfly.
5. The input data sequence needs to be suitably scrambled if the output sequence is to be in the proper order. This scrambling is easily accomplished by using the so-called Bit-Reverse counter as outlined in reference 2.
6. The outputs from each stage can be stored back again in the same storage area as the input sequence. This gives the algorithm the in-place property. Thus the final DFT results overwrite the initial data.

THE INVERSE FFT

If $X(k)$ $k = 0, 1, \dots, N-1$ is the DFT of a sequence, then its inverse DFT, $x(n)$, is defined as follows:

$$x(n) = \left(\frac{1}{N}\right) \sum_{k=0}^{N-1} X(k) W^{-nk} \quad n = 0, 1, \dots, N-1.$$

Thus the Inverse FFT is the same as the forward FFT except for the following: 1. Negative powers of W are used instead of positive powers; and 2. The final sequence is scaled by $1/N$. The basic FFT program can therefore be used to compute the inverse FFT with these two changes. This is the approach used in the HPC implementation.

TWIDDLE FACTOR TABLE

The brief description of the FFT in the previous section shows that the algorithm needs to use the Twiddle Factors W^k in the computation. The twiddle factors can either be computed as required, they can be computed using a recursive relation, or they can be obtained by looking up in a table (Ref. 2). The approach used in the HPC implementation is to construct a table containing the needed twiddle factors. This table is stored in ROM and values needed are looked up from this table. The length of the table needed is determined by the maximum FFT length that you want to use. The HPC FFT implementation is presently limited to a maximum length of 256. This requires that the twiddle factors W^0, W^1, \dots, W^{255} be available, where

$W = e^{-j2\pi/256}$. Since $e^{ix} = \cos(x) + j\sin(x)$, the values stored in this table are $\cos(0)$, $\sin(0)$, $\cos(2\pi/256)$, $\sin(2\pi/256)$ etc., up to $\cos(2\pi \times 255/256)$, $\sin(2\pi \times 255/256)$. The table used in the implementation is organized as follows:

```
.WORD cos(0) × 214
.WORD sin(0) × 214
.WORD cos(2π/256) × 214
.WORD sin(2π/256) × 214
.
.
.
.WORD cos(2π255/256) × 214
.WORD sin(2π255/256) × 214
```

This table is available in the file TWDTBL.MAC and occupies 1024 bytes of storage.

DATA STORAGE

The data to be transformed, $x(0), \dots, x(N-1)$ are also regarded as complex numbers with a real and an imaginary part. Let $x_r(i)$ be the real part of $x(i)$ and $x_i(i)$ the imaginary part of $x(i)$. Then the data needs to be stored as follows:

```
.WORD xr(0)
.WORD xi(0)
.WORD xr(1)
.WORD xi(1)
.
.
.
.WORD xr(N-1)
.WORD xi(N-1)
```

The length of this storage area obviously depends on the number of data points to be transformed. Note that the FFT program itself does not use any base page user RAM. Also, only 8 words of stack are needed. Thus the base page user RAM can be used to store the data to be transformed. Since 192 bytes are available in this area, transforms of up to 32 point in length can be in the single chip mode with no external RAM.

USING THE FFT PROGRAM

The FFT program along with test data to test the program is provided in the files FFT.MAC, TSTDAT.MAC and TWDTBL.MAC. TSTDAT.MAC contains the test data, and the output from the FFT routines. TWDTBL.MAC contains the Twiddle Factors. The FFT computation involves the use

of 4 different subroutines: FFT, IFFT, BRNCNTR and SMULT. FFT does the forward FFT calculation, IFFT the Inverse FFT calculation, BRNCNTR implements the bit reversed counter, and SMULT does signed multiplication.

Two global symbols need to be defined by the user to use the FFT routines. The first, called TWSTAD should be set to the address of the start of the twiddle factor table. The second, called DTSTAD, should be set to the address of the start of the data area to be transformed. For details on the organization of these storage areas, see the preceding sections.

The actual number of data points to be transformed needs to be passed to the FFT routines. This is done as follows.

Two symbols that refer to words of on-chip RAM have been defined. The first is NUMB = W(01C0) and the second is L1 = W(01C2). Before calling the FFT routine, the user should load NUMB with N, the number of data points to be transformed, and L1 with L, $N = 2L$.

To do a forward FFT, call FFT; to do an inverse FFT, call IFFT. In both cases, the output of the transform overwrites the input data.

INCREASING THE MAXIMUM TRANSFORM LENGTH

The maximum transform length for the FFT program is primarily limited by the size of the Twiddle Factor table. To increase the transform length, the following needs to be done.

1. Increase the Twiddle Factor table. Thus, if the maximum transform length required is 1024, the table needs to store the cosine and sine of the angles

$$0, 2\pi/1024, 2\pi \times 2/1024, \dots, 2\pi \times 1023/1024$$

2. Change the global symbol LMAX such that the maximum transform length is 2^{LMAX} .

FFT/IFFT TEST PROGRAM

The data in the file TSTDAT.MAC can be used to test the FFT program. The data and its transform value is from reference 3. The program in reference 3 is for a Floating point FORTRAN FFT program. Since the HPC FFT program is a fixed point one, the input data needs to be suitably scaled. The scale factor chosen is 2^{10} . The file TSTDAT.MAC contains the scaled input data, and the expected transform. The input data is stored in memory words 200/27E and the expected transform is stored in memory words 280/2FE. To run the test program, do the following.

Set up the MOLE Development System with Blocks 0, 13, 14 and 15 mapped ON. Download the program to the MOLE. Set up a Breakpoint at F410. Run the program starting at F400. When the program is breakpointed, list memory words 200/27F and compare them with memory words 280/2FE.

Note that any difference between the expected DFT values and the DFT values actually computed is due to the fixed point computations in the FFT program.

The code listed in this App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be down loaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Expanding the HPC Address Space

National Semiconductor
Application Note 497
Joe Cocovich

INTRODUCTION

The maximum address range of the HPC family of 16-bit High Performance microControllers is 64k bytes using the external address/data bus to interface with external memory. This application note describes a method to increase the amount of memory in a system to 544k bytes utilizing bank switching techniques. Block diagrams are presented to aid in circuit design. Software examples are given for memory and bank management.

HPC ADDRESSING

Program memory addressing is accomplished by the 16-bit Program Counter on a byte basis (instructions are always fetched a byte at a time). Memory can be addressed as words or bytes directly by instructions or indirectly through the B, X and SP registers. Words are always addressed on even-byte boundaries. The HPC uses memory-mapped organization to support registers, I/O and on-chip peripheral functions.

The external address/data bus of the HPC is 16 bits wide. This means the maximum address that the bus can hold is FFFF for a maximum address range of 64K bytes (65,536). Keep in mind, this uses the external address/data bus (A0:A15 for Address/Data and B10, 11, 12, 15) for Control.

BANK SWITCHING

If more than 64k of addressing is needed in the HPC system, the following method of increasing memory space can be used. Divide the total address range into two halves (32k bytes each). One half of this address range will be the MAIN memory address space. The MAIN memory address space will contain logical addresses (those addresses which the Program Counter can generate) in the range 8000 to FFFF and is accessed when A15 is a '1'. This includes the Interrupt vectors and the Reset vector memory locations. The other half of the address range will be the BANK memory address space. The BANK memory address space will contain logical addresses in the range 0000 to 7FFF and is accessed when A15 is a '0'. This includes the on-chip I/O, registers, and RAM at locations 0000 to 01FF.

Now, four additional address lines are created using Port B pins (B8, B9, B13, B14). This prevents the use of the four timer synchronous outputs TS0-TS3 which are the alternate functions for these pins. The BANK memory is now addressed using A0:A14, B8, B9, B13, B14 and is accessed when A15 is a '0'. The BANK memory address space is now expanded to 512k bytes broken down into 16 individually selectable banks of 32k bytes each selected by these four bits of Port B.

A look at Table 1 and Figure 1 quickly tells you that only one bank in the BANK memory space can share the logical address range 0000:7FFF at any one time. Therefore, programs running in the BANK memory address space can only directly access data and programs in the MAIN memory address space or in it's own bank (selected by B8, B9, B13, B14). On chip resources, which include RAM, I/O, and registers are mapped into logical addresses 0000 to 01FF. These logical addresses are in the BANK memory address space, but, since these addresses are considered to be al-

ways on-chip by the HPC, it never looks at the external address/data bus and will not read external memory in this range. Therefore, the first 256 bytes in each bank of memory in the BANK memory space will not be accessible by the HPC, but this address range (on chip resources) is directly accessible by any bank of memory in the BANK memory address space. This is why Figure 1 shows a total available memory of 536.5k.

The interrupt vectors are mapped into logical addresses FFF0 to FFFF which are in the MAIN memory address space. Interrupts are handled properly if they occur while executing a program out of one of the banks of memory in BANK memory space, since the interrupt vector locations have A15 set to '1' which will allow access to the MAIN memory space. However, these interrupt vectors must either point to a routine in the MAIN memory address space which performs the interrupt service or point to code that selects the appropriate bank of memory in the BANK memory space and go there if the interrupt service routine is located there.

The stack must be located so that it can be directly accessible from anywhere in memory. It can be placed in the MAIN memory space or in the on-chip RAM. Programs and data storage that must be shared and directly accessed by all memory banks in the BANK memory space should also reside in the MAIN memory space.

HPC OPERATING MODES

The HPC must be configured to run in one of it's Expanded modes of operation by setting the EA bit in the PSW to be able to address the BANK memory range of 0000 to 7FFF. This memory expansion addressing scheme will work if the HPC is configured in either the Normal Expanded mode (EXM pin tied low) or ROMless Expanded mode (EXM pin tied high). The Normal mode differs from the ROMless mode only by the fact that the HPC will access the on-chip ROM for addresses in the range of E000 to FFFF (in the case of the HPC16083) and will access the external MAIN memory for addresses in the range of 8000 to DFFF.

The external data bus size is determined once, at reset, by sampling the state of \overline{HBE} (B12). If \overline{HBE} is high when sampled, the HPC enters 8-bit mode. In 8-bit mode, only pins A0-A7 are used to transfer data and pins A8-A15 continue to hold the most-significant eight bits of the address. So, only the lower eight bits of the address need to be latched externally (Figure 2). If HBE is low when sampled, the HPC enters 16-bit mode. In 16-bit mode, all 16 pins of Port A are used to transfer data as well as addresses. Two octal latches are then required externally to hold each address as it is issued by the HPC. The signal ALE from the HPC clocks the latches (Figure 3).

Keep in mind that if the external memory is configured as 8-bit memory, then the program stack must be in internal on-chip RAM because it has to be accessible as 16-bit words. If the external memory is configured as 16-bit memory then the stack can be in external RAM but must be in the MAIN memory address space to be directly accessible by all banks.

PROGRAMMING CONVENTIONS

A convention must be followed for maintaining linkages between the programs and data running in the MAIN memory space and the programs and data running in the BANK memory space. For the following discussion, the MAIN memory space will be referred to as just another bank of memory.

MAIN bank reserved portion

A portion of the MAIN memory bank should be reserved for Jump instructions to subroutines in the MAIN memory bank that need to be called by programs running in any selected bank in the BANK memory space. These Jump instructions serve as entry points for programs and subroutines. Typically, common functions that are required by programs running in several banks would be put in the MAIN memory bank. These could include: interrupt service routines, I/O drivers, and data handling and conversion routines. This portion also contains address pointers to tables of data in the MAIN memory bank that also are required by programs running in any selected bank in the BANK memory space. See Listing 1 for an example.

BANK memory reserved portion

A portion of each bank in the BANK memory space should be reserved for Jump instructions to subroutines in that bank that need to be called by programs running in the MAIN memory bank. These Jump instructions serve as entry points for programs and subroutines. For example, each bank in the BANK memory space could contain routines that perform unique but related functions. One bank could be reserved for math routines; another bank could perform message handling; and yet another could contain diagnostic routines. All of these functions could be scheduled and executed from some sort of Supervisor running in the MAIN memory bank performing the linkages to all these routines thru the entry points. This reserved portion of each bank also contains address pointers to tables of data in that bank that also are required by programs running in the MAIN memory bank. In the case of a bank running message handling routines, address pointers could be inserted to point to buffers that programs running in MAIN memory need to access. See Listing 2 for an example.

Linkage areas

These reserved portions of each memory bank (MAIN space or BANK space) must be fixed and known to each other memory bank that requires access to programs and data in that bank. Therefore, one other requirement in each bank is a set of labels that are assigned the values of the pointer locations to subroutines and tables in the bank of interest (see Listings 3 and 4).

One last requirement in the MAIN memory bank, if it is to perform bank to bank moves and for general housekeeping, is to reserve two byte locations to be used to keep track of the bank currently selected (high byte value on Port B) being used in the transfer of data (see Listing 5).

From the MAIN memory bank, the user can access all memory in the system. He can call subroutines in any bank in the BANK memory space and read/write data to the entire memory. From any bank in the BANK memory space, the user can call subroutines in the MAIN memory bank and read/write data to the MAIN memory bank in addition to his own local bank.

The basic procedure used to call a program in the BANK memory space from the MAIN memory bank is merely to set the proper value on the Port B select lines and execute a Jump to SubRoutine through a pointer in the selected bank:

Interrupts

Regardless of where the interrupt service routine actually resides, an image of the bank selected must be retained by the service routine to allow it to return to the appropriate bank when complete. If the interrupt service routine is in the MAIN memory bank, the linkage is handled in the normal fashion where the interrupt vector points to the service routine. The interrupt service can reside in the BANK memory space and takes a little extra overhead for the linkage.

To call a program in the MAIN memory bank from the BANK memory space, merely execute a Jump to SubRoutine through a pointer in the MAIN memory bank:

```
JSRL CMPBLNK ;see Listing 1 and 4
```

EXAMPLE SOFTWARE

Now that a convention has been established for communicating between the MAIN memory space and the BANK memory space, let's take a look at some sample code that can be used to move data between these memory spaces. In order to make the selection of bank memory efficient, it is important to keep in mind that the four bits of the high byte of Port B that are used to select a bank of memory in the BANK memory space can be written to directly since the other 4 bits of this byte of Port B are used for memory control outputs (the external control bus) and are not affected by a write to the high byte of Port B.

Bank to Bank data transfer by MAIN

Listing 6 shows the setup required to initialize the linkage area in order to perform a transfer of data from one bank to another bank in the BANK memory space by a program running in the MAIN memory space. This involves setting up the RAM locations that are used to 'select' the source bank and the destination bank, select the source bank to determine the starting address of the area to move, select the destination bank to determine the starting address of the area to move data into, then finally calling the subroutine in MAIN memory that performs the move. After the setup portion, the subroutine that performs the transfer is presented. This code assumes that the external memory is configured in 16-bit mode.

Bank to MAIN data transfer by Bank

Listing 7 presents a similar example for moving blocks of data from a bank in BANK memory to MAIN memory by a program running in that bank. This code also assumes that the external memory is configured in 16-bit mode.

External 8-bit mode

If the external memory is configured in 8-bit mode, the setup portion changes because the initialization of the RAM address pointers SSTART, DSTART and DEND requires building word address pointers from word pointers in the external reserved areas of each bank. In 8-bit mode, this requires two 8-bit transfers compared to one 16-bit transfer in 16-bit mode (see Listing 8). Once these address pointers have been built, however, the subroutine that actually performs the move does not have to change because 1) word transfers are allowed between On-chip RAM and registers regardless of the mode and 2) the subroutine performs byte moves. To improve speed in the 16-bit mode, this subroutine can be modified to perform 16-bit moves. However, keep in mind that this will impose the restriction on the address pointers in the linkage areas of requiring that addresses be on word boundaries. Listing 9 presents a similar example for moving blocks of data from a bank in BANK memory to MAIN memory by a program running in that bank.

PROGRAM DEVELOPMENT

The MOLE monitor software can support the development of HPC programs in multiple banks of memory. It provides the means of qualifying a trigger condition, as set in Trace or Breakpoint functions, with the memory bank number. The BANK command will allow a trigger only when executing in the memory bank of interest. The MOLE supports a total of 16 memory banks which are normally selected by 4 bits of Port B as described earlier. See the HPC Personality Board User's Manual for further detail on this command.

CONCLUSION

What has been presented is a method to expand the memory space of the HPC to 544k. Although this method utilized four bits of Port B to accomplish the extra addressing, theoretically, the remaining 8 bits could have been used if not required for other purposes. This could mean a maximum addressability for the HPC of greater than 128 Megabytes. However, the MOLE will only support the fixed definition of four extra address lines. Clever utilization of existing resources can enable you to get the most out of hardware and software limited only by one's imagination.

TABLE I. Logical Addresses vs Physical Memory Locations

Logical Address	Bank #	Hi Byte Port B	Physical Address
0000:7FFF	0	00	00000:07FFF
0000:7FFF	1	01	08000:0FFFF
0000:7FFF	2	02	10000:17FFF
0000:7FFF	3	03	18000:1FFFF
0000:7FFF	4	20	20000:27FFF
0000:7FFF	5	21	28000:2FFFF
0000:7FFF	6	22	30000:37FFF
0000:7FFF	7	23	38000:3FFFF
0000:7FFF	8	40	40000:47FFF
0000:7FFF	9	41	48000:4FFFF
0000:7FFF	A	42	50000:57FFF
0000:7FFF	B	43	58000:5FFFF
0000:7FFF	C	60	60000:67FFF
0000:7FFF	D	61	68000:6FFFF
0000:7FFF	E	62	70000:77FFF
0000:7FFF	F	63	78000:7FFFF
8000:FFFF	—	—	08000:0FFFF (MAIN)

LISTING 9. Move Data by BANK from BANK to MAIN (8-Bit Mode)

The code listed in the App Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this App Note can be downloaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162
Voice (408) 721-5582

AN-510

HOW TO WRITE SHORT, EFFICIENT, BUT UNDERSTANDABLE ASSEMBLER PROGRAMS

INTRODUCTION

One of the design objectives of the HPC family was that it should be very easy to use. With this in mind the instruction set has been designed so that it obeys a very simple set of rules. Once these rules have been learned, the programmer can write code with very little reference to instruction manuals.

The HPC is fully memory mapped. Every piece of hardware attached to an HPC core appears as a byte or a word in a linear 64K byte address space. Any data movement or arithmetic instruction can operate on any memory location and everything in the HPC has a memory location, including the accumulator. All of the I/O ports, the peripheral control registers, RAM and ROM are treated in exactly the same fashion as far as the assembly language programmer is concerned.

The HPC assembly language syntax can be explained by describing the instruction codes and the addressing modes. The instruction code tells the processor what operation it is performing, such as an add, a subtract, a multiply, a divide or a data movement instruction. The addressing mode is the way that the programmer specifies the value or values to be operated on to the microprocessor itself.

ADDRESSING MODES

Operations can be performed on any memory location. One can, for example, increment or decrement any byte or word of any memory location in the HPC. Increment and decrement are examples of single address instructions. These are instructions which have only one operand. Other examples are the bit set, bit test and bit clear instructions. These five instructions are good examples of the basic thinking behind the HPC instruction set. All of these instructions use the same four addressing modes.

Direct

The simplest addressing mode to understand is that known as direct. In this mode the address of the variable to be operated on is included as part of the sequence of bytes that comprises the entire instruction. For example, in order to perform a decrement on memory location 0F0 this value is included in the string of bytes that forms the instruction.

Examples:

```
DECSZ 0F0.B
INC    0F0.W
```

The increment instruction, like most other instructions with HPC, can operate on either a byte or a word. A byte access is specified by putting a B after the address of the variable, a word access by writing W.

Register Indirect

This addressing mode usually generates less bytes of code than any other. HPC has two 16-bit registers, B and X, which

can be used as general purpose memory locations but also have a specific function as pointers to memory. These instructions take up very little ROM space because the address of the variable to be operated on is contained in the pointer register and the pointer register to be used is specified as part of the instruction. An instruction such as increment, using register indirect, can thus be only 1 byte long as it does not need to be followed by a byte specifying the address of the variable.

Examples:

```
INC    [B].B ;byte increment, B pointer
INC    [X].W ;word increment, X pointer
```

Indirect

B and X provide two 16-bit pointers to memory. Programmers will often wish to have more than two pointers in use at any one time. HPC therefore provides indirect addressing mode. In this mode a 16-bit pointer to the location to be accessed is stored in the basepage of the HPC. The instruction, therefore, is followed by a single byte which specifies the address of this 16-bit pointer. The bottom 192 bytes of RAM are on chip with the HPC and are in the so-called base page. The base page is normally used for storing frequently accessed variables as only a single byte of address is required to access a base page variable. When using indirect addressing mode, the 16-bit pointer value must always be in the base page.

Examples:

```
DECSZ [0].W ;decrement a word
INC    [0FE].B ;increment a byte
```

The base page is in the region of 0 to 0FF bytes. This area also contains the most frequently used registers such as the accumulator. The programmer can thus use indirect addressing mode with registers such as the accumulator acting as the pointer. This is an example of the simplicity of the HPC instruction set. Any operation can be performed on any HPC register simply by invoking its address in the HPC 64 kbyte addressing space.

Indexed

The last of the four basic addressing modes is indexed mode. Indexed is very similar to indirect except that an 8- or 16-bit immediate value precedes the address of the 16-bit pointer and is added to it to generate the address of the variable to be accessed. This allows a table of values to be located anywhere in memory and the pointer register need only be incremented or decremented to move through the table of values.

Examples:

```
INC    OFF00 [4].W ;increment a word
DECSZ 02 [2].B ;decrement a byte
```

Bit Operations

The bit operations of the HPC allow any bit in the memory of the HPC to be accessed. The addressing modes for these three operations, SBIT, RBIT and IFBIT, always refer to the memory location as a byte. The individual bit of the byte to be tested, using the four addressing modes already described, is actually coded into the opcode itself. This could be described as an implied addressing mode but this definition is not normally used in HPC. The way this works can be seen from the opcode map in the programmers guide of the HPC, where it can be seen that there are in fact eight opcodes shown for each of the three different bit instructions.

Example:

```
SBIT 5, 2.B ;set bit 5 of byte
           ;at address 2.
```

Double Register Indirect

A rule of thumb when trying to decide which addressing mode one can use with which opcode in HPC is that you can use any combination of addressing mode and opcode that is sensible. An example of this is a special addressing mode which works only for the bit instructions. This addressing mode is known as double register indirect and uses a combination of the B and X registers to index into any bit of a 64k bit string, the lower boundary of which can be located anywhere in memory.

When using this addressing mode the B register points to the lowest byte of this 8k byte string, while the most significant 13 bits of the X register point at the individual byte in the string that is being accessed. The three least significant bits of the X register point at the bit of the byte that the instruction is pointing at. By using this addressing mode, words of any length can be scanned for whether individual bits are set or cleared. This addressing mode, while unusual, fits into the scheme of things as it clearly is only of any relevance to the individual bit instructions.

Examples:

```
SBIT X, [B].B ; Set bit
IFBIT X, [B] B ; test bit
```

Note that the bit instructions only operate on bytes, to allow operations on words would require twice as many opcodes for no gain.

Two Address Instructions

The five instructions described so far have only one operand. There are many more instructions in the HPC instruction set which have two operands, such as arithmetic instructions, the comparison instructions and data movement instructions. The HPC instruction set allows any of these instructions to use any of the four addressing modes already described. An instruction such as multiply, for example, when written in the HPC assembler syntax as shown below shows the opcode followed by the destination operand, which is then followed by the source operand. The result of the operation in all cases except the comparison instructions winds up in the destination operand. The comparison instructions, IFEQ and IFGT do not affect the values of any memory location but, like all other two operand instructions, can operate on any two words or bytes in the HPC addressing space.

Examples:

```
MUL A, [B].B
MUL 0.W,2.W
```

The destination operand in HPC may be either the accumulator or a byte or word of memory accessed using the direct addressing mode. If the destination operand is the accumulator, the source operand may be addressed using direct, register indirect, indirect or indexed addressing modes as well as the familiar immediate addressing mode. The programmer can thus load the accumulator with an 8- or 16-bit immediate value which follows the opcode, multiply the accumulator with that value, divide the accumulator by that value or compare the accumulator by that value. Using the accumulator as the destination operand gives maximum flexibility in the choice of addressing mode for the source operand and also tends to produce a shorter instruction in terms of its length in bytes as the opcode does not have to include the address of the destination operand.

Examples:

```
LD A, #37 ;load A With
           ;immediate value.

add OFE.W,# OF000 ;Add immediate to
                  ;memory.
```

Instruction Lengths

Tables are provided in the HPC users manual to allow the user to estimate the number of bytes an instruction will use and the time this instruction will take to execute. To use these tables the programmer must be aware of the name of the addressing mode he is using. This is perfectly clear for the single address instructions described at the beginning of this note but perhaps needs some explanation for two operand instructions.

For two operand instructions with the accumulator as the destination, the addressing mode is named after that used for the source operand. For example, load accumulator using a value pointed at by indirect addressing mode is referred to simply as indirect addressing mode.

Operations on Direct Memory

There are two addressing modes which allow operations to be performed directly on memory locations. If the destination operand is directly addressed memory, then the source operand may be directly addressed memory or an immediate value. These two are the only combinations of addressing modes that can be used where the destination operand is a memory location.

Examples:

```
DIV 010.W, OF000.W
direct-direct mode

DIV OF0.B,#10
immediate direct mode.
```

Special Symbols

Some special symbols have been allocated in the HPC cross assembler. These are A, B, K, X, PC and SP. The programmer can also define his own symbols using the equals directive of the assembler. The way that the symbols described above would be defined using the equals directive are shown below by way of example.

Example:

```
A = 0C8.W
B = 0CC.W
X = 0CE.W
K = 0CA.W
PC = 0C6.W
SP = 0C4.W
```

Note that these symbols cannot be redefined so the above set of definitions should never be included in a user program.

IMPLIED ADDRESSING MODES

Some of the HPC's opcodes have been shortened by using implied addressing mode. A few examples have already been shown. This section describes some more special cases. It could be said that accumulator as destination is an example of an implied addressing mode, where the address of the destination is coded into the instruction. There are some special purpose instructions which use implied addressing mode for instructions which are used very frequently. In most cases these instructions look exactly the same to the programmer as instructions using the addressing modes described earlier. For example there is a special opcode for load B with an immediate value. The programmer could do this using the immediate direct addressing mode but a special opcode has been provided to make this instruction shorter.

Load B and K is a special immediate load which loads both the B and K registers in one operation.

Carry Flag

The carry flag may be accessed using the standard bit test instructions because it can be read in the processor status word, but as carry must so often be set and tested, special instructions to do this have been included which do not require the address of the carry flag.

Multiply and Divide

Finally, the divide double and multiply instructions both have to manipulate 32-bit values. These therefore have to store an operand in two concatenated registers. The HPC instruction set cannot specify two registers with one address. Therefore these instructions default to using the X register as the high word of their 32-bit value.

The source and destination of a multiply instruction are specified as normal except that the 32-bit answer is stored in the destination operand with the 16 high bits of the answer stored in the X register. The divide double instruction basically performs the inverse of multiply, taking the 32-bit value formed by X concatenated with the destination value and dividing it by the source value. Divide double, like divide, yields a 16-bit result and a 16-bit remainder. For both divide double and divide the remainder is stored in the X register. In both cases the K register is used for intermediate value storage and is cleared as a result of this operation.

As the result of divide double can only be a 16-bit value, a full 32-bit divide is performed by following a 16-bit divide with a 32-bit divide as shown below. The example below shows how the divide instructions work together and also highlights the combinations of addressing modes that can and cannot be used with HPC.

```

LD      B, #11
DIV     HIGH.W, #10
LOOP:  DIVD    LOW.W, #10
LD A, X
ST A, [B].B
DECSZ B
JP LOOP

```

This example shows the conversion of a 32-bit binary value in words low and high into a 10-digit BCD number in the 10 bytes starting from 1. The conversion is performed one digit at a time and the B register is used to point at the byte's location where the digit is to be stored. The first instruction of the programme therefore is to initialize the B register. The divide instruction divides word high by 10 using immediate direct addressing mode and stores the answer back in word high. The remainder is stored in the X register. The divide double instruction then divides X concatenated with word low by 10. Because X contains a remainder, the result of this division will always be a 16-bit value and can thus be stored in word low. The remainder is stored in X and is in fact the modulus and is thus the BCD digit that we have derived on this pass through the numbers.

We now wish to store the remainder into one of our BCD digit locations using register indirect mode. We need to load the value into the accumulator from X. The X register is nothing special in this application, so load A with word X is in fact an example of direct addressing mode.

Now that our BCD value is in the accumulator, we can store this in the byte location using B register indirect addressing mode.

The next instruction is decrement skip on zero. This uses direct addressing mode to decrement the B register. This instruction is an example of many in HPC which perform more than one function. As well as decrementing the memory location specified, this instruction also compares it with zero after the decrement has been performed. If the result is zero, the instruction following the decrement skip on zero instruction is skipped. That is to say it is ignored and control passes to the instruction following it. In this example the final instruction of the routine is a single byte jump back to the divide instruction. The overall loop is executed ten times in order to perform the conversion. On the final pass through the loop, B becomes zero and execution of this algorithm is terminated.

Auto Increment/Decrement Instructions

This multi-function instruction capability is best illustrated by the four special addressing modes register increment or decrement with or without conditional skip, which work only with the data movement instructions load and exchange. The load instruction in general uses any of the five two-address modes or the two combination modes to transfer data from one location to another.

The exchange instruction is similar except that the destination must always be the accumulator. Exchange not only takes the source and puts the value into the destination but also takes the value from destination and puts it into source. Clearly there is no immediate addressing mode for exchange as a destination cannot be stored into an immediate value.

When load and exchange are used with the X register as a pointer and register indirect mode, a suffix + or - can be added after the X. In this case, once the data movement operation has been performed, the X register is incremented or decremented by one or two according to whether

there has been a byte or a word access respectively. A further refinement on this is provided by the load and exchange with conditional skip instructions, LDS and XS respectively. These only work with the B register as the pointer and perform two more operations rather similar to the decrement skip on zero instruction. Once the increment or decrement has been performed, the B register is compared with the K register, otherwise known as the limit register. If an increment has been performed and B is greater than K, the instruction following the movement instruction will be skipped. If a decrement is performed, the instruction is skipped if B is less than K.

An example of how these specialized instructions are used is given by the block move routine shown below;

```
LD X, #START
LD BK, #BEGIN, #END
LOOP: LD A, [X+].W
XS A, [B+].W
JP LOOP
```

This routine moves a block of data from one location to another. The X register is initialized first and is used as a pointer to the first value to be moved in the source block. The B and K registers point to the first and last values respectively in the destination block. The loop itself consists of only three bytes. The first instruction loads the accumulator with the word pointed to by the X register and increments X by two. A second instruction exchanges the accumulator with the word pointed to by the B register, increments the B register by two and compares it with K. If B is greater than K, the jump instruction is skipped and this loop is terminated.

The example shows how HPC code can perform a great deal with very few instructions and use up very few bytes of code while doing so.

These auto increment/decrement instructions are the only examples where an addressing mode cannot be used for any instruction where it might make sense. It is however fairly easy to remember which addressing modes these can be used with. Auto increment/decrement can be used with the load and exchange instructions for the X register. Auto increment or decrement with conditional skip can be used with load and exchange instructions using the B register as a pointer. No other combinations are allowed.

We have not provided specific string move or search instructions but the auto increment/decrement operations provide building blocks allowing the programmer to assemble his own stock. In the block move instruction shown above, the value being moved is in the accumulator in between the load and exchange instructions. The programmer can then compare this value with anything he wishes, fill BCD to ASCII, pack BCD, unpack BCD or perform any operation he likes on a string of data.

HPC ASSEMBLY CODE

The addressing modes usable for each opcode are described in a shorthand form.

Example :

```
ADD MA < MA + MemI
```

In the above syntax MA means directly addressed memory or the accumulator and MemI means memory addressed using any of the four basic single-address addressing modes or an immediate value. This would be better written as shown below:

```
A < A + MemI
or M < M + M
or M < M + I
```

Expanding the syntax highlights that the flexible addressing modes such as register indirect may only be used if the destination is the accumulator. It also shows that if the destination is direct memory the source may only be an immediate value or another direct memory location.

When writing assembly code the programmer writes the same mnemonic whether a memory location is a piece of RAM or ROM or an I/O port or the accumulator. In general any source or destination variable may be a byte or a word and combinations are allowed. Care must be taken when storing word into a byte location that the programmer really wishes to truncate that value to byte and throw away the upper 8 bits of the value. When loading a byte into a word location the upper 8 bits of the word location will be filled with zeros. If memory external to the HPC is used, this may be 8 or 16 bits wide. The programmer must be aware of this when writing his assembly language as HPC cannot cope with the programmer requesting a 16-bit access to 8-bit wide external memory. The HPC will not convert this to two sequential 8-bit accesses.

The only exception to this rule is that a pointer word in indirect or indexed addressing modes must always be in the base page. This is because only one byte has been allowed in the overall length of the instruction for the address of the pointer.

For all other addressing modes there is no difference in the assembly language the programmer writes between accessing a variable that is in the base page and a variable that is above address OFF.

The programmer should be aware however that variables in the base page consume less bytes per access and the instruction will execute more quickly than non-base page variables. When studying the data sheet to see how long an instruction is, the programmer will see that the table result is different according to whether variables are base page or not. The programmer should therefore allocate base page to variables which are used most often.

EXECUTION SPEED

There are 64 bytes of RAM above the base page. These, like the base page RAM, require zero wait states to access even when the processor is running at full speed. They do however require 2 bytes of code for their addresses. These

64 bytes may best be made use of by using them as the stack area as the 16-bit stack pointer contains the full address and therefore there is no penalty in instruction length in putting the stack in this non-base page on-chip RAM.

Note that there is no difference in execution time between byte and word accesses, that is to say accesses to byte or word variables. When studying the data sheet, differences in program length and therefore in execution time will be observed according to whether the address of a directly addressed variable is a byte or a word. It is important to understand the difference between the width of the variable and the width of the address that is used to access that variable.

The cycles per instruction table is not always clear about the number of wait states applied to different variables. The HPC includes a wait state register which sets the number of wait states to be used when accessing external memory, the internal ROM, or internal registers associated with ports A and B. Wait states may be applied to these on-chip registers to allow compatibility with development tools such as the MOLE™ and HPC Designer Kit board, as when these tools are run on high clock speeds wait states must be applied for accesses to the port recreation logic. The HPC needs wait states for accessing slow external memory and when running at high clock rates.

These wait states may be applied in order that the MOLE can provide a perfect emulation of a single-chip HPC. In the MOLE the HPC is running with external memory and thus the A port and some of the B port are used for address/data and control lines respectively. The A port and part of the B port must therefore be recreated external to the HPC. In the case of the MOLE this is done using a large array of PAL®s. Because they are external to the HPC, one wait state must be applied when accessing these externally recreated ports at high clock speeds. If wait states could not be applied to

these ports in a masked ROM HPC, the MOLE would not be able to provide full speed emulation. This is just one example of how the design of the HPC has been influenced by the need to emulate it 100% exactly at full speed. Apart from this no wait states are applied to any access to address locations below 200 HEX, regardless of the addressing mode used.

The HPC data sheet does not make it clear how many wait states are applied when register indirect addressing mode is used. It implies that wait states are always applied when register indirect or similar addressing modes are used, but this is not the case.

The best way to time a piece of code is to write the code and then run it through the cross assembler to generate a source plus object listing. The number of bytes generated by each instruction can then be easily read and only the cycles and accesses table need be looked up in order to calculate how long each instruction takes to execute.

Note that accesses to internal ROM are subject to at least one wait state for exactly the same reason as accesses to the A or B ports.

SUMMARY

The HPC is fully memory mapped. The I/O Ports, Peripheral Control Registers, RAM and ROM are treated exactly the same. This makes the HPC easy to program. The HPC instruction set has relatively few opcodes but allows any of these opcodes to be used with any addressing mode so as to provide an Instruction Set with great power and flexibility.

Once the contents of this note have been understood, HPC code can be written without referring to any document more lengthy than the HPC Instruction Set description in the data sheet.

A Software Driver for the HPC Universal Peripheral Interface Port

National Semiconductor
Application Note 550
Brian Marley

ABSTRACT

This application note covers the use of the National Semiconductor HPC46083 High-Performance microController as an intelligent Peripheral Interface and Interrupt controller for another "Host" CPU, using its 8-bit or 16-bit parallel UPI (Universal Peripheral Interface) Port. Included in the discussion is the source text of an HPC driver program, which can be tailored as an "executive" for a wide variety of HPC tasks. A simple application is built from this software, which interfaces a National NS32CG16 CPU to a typical front panel (LED indicators, LCD alphanumeric display, pushbuttons and beeper).

1.0 INTRODUCTION

The National Semiconductor HPC family of microcontrollers includes as a feature the ability to be slaved to another "Host" processor over that processor's memory bus. This feature, called the Universal Peripheral Interface (or UPI) Port, allows:

1. Transfer of either 8-bit or 16-bit data in a single bus transaction,

2. Polling to determine the status of the port from either side (Ready for Write/Ready for Read), and
3. Interruption of the host by the HPC with full vectoring.

The HPC, then, can serve as a front-end controller for the host, freeing it from control and/or communication tasks that might burden its capacity for interrupt service, and providing vectored interrupting for higher-level (and therefore less frequent) communication.

2.0 THE UPI PORT

2.1 Internal Structure

Figure 1 shows the internal structure of the UPI Port. It connects via three registers to the HPC's on-chip data bus, and via a set of pins (Port A) to the host's bus. The control interface between the HPC and the host consists of two low-active strobe signals ($\overline{\text{URD}}$ and $\overline{\text{UWR}}$) and an address signal (UA0) output by the host, and two handshake signals ($\overline{\text{RDRDY}}$ and $\overline{\text{WRRDY}}$) output from the HPC.

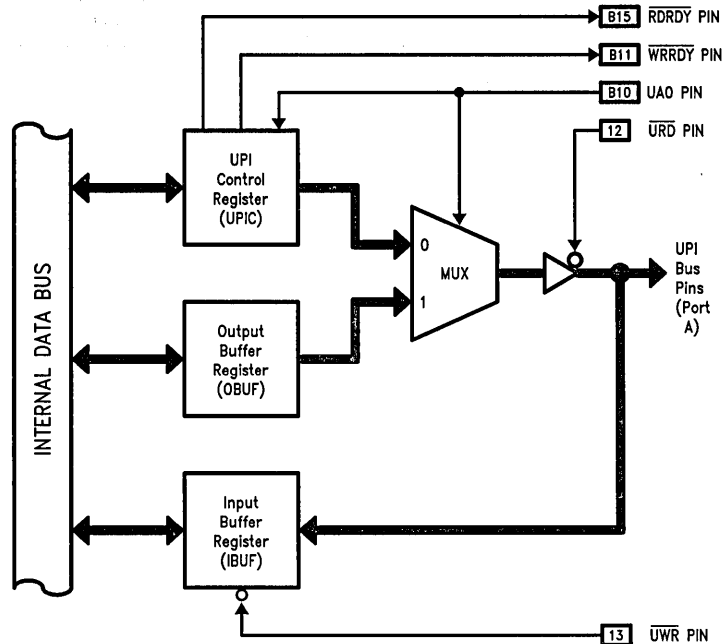

FIGURE 1. UPI Internal Structure

TL/DD/9976-1

The UPI Port may be configured either as a 16-bit bus (using all of Port A: pins A0–A15) or as an 8-bit bus (pins A0–A7), allowing pins A8–A15 to be used as general-purpose bit-programmable I/O pins. This selection is made by HPC firmware.

2.2 Basic Operations

Three types of operation may be performed over the UPI Port:

1. Transfer of a byte or word of data from the host to the HPC's IBUF register. This is called a "UPI Write" operation.
2. Transfer of a byte or word of data from the HPC's OBUF register to the host. This is called a "UPI Read" operation.
3. Polling by the host to determine whether the HPC is ready for the next UPI Write or UPI Read operation. This involves the host reading the UPIC (UPI Control) register, which contains the states of the \overline{WRRDY} and \overline{RDRDY} pins as two of its bits.

As shown in *Figure 2*, whenever the host writes to the HPC (by pulsing the \overline{UWR} signal low) data is latched into the HPC's IBUF register. At this time also, the value on the UA0 pin is latched into the UPIC (UPI Control) register, allowing

HPC firmware to route the data just written. (For example, this bit can be used by the HPC firmware to distinguish between commands and data written to it.) The rising edge of \overline{UWR} is detected by an edge-trigger circuit on-chip, which may be used to trigger an interrupt or for polling, to alert the HPC firmware to the presence of new data. The \overline{WRRDY} handshake signal, normally low, goes high until the HPC firmware has sampled the data written to it (by reading internally from the IBUF register).

Figure 3 shows the sequence of events in reading data from the HPC. The transfer starts when the HPC writes a value to the internal OBUF register. The \overline{RDRDY} handshake signal, normally high, goes low to indicate that data is present for the host. (This pin can be used to interrupt the host as well.) By pulsing the \overline{URD} pin low while holding the UA0 pin to a "1", the host reads the contents of the OBUF register, and the \overline{RDRDY} pin goes back high.

The polling operation (*Figure 4*) allows the host to monitor the \overline{RDRDY} and \overline{WRRDY} conditions as data bits, by pulsing the \overline{URD} pin low with a "0" held on the UA0 pin. This effectively reads from the UPIC register; the \overline{WRRDY} condition appears on bit 0 (the least-significant bit), and the \overline{RDRDY} condition appears on bit 1 (the next most significant bit). Polling in this manner does not affect the state of the \overline{RDRDY} bit.

TL/DD/9976-4

2.3 Typical Hardware Configurations

Typical connections between the host and the HPC are shown in *Figures 5* through *7*.

2.3.1 Polled Synchronization

In the simplest case (*Figure 5*), the \overline{WRRDY} and \overline{RDRDY} signals are not used, and the host synchronizes itself with the HPC strictly by polling the UPIC register for the Read Ready and Write Ready conditions. The only additional logic always required is a pair of OR gates to activate \overline{URD} and \overline{UWR} only when the HPC is selected by the host's address decoder. Depending on the host, it may also be necessary to add WAIT states, as is often required in peripheral interfaces to match the bus timing characteristics of the two ends.

Sophisticated synchronization schemes are not available using this simple an interface, but it does save the HPC \overline{RDRDY} and \overline{WRRDY} pins for any other general-purpose I/O functions.

2.3.2 Interrupt-Driven Synchronization

Assuming that the host has interrupt control capability, the circuit above can be enhanced to implement an interrupt-driven synchronization scheme, as shown in *Figure 6*. A falling edge on either \overline{RDRDY} or \overline{WRRDY} will trigger an interrupt to the host, informing it when the HPC becomes ready for either direction of data transfer. No additional logic is required (except for possible buffering or inversion), but only dedication of the \overline{WRRDY} and/or \overline{RDRDY} pins for the interrupt function. It is not necessary for both \overline{RDRDY} and \overline{WRRDY} conditions to trigger interrupts; one can be polled and the other interrupt-driven, as dictated by the require-

ments of the system and the structure of the host and HPC software. Also, depending on the host, it is often possible for the HPC itself to provide interrupt vectoring, thus eliminating the need for an external interrupt controller entirely. The approach taken in the driver program, described below, implements the HPC as the interrupt controller, with interrupts asserted only by the \overline{RDRDY} pin.

2.3.3 Hardware Synchronization

Figure 7 shows the connections required to implement hardware synchronization between the host and the HPC. In this scheme, there is no host software involved in synchronizing with the HPC; if the host attempts a UPI transfer for which the HPC is not prepared, the host is held in "Wait states" until the HPC is ready. Note that the UPIC register is an exception; Wait states are not to be inserted when the CPU polls the UPI port's status ($UA0 = 0$).

The main advantage of this scheme is speed: the CPU and HPC transfer data as fast as they can both run the transfer loop. (One will generally find that the HPC stays ahead of the CPU; the CPU tends to be in the critical path due to more complex buffer management algorithms.) The main disadvantage is that if the HPC is allowed to be interrupted in the middle of the transfer, the CPU is not free to do anything else at all, including servicing its own interrupts.

In addition to the logic to detect when to hold the host (at the bottom of the figure), additional gating is required on the \overline{UWR} signal, to prevent it from being asserted until the \overline{WRRDY} signal is active. This is required because the IBUF register of the HPC is a fall-through latch, and its contents would be lost if \overline{UWR} were allowed to go active too soon.

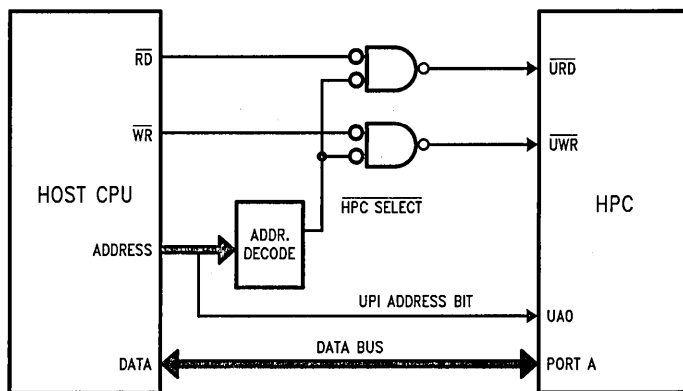

FIGURE 5. Polling Interface

TL/DD/9976-5

FIGURE 6. Interrupt-Driven Interface

TL/DD/9976-6

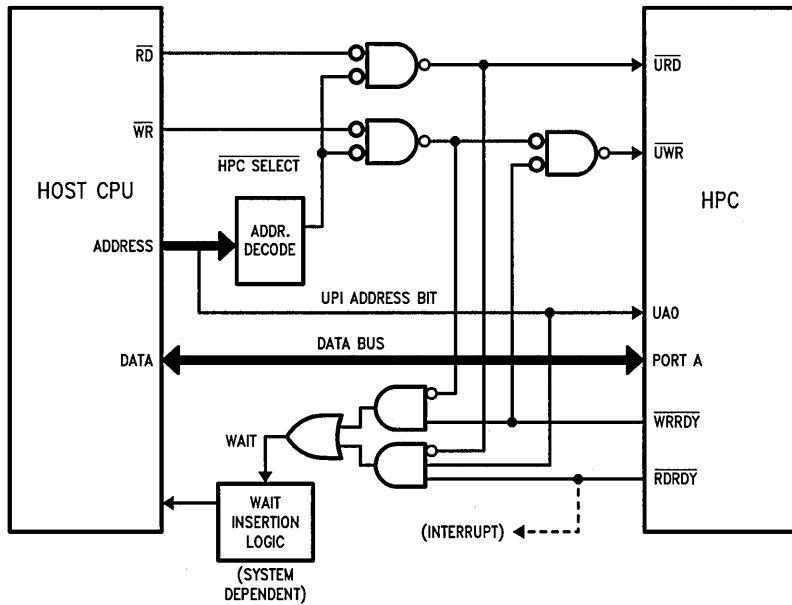

FIGURE 7. Hardware-Synchronized Interface

TL/DD/9976-7

Figures 8 and 9 illustrate the timing involved in hardware synchronization. Figure 8 shows the host attempting two UPI Read accesses in quick succession; the second Read access is held pending until the HPC has supplied the data. Figure 9 shows the host attempting two UPI Write accesses in quick succession; it is held in Wait states (with the \overline{UWR} signal suppressed) until the HPC has emptied the first value from the IBUF register.

This scheme and the interrupt-driven scheme above are not mutually exclusive; as shown in Figure 6, one might tie \overline{RDRDY} or \overline{WRRDY} , or both, to CPU interrupts. The application hardware described implements both schemes, leaving CPU software the option of using hardware synchronization or not. The driver program in the HPC operates the same, independent of the option used.

3.0 A UPI DRIVER AND SAMPLE APPLICATION

The circuit and program described below implement an interface between the HPC and a National microprocessor, the NS32CG16, as the host CPU. The UPI port is configured to be 8 bits wide. The hardware supports both interrupt-driven (\overline{RDRDY} only) and hardware synchronization, as well as polling.

In order to demonstrate some real commands to support, a set of simple interfaces is attached to the HPC, typical of a front panel.

- Up to 8 pushbuttons
- Up to 8 LED indicators
- A 16-character alphanumeric LCD display
- A speaker for “beeps” on alert conditions or input errors
- A real-time clock interrupt function, giving the CPU the means to measure time intervals accurately.

This application by itself is admittedly not enough to justify the presence of an HPC in a system, but it is a simple application, and we expect that this will often be part of the HPC's job. For a much more comprehensive application, which includes this one as a subset, see the next application note in this series: “The HPC as a Front-End Processor”.

We will describe in this section a specific set of hardware and software, and a UPI command and response protocol to make these interfaces play.

3.1 UPI Port Connections to NS32CG16

The attached schematic shows the HPC UPI port as it has been used a real application. On Sheet 1, a block diagram is given, showing the components involved. The CPU is an

NS32CG16 microprocessor, running at a 15 MHz clock rate (crystal frequency 30 MHz). The HPC component is the HPC46083, running at a crystal frequency of 19.6608 MHz.

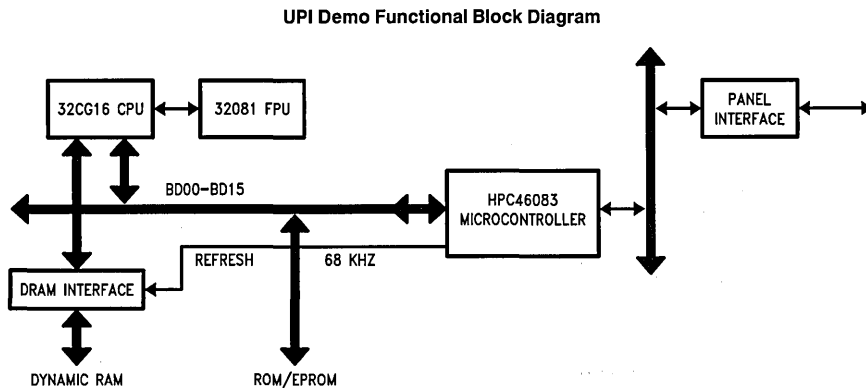

It would be unrealistic to present only the UPI interface section, since tradeoffs and implementation considerations abound when dealing with fast processors and large addressing spaces. For this reason, we include on sheets 5, 6 and 7 the circuitry involved in NS32CG16 address decoding and dynamic RAM control.

The \overline{UREAD} and \overline{UWRITE} UPI strobes are generated for the HPC in area B1 of Sheet 6. In addition, the latched CPU address bit BA09 is used as the UA0 addressing bit.

Hardware and Interrupt synchronization are accomplished as follows. On Sheet 6, area D8, the HPC signals \overline{URDRDY} and $\overline{UWRDRDY}$ enter a synchronizer, and emerge as $\overline{URDRDYS}$ and $\overline{UWRDRDYS}$. The $\overline{URDRDYS}$ signal goes to the CPU as its Maskable Interrupt signal (Sheet 5, area C8). After gating, which yields $\overline{URDRDYSQ}$ and $\overline{UWRDRDYSQ}$, they enter the PAL16L8 in area C7 of Sheet 6. This PAL's relevant outputs are $\overline{WAIT1}$ and $\overline{WAIT2}$, which go to the CPU for Wait State generation, and \overline{ACWAIT} , which also goes to the CPU (as \overline{CWAIT}) after passing through the PAL20R8 device in area D4 of Sheet 6.

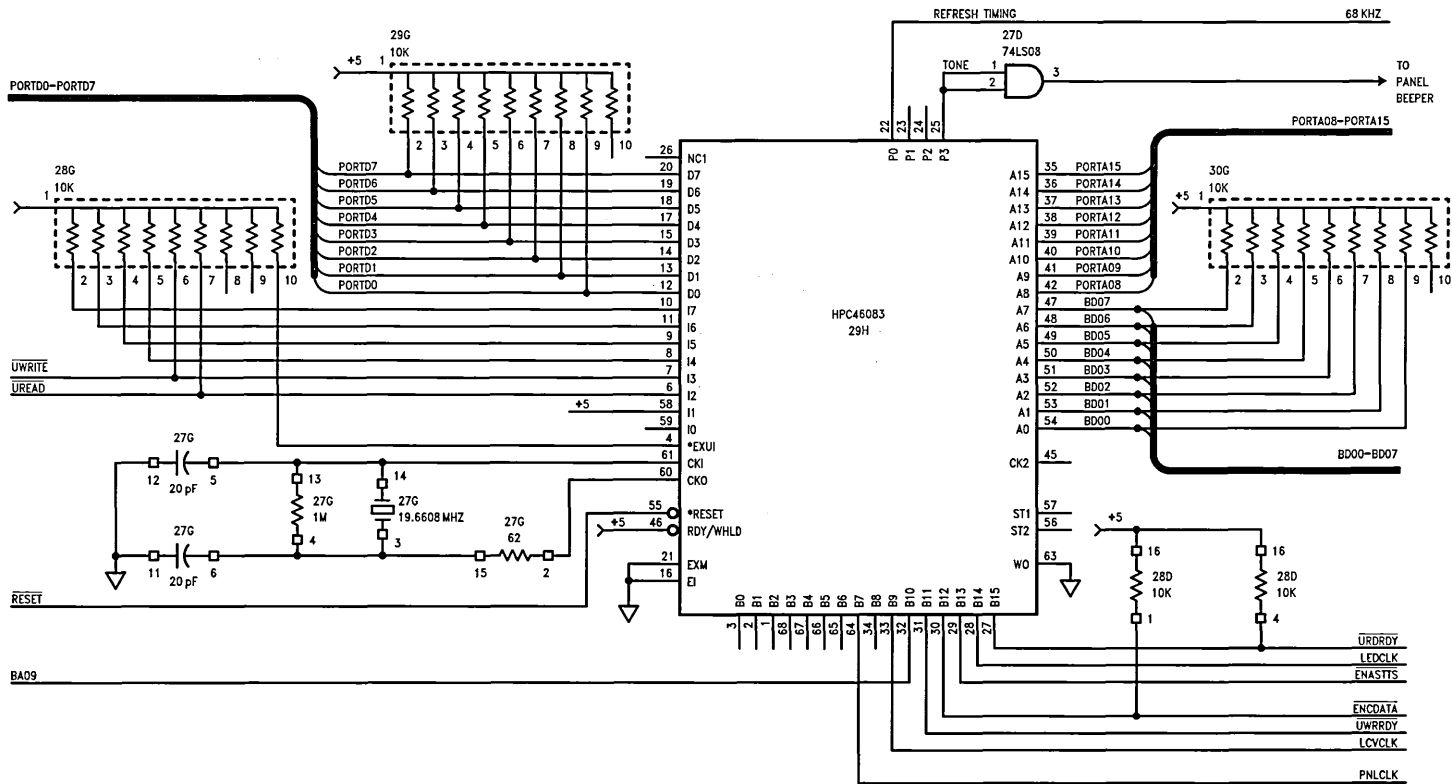

In addition, the HPC provides from Timer T4 a square wave at approximately 68 kHz, which triggers refreshes of dynamic RAM. The signal involved is called “68 kHz”, and goes from the HPC on Sheet 4, area D1, to Sheet 6, area D8. Note that the detector in area D7 is held on at Reset, to preserve RAM contents by continuous refreshing while the HPC is being reset.

3.2 Application Connections

The connections made to the HPC are shown in schematic sheets 2 through 4.

3.2.1 LCD Data

An 8-bit parallel interface connects the upper half of Port A, through buffers and latches on Sheet 4, to a Hitachi HD44780 alphanumeric LCD display controller. The signals in our application are inverted with respect to the HD44780 documentation, due to the nature of the front panel module we used.

Sending data from the HPC to the LCD display involves the following procedure:

1. Setup the \overline{RS} signal: 1 for a command, 0 for data.
This is done by setting up LCD Contrast status on the high-order byte of Port A (pins A8–A15), with the desired \overline{RS} state on pin A11, then pulsing the signal LCVCLK (pin B9) high, the low.
2. Setup the panel data on HPC pins A8–A15.
3. Set the PNLCLK signal (pin B7) low for 1.2 μ s, then high.
This clocks the data into the LCD display controller. Note that the latch in area B6 of Sheet 4 is effectively serving only as a buffer; the PNLCLK Enable signal, being normally high, allows data to fall through whenever it changes when used as described here.
4. Since the handshaking capability of the HD44780 is not being used here, it is necessary for the HPC to use an internal timer to determine when the controller is ready after sending a command or data. The delay time is either 120 μ s or 4.9 ms, depending on the type of command sent.

3.2.2 LCD Contrast (LCD Voltage)

A three-bit value is presented for LCD contrast on signals $\overline{CTRST0}$ through $\overline{CTRST2}$. A value of 000 is highest contrast, and 111 is lowest contrast. To change the contrast, the value is placed on HPC pins A8 (LSB), A9 and A10 (MSB), the LCVCLK (pin B9) is pulsed high, then low.

Note that some other bits within this latch have other functions: bit 3 (from HPC pin A11) is the \overline{RS} signal to the LCD controller, and bit 7 (from pin A15) is used by the HPC firmware as a Fatal Error flag. These bits must be setup correctly whenever the LCD Contrast latch is written to.

3.2.3 LEDs

Up to 8 LED indicators may be connected, through the latch in area A6 of Sheet 4, to the upper byte of Port A. The LED's are assumed to be connected already to their own current-limiting resistors.

The desired data is setup on Port A pins A8–A15, then a pulse is presented on the LEDCLK signal (pin B14); high and then low. Data is presented in complemented form by the HPC (0 = on, 1 = Off). Any or all (or none) of the latch bits may be connected to drive LEDs.

3.2.4 Speaker (Beeper)

A tone is produced on a speaker by enabling Port P pin P3 as the Timer T7 output, and running Timer T7 so as to produce a 3 kHz square wave. Since timer outputs toggle on underflows, this corresponds to a timer underflow rate of 6 kHz. The tone signal is shown in area D1 of Sheet 2.

3.2.5 Pushbutton Switches

Up to eight pushbuttons may be connected to the HPC's Port D pins, through the buffer in area D6 of Sheet 3. Each

pushbutton is assumed to be an SPST switch, shorting to ground when depressed. The pull-up resistors present a "1" level otherwise. The HPC must de-bounce the inputs in its firmware before issuing them to the CPU.

The pushbuttons are examined every 10 ms, by setting the ENASTTS signal (pin B13) low while ensuring that $\overline{ENCDATA}$ (pin B12) is high. This presents the switch outputs onto Port D. Unused bits should be pulled high to avoid triggering spurious pushbutton events.

3.3 Protocol Between CPU and HPC

The scheme supported by the UPI Driver program is asynchronous full-duplex communication with CPU. That is, either side is allowed to speak at any time. To avoid confusion, however, any message is restricted to send data in only one direction: in sequences initiated by the CPU ("Command" sequences), only the CPU talks, and in sequences initiated by the HPC ("Interrupt" sequences), only the HPC talks. Thus, a Command sequence and an Interrupt sequence can be in progress simultaneously without confusion.

Acknowledgement of a Command or an Interrupt sequence is possible; a Command can trigger an acknowledgement Interrupt sequence, and an Interrupt sequence can result in a subsequent Command sequence. The critical distinction, though, is that the acknowledgement need not come immediately. If, for example, the HPC is already in the process of sending an Interrupt message, and receives a Command, it will complete the current Interrupt sequence before acknowledging the Command with a new Interrupt.

Command sequences (from the CPU to the HPC) consist of a one-byte command code, followed by any argument values necessary to complete the command. Each byte written to the HPC triggers an internal interrupt (I3); the HPC buffers up these bytes until a full command has been received, then acts on it in the last byte's interrupt service routine. Commands taking a significant amount of processing time can be scheduled within the HPC using interrupts, either from external events or from one of the HPC's eight timers; each interrupt triggering the next step of the command.

Interrupt sequences (from the HPC to the CPU) operate similarly, but with a small difference. Only the first byte presented by the HPC causes an interrupt to the CPU; this byte is the interrupt vector value, which triggers the interrupt (through the \overline{RDRDY} pin) and selects the CPU's service routine. The CPU remains in its interrupt service routine until the transfer of data associated with that interrupt event is finished, then returns to its previous task. This is not to say that the CPU must keep all other interrupts disabled during an Interrupt sequence, but only that no other interrupt occurring during this time may cause the CPU to read from the HPC, or to terminate reading, until the current Interrupt sequence is complete. With the NS32C016 processor as host, the main challenge is to keep the Interrupt Acknowledge bus cycles from other interrupts, which appear as Read cycles, from causing URD pulses to the HPC. It is possible to distinguish a Non-Maskable Interrupt from a Maskable Interrupt by the address asserted by the CPU in acknowledging the interrupt, and in a larger kind of system containing an NS32202 Interrupt Control Unit, the NS32000 Cascaded Interrupt feature can be used to prevent unwanted reads from the HPC from occurring as a result of other Maskable interrupts as well. In our application hardware, the only type of extraneous interrupt occurring is the Non-Maskable Interrupt; address decoding logic isolates the HPC's UPI port from these.

3.4 Commands

The first byte (command code) is sent to address FFFC00, and any argument bytes are then written to address FFFE00. The CPU may poll the UPIC register at address FD0000 to determine when the HPC can receive the next byte, or it can simply attempt to write, in which case it will be held in Wait states until the HPC can receive it. Unless noted, the CPU may send commands continuously, without waiting for acknowledgement interrupts from previous commands.

- 00 INITIALIZE This command has two functions. The first INITIALIZE command after a hardware reset (or RESET command) enables the !RTC and !BUTTON-DATA interrupts. The INITIALIZE command may be re-issued by the CPU to either start or stop the !RTC interrupts. There is one argument:
 RTC-Interval: One-byte value. If zero, !RTC interrupts are disabled. Otherwise, the !RTC interrupts occur at the interval specified (in units of 10 ms per count).
- 01 SET-CONTRAST The single argument is a 3-bit number specifying a contrast level for the LCD panel (0 is least contrast, 7 is highest contrast). There is no response interrupt. Does not require INITIALIZE command first.
- 02 SEND-LCD This writes a string of up to 8 bytes to the LCD panel. Arguments are:
 flags: a single byte, containing the RS bit associated with each byte of data. The first byte's RS value is in the least-significant bit of the FLAGS byte.
 #bytes: The number of bytes to be written to the LCD display.
 byte[1]—byte[#bytes]: The data bytes themselves.
 The HPC determines the proper delay timing required for command bytes (RS = 0) from their encodings. This is either 4.9 ms or 120 μ s.
 The response from the HPC is the IACK-SEND-LCD interrupt, and this command must not be repeated until the interrupt is received. This command does not require an INITIALIZE command first.
- 03 SEND-LED The single argument is a byte containing a "1" in each position for which an LED should be lit.
 There is no response interrupt, and this command does not require the INITIALIZE command first.
- 04 BEEP No arguments. This beeps the panel for approximately one second. No response interrupt. If a new BEEP command is issued during the beep, no error occurs (the buzzer tone is extended to one second beyond the most recent command). Does not require INITIALIZE command first.

- A5 RESET-HPC Resets the HPC if it is written to address FFFC00. It may be written at any time that the UPI port is ready for input; it will automatically cancel any partially-entered command. The CPU's Maskable Interrupt must be disabled before issuing this command.

After issuing this command, the CPU should first poll the UPIC register at address FD0000 to see that the HPC has input the command (the least-significant bit [Write Ready] is zero). It must then wait for at least 25 μ s, then read a byte from address FFFE00. The HPC now begins its internal re-initialization. The CPU must wait for at least 80 μ s to allow the HPC to re-initialize the UPI port. Since part of the RESET procedure causes Ports A and B to float briefly (this includes the CPU's Maskable Interrupt input pin), the CPU should keep its maskable interrupt disable during this time. It also must not enter a command byte during this time because the byte may be lost.

3.5 Interrupts

The HPC interrupts the CPU, and provides the following values as the interrupt vectors for the CPU hardware. The CPU then reads data from the HPC at address FFFE00. All data provided by the HPC must be read by the CPU before returning from the interrupt service routine, otherwise the HPC would either hang or generate a false interrupt. The CPU may poll the UPIC register at address FD0000 to determine when each data byte is ready, or it may simply attempt to read from address FFFE00, and it will be held in Wait states until the data is provided by the HPC.

Note: All CPU interrupt service routines, including the NMI interrupt routines, must return using the "RETI 0" instruction. Do NOT use "RETI".

- 00–0F (Reserved for CPU internal traps and the NMI interrupt.)
- 11 !RTC Real-Time Clock Interrupt. No data returned. Enabled by INITIALIZE command if interval value supplied is non-zero. Note: this version of HPC firmware issues a non-fatal !DIAG interrupt if the CPU fails to service each !RTC interrupt before the next one becomes pending.
- 17 IACK-SEND-LCD This is the response to the SEND-LCD command, to acknowledge that data has all been written to Panel LCD display. No other data is provided with this interrupt. Always enabled, but occurs only in response to a SEND-LCD command.
- 18 !BUTTON-DATA Pushbutton status has changed: one or more buttons have been either pressed or released. The new status of the switches is reported in a data byte, encoded as follows:
 Any pushbutton that is depressed is presented as a "1". All other bit positions, including unused positions, are zeroes. The pushbuttons are debounced before being reported to

1D IDIAG

the CPU. This interrupt is enabled by the first INITIALIZE command after a reset.

Diagnostic Interrupt. This interrupt is used to report failure conditions and CPU command errors. There are five data bytes passed by this interrupt:

- Severity
- Error Code
- Data in Error (passed, but contents not defined)
- Current Command (passed, but contents not defined)
- Command Status (passed, but contents not defined)

The Severity byte contains one bit for each severity level, as follows:

x	x	x	F	x	x	C	N
---	---	---	---	---	---	---	---

N (Note): least severe. The CPU missed an event; currently only the IRTC interrupt will cause this.

C (Command): medium severity. Not currently implemented. Any command error is now treated as a FATAL error (below).

F (Fatal): highest severity: the HPC has recognized a non-recoverable error. It must be reset before the CPU may re-enable its Maskable Interrupt. In this case, the remaining data bytes may be read by the CPU, but they will all contain the value 1D (hexadecimal). The CPU must issue a RESET command, or wait for a hardware reset. See below for the procedure for FATAL error recovery.

The Error Code byte contains, for non-FATAL errors, a more specific indication of the error condition:

RTC	(Reserved for COMMAND)
-----	------------------------

RTC = Real-Time Clock overrun: CPU did not acknowledge the RTC interrupt before two had occurred.

The other bits are reserved for details of Command errors, and are not implemented at this time.

The remaining 3 bytes are not yet defined, but are intended to provide details of the HPC's status when an illegal command is received.

Note: Except in the FATAL case, all 5 bytes provided by the HPC *must* be read by the CPU, regardless of the specific cause of the error.

Fatal Error Recovery:

When the HPC signals a IDIAG error with FATAL severity, the CPU may use the following procedure to recover:

1. Write the RESET command (A5 hex) to the HPC at address FFFC00.

2. By inspecting the UPIC register at address FD0000, wait for the HPC to read the command (the *WRRDY bit will go low).

3. Wait an additional 25 μ s.

4. Read from address FFFE00. This will clear the OBUF register and reset the Read Ready status of the UPI port. The HPC will guarantee that a byte of data is present; it is not necessary to poll the UPIC register. This step is necessary because only a hardware reset will clear the Read Ready indication otherwise (HPC firmware cannot clear it).

5. Wait at least 80 μ s. This gives the HPC enough time to re-initialize the UPI port.

6. After Step 5 has been completed, the CPU may re-enable the Maskable Interrupt and start issuing commands. Since the HPC is still performing initialization, however, the first command may sit in the HPI IBUF register for a few milliseconds before the HPC starts to process it.

4.0 SOURCE LISTINGS AND COMMENTARY

4.1 HPC Firmware Guide

Refer to this section for help in following the flow of the HPC firmware in the listing below. Positions in the code are referenced by assembly language labels rather than by page or line numbers.

The firmware for the HPC is almost completely interrupt-driven. The main program's role is to poll mailboxes that are maintained by the interrupt service routines, and to send an interrupt to the CPU whenever an HPC interrupt routine requests one in its mailbox.

On reset, the HPC firmware begins at the label "start". However, the first routine appearing in ROM is the Fatal Error routine. This was done for ease of breakpointing, to keep this routine at a constant address as changes were made elsewhere in the firmware.

4.1.1 Fatal Error Routine

At the beginning of the ROM is a routine (label "hangup") that is called when a fatal error is detected by the HPC. This routine is usually called as a subroutine (although it never returns). It disables HPC internal interrupts, and then sets bit 7 of the LCD Contrast Latch as a trigger for a logic analyzer, MOLE or ISE system.

Its next action is to display its subroutine return address in hexadecimal on the LCD panel. This address shows where the error was detected. The HPC then enters an infinite loop, which continuously presents the IDIAG interrupt. It may be terminated either by a hardware reset or by sending the RESET command from the CPU. On receiving the RESET command, the HPC jumps to label "xreset", which is within the command processing routine. The "xreset" rou-

time waits for the CPU to read from the UPI port, then clears a set of registers to simulate a hardware reset and jumps to the start of the program.

4.1.2 Initialization

On receiving a Reset signal, the HPC begins execution at the label "start". A required part of any application is to load the PSW register, to select the desired number of Wait states (without this step, the Reset default is 4 Wait states, which is safe but usually unnecessary).

Other initializations here are application-dependent, and so they relate to our application system and front-panel operations.

At label "srfsh", the program starts the Refresh clock pulses running for the dynamic RAM on our application hardware, from HPC pin P0 (controlled by Timer T4). For debugging purposes, a circuit within the RAM controller section performs continuous refreshes during Reset pulses, so data in dynamic RAM is never lost unless power is removed.

At "supi", the UPI port is initialized for transfers between the HPC and the CPU.

At label "sram", all RAM within the HPC is initialized to zero. This is done for debugging purposes, to help ensure that programming errors involving uninitialized data will have more consistent symptoms.

At "sskint", the stack pointer is initialized to point to the upper bank of on-chip RAM (at address 01C0). The address of the fatal error routine "hangup" is then pushed, so that it will be called if the stack underflows. This is not necessary in all applications, since the Stack Pointer starts at address 0002, but for our purposes it was more convenient to relocate it.

At "tmnit", the timers T1–T3 are stopped and any interrupts pending from timers T0–T3 are cleared.

In addition, some miscellaneous port initializations are performed here. The upper byte of Port A is set as an output port (for data going to the LCD and LED displays), and the Port B pins which select pushbutton data are initialized.

At "sled", the LED control signals are initialized, and all LED indicators on the panel are turned off.

At "stmrs", all timers are loaded with their initial values, and timers T5–T7 are stopped and any interrupts pending from them are cleared. (Timer T4 keeps running for dynamic RAM refresh.)

At "sled", the panel LCD display is initialized to a default contrast level of 5, then commands are sent to initialize it to 8-bit, 2-line mode, with the cursor visible and moving to the right by default. This section calls a subroutine "wrpn!", located at the end of the program, which simply writes the character in the accumulator out to the LCD display and waits for approximately 10 ms. Note that if the CPU fails to initialize the LCD display further, a single cursor (underscore) character is all that appears: a recognizable symptom of a CPU problem.

The program now continues to label "minit", which performs some variable initializations which are necessary for operation of the UPI Driver itself (as opposed to the application). This much must always be present, but any other initializations required by the application should appear here as well. For our front-panel application, there are no such initializations required.

At label "runsys", the necessary interrupts are enabled (from the timers, and from pin I3, which is the UPI port interrupt from the CPU), and the program exits to the Main Program loop at label "mainlp".

4.1.3 Main Program (UPI Output to CPU)

The Main Program is the portion of the UPI Driver that runs with interrupts enabled. It consists of a scanning loop at label "mainlp", calling a set of subroutines (explained below). It is responsible for interrupting the CPU and passing data to it. The HPC is allowed to write data to the CPU only after interrupting it. The main loop scans a bit-mapped variable in on-chip RAM that is set up by interrupt service routines (a word called "alert") to determine whether any conditions exist that should cause an interrupt to the CPU.

The "alert" word contains one bit for each interrupt that the HPC can generate. If a bit is set (by an interrupt service routine), the Main Program jumps to an appropriate subroutine to notify the CPU. Each subroutine first checks whether the UPI interface's OBUF register is empty, and if not, it waits (by calling the subroutine "rdwait"). It then writes the 32000 interrupt vector number to the OBUF register. This has the effect of interrupting the CPU (Because the pin \overline{URDRDY} goes low), and the CPU hardware reads the vector from the OBUF register. If there is more information to give to the CPU, the HPC places it, one byte at a time, into the OBUF register, waiting each time for OBUF to be emptied by the CPU. This technique assumes that the CPU remains in the interrupt service routine until all data has been transferred. If the CPU were to return from interrupt service too early, the next byte of data given to it would cause another interrupt, with the data value taken as the vector number. (Note, however, that a Non-Maskable interrupt is allowed. It simply delays the process of reading data from the HPC. Since the HPC is running its main program at this point, with its internal interrupts still enabled, it is not stalled by this situation.)

Subroutines called from the Main Program loop are:

- sndrtc: sends a Real-Time Clock interrupt to the CPU. No data is transferred; only the interrupt vector.
- sndlak: interrupts the CPU to acknowledge that a string of data (from a SEND-LCD command) has been written to the LCD display. No data is transferred for this interrupt.
- sndbtn: interrupts the CPU to inform it that a pushbutton has been pressed or released. A data byte is transferred from variable "swlsnt", which shows the new states of all the pushbuttons.
- sndiag: interrupts the CPU to inform it of a DIAG interrupt condition, when it is of NOTE severity. (Other !DIAG conditions are handled at label "hangup".)

4.1.4 Interrupt Service Routines

All of the remaining routines are entered by the occurrence of an interrupt.

4.1.4.1 UPI Port Input from CPU (Interrupt I3)

This interrupt service routine, at label "upiwr", accepts commands from the CPU. Each byte of a command triggers an interrupt on the I3 pin. When the last byte is received, the command is processed before the I3 interrupt routine returns. The HPC is therefore immediately ready to start collecting another command.

Any command that involves waiting is only initiated before the I3 routine returns, and interrupts are set up to activate more processing when the time is right. Therefore, this interrupt service routine returns promptly, even for time-consuming commands.

At any time, the "upiwr" routine may be in one of the following states:

1. Waiting for the first byte of a command. In this state, the variable "curcmd" (Current Command) has its top bit ("cmdemp") set, meaning that it is empty. When a byte is received from the CPU in this state, this routine jumps to the label "firstc". The byte is placed in the "curcmd" byte (clearing the top bit), and then a multi-way branch (jidw) is performed, whose destination depends on the contents of the byte. The possible destinations have labels starting with the letters "fc". If the command has only one byte (for example, the command BEEP), it is processed immediately in the "fc" sequence, and the "curcmd" variable is set empty again. If, however, the command is longer than one byte, its "fc" routine will place a value into the variable "numexp", which gives the number of additional bytes that are expected for this command, and then will return from the interrupt. Note that the "curcmd" byte now appears to be full, because its top bit is no longer set.
2. Collecting bytes of a command. The code that is relevant in this state is between the labels "upiwr" and "lastc". This state is in effect while the "cmdemp" bit of "curcmd" is zero and the "numexp" variable is non-zero. Each I3 interrupt causes the routine to place the command byte into a buffer ("cpubuf"), with pointer variable "cpud", decrement the "numexp" variable, and return if the result is non-zero. If the result is zero, then the routine has collected an entire command, and it goes to the label "lastc", and enters state (3) below.

3. In this state, the requested number of bytes has been collected, and this usually means that the entire command, except for the first byte, is in the "cpubuf" area of RAM. The code for this state is at label "lastc". First, the "curcmd" byte is checked to see whether "extended collection" is being performed (bit 6 set: see below). If not, the "curcmd" byte is set empty. A multiway branch is then performed (jidw), which transfers control depending on the command byte in "curcmd". All routines that are destinations of this branch start with the letters "lc". The "lc" routine for each command uses the data in "cpubuf" to process the current command. In some cases, this processing is completed very quickly. For example, at label "lcsled", a value is simply transferred from "cpubuf" to a latch that drives the LEDs on the front panel, and this interrupt service routine returns. But a more complex command can move data out of "cpubuf" to other variables in RAM, and start a timer to sequence the process of executing the command.

In some commands (for example, SEND-LCD), state (3) above is entered twice. This is called "extended collection", and occurs when a command has variable length. State (3) is entered once to collect enough information to determine the exact length of the command. It then sets up the "numexp" variable again, re-entering state (2) to collect the remainder of the command. When state (3) is entered the second time, it processes the command. A bit in the "curcmd" variable (bit 6, called "getcnt") is set in state (1), which indicates that another collection will be performed, and prevents state (3) from setting the "curcmd" byte empty the first time it is entered.

Command Processing Routines

INITIALIZE	I3 interrupt labels:	State 1 = fcinit	State 3 = lcinitt
SET-CONTRAST	I3 interrupt labels: At label "lcsclv" (Set LCD Voltage), the LCD Contrast latch is loaded from the value supplied by the CPU.	State 1 = fcsclv	State 3 = lcsclv
SEND-LCD	I3 interrupt labels: This command uses the "extended collection" feature. At label "fcsclcd", two bytes are requested for collection, but the "getcnt" bit of "curcmd" is set, meaning that these are not the last bytes of the command. At label "lcsclcd" (jumping to label "lcscl1"), the length of the instruction is determined from the # bytes value supplied by the CPU, and a second collection of bytes is requested, this time with the "getcnt" bit off. When the last byte has been collected, control is transferred to the label "lcsclcd", then to "lcscl2". Here, the data bytes for the panel are unloaded from the CPU buffer area "cpubuf" into the LCD string buffer "lcsdbuf". The flag (RS) bits are loaded into variable "lcsdsg", and the number of bytes to be sent to the LCD display is placed into variable "lcsdsc". Timer T6 is now started, to provide scheduling interrupts for writing the bytes from the LCD string buffer to the LCD display.	State 1 = fcsclcd	State 3 = lcsclcd

On occurrence of each T6 interrupt (labels "t6int" and "t6nxt"), one byte is written to the LCD display. Depending on the state of the RS flag for that byte, and the value sent to the panel, T6 may run for either 120 μ s or 4900 μ s before it triggers the next transfer. When the last character has been transferred, and Timer T6 has provided the proper delay after it, the bit "alcdak" is set in the "alert" word, requesting the main program to send an IACK-SEND-LCD interrupt to the CPU.

SEND-LED	I3 interrupt labels: At label "lcsled", the byte provided by the CPU is written to the LED latch.	State 1 = fcsled State 3 = lcsled
BEEP	I3 interrupt labels: At label "fcbEEP", Port P pin P3 is enabled to toggle on each underflow of Timer T7, which has been initialized at the beginning of the program (label "stmrS") to underflow at a rate of 6 kHz. Pin P3, then, presents a 3 kHz square wave to the panel buzzer. To time out the duration of the beep tone, interrupts from Timer T0 are enabled, which then occur once every 53 ms. The variable "beepct" is set up with the number of T0 interrupts to accept, and is decremented on each T0 interrupt. When it has been decremented to zero (meaning that one second has elapsed), pin P3 is reset to a constant zero to turn off the tone.	State 1 = fcbEEP State 3 = (none)

4.1.4.2 Background Timer (T1) Task

The Timer T1 interrupt service routine represents a task that is not triggered directly by CPU commands. Its functions are to interrupt the CPU periodically for the Real-Time Clock function, and to present the !BUTTON-DATA interrupt whenever the pushbutton inputs change state.

Timer T1 is loaded with a constant interval value which is used to interrupt the HPC at 10 ms intervals. When the Timer T1 interrupt occurs (labels 'tmrint', to 't1poll', to 't1int'), then if the real-time interrupt is enabled, the variable "rtcnt" is decremented to determine whether an !RTC interrupt should be issued to the CPU. If so, the bit "artc" in the "alert" word is set, requesting the main program to issue the interrupt. The main program, at label "sndrtc", actually interrupts the CPU. No other data is passed to the CPU with the interrupt.

At label "kbdchk" the panel pushbutton switches are also sampled. If the pattern matches the last sample taken (saved in variable "swlast") then it is considered to be sta-

ble, and it is then compared to the last switch pattern sent to the CPU (in variable "swlsnt"). If the new pattern differs, then it is placed in "swlsnt", and the bit "abutton" in variable "alert" is set, requesting the main program to send a !BUTTON-DATA interrupt. The main program, at label "sndbtn", triggers the interrupt and passes the new pattern to the CPU from variable "swlsnt".

4.1.4.3 Timer T6 Interrupt

Because the LCD controller's command acknowledgement capability was not used in our application, Timer T6 is used to time out the LCD controller's processing times. See the description of the SEND-LCD command above.

4.1.4.4 Timer T0 Interrupt

The interrupt service routine for Timer T0 (labels "tmrint", to "t0poll", to "t0int") is used simply to provide timing for the duration of the speaker tone. The interrupt is enabled in response to the BEEP command from the CPU, and is disabled on occurrence of the interrupt. It provides an interval of approximately one second.

4.3 Two Demo Programs (NS32CG16 Source Code)

The following two programs run on the NS32CG16 CPU, and exercise the functions implemented in the HPC firmware.

One thing to note in this software is that the interrupt service routines are not written as such; they are simple subroutines called by the actual service routines, which are contained within a modified version of the MON16 monitor program. The reasons for modifying MON16 were two-fold:

1. There is no RAM in the application system within the first 64k of the addressing space. The presence of RAM there is necessary for MON16 to support custom interrupt handlers without internal modification.
2. The HPC requires use of the "RETT 0" instruction, rather than "RETI", to return from maskable as well as non-maskable interrupts.

Given these two constraints, it was considered most useful to modify MON16 to contain a set of interrupt service routines, which would then use a set of addresses in RAM (a table at address "vex") to call custom interrupt servers as standard subroutines. An interrupt service routine calls its custom subroutine after saving the dedicated registers and the general registers, R0, R1 and R2 on the stack.

The symbol "vex" is defined externally, and must be declared to match the address used by the modified MON16. Details of the modified MON16 are available from National Semiconductor Corporation, Microprocessor Applications

Group or the Microcontroller Applications Group, phone (408) 721-5000. These modifications are also a standard part of the MONCG monitor program for the NS32CG016 microprocessor.

4.3.1 Panel Exerciser Program

This program for the NS32CG16 CPU exercises several functions of a panel consisting of the following:

- A two-line (8 chars. per line) LCD panel, arranged horizontally into a single 16-line display.
- A speaker, activated by the BEEP command.
- Six pushbuttons, which are presented by the IBUTTON-DATA interrupt to the CPU as follows:

Keyboard Status Byte

0	PB6	PB5	PB4	0	PB2	PB1	PB0
---	-----	-----	-----	---	-----	-----	-----

- Five LED's, activated in the SEND-LED command by the following bits:

LED Control Byte

—	—	LD5	LD4	LD3	LD2	LD1	—
---	---	-----	-----	-----	-----	-----	---

The intended layout for the front panel is as shown below. (Please pardon the apparently haphazard assignment of the pushbuttons and LED's; this was dictated by the nature of the module we used for developing this application.)

Front Panel Layout

The locations shown with asterisks on the LCD panel above will display an asterisk character while the corresponding pushbutton below it is depressed. (The number above each LCD location indicates its cursor address in hexadecimal.)

Each time a pushbutton (except PB2) is pressed, the corresponding LED indicator above it is toggled. Rather than toggling an LED, PB2 causes a BEEP command to be issued. The program starts up the panel with the LCD display blank, and LED's LD1 and LD2 on.

```

4.3.2 Real-Time Clock Display Program

This program (rtc.s) enables the Real-Time Clock interrupts from the HPC, and counts them to generate a display of elapsed time on the LCD panel.

GNX Series32000 COFF ASSEMBLER Version 2.5 6/6/88

Page: 1

The HPC as a Front-End Processor

National Semiconductor
Application Note 551
Brian Marley

AN-551

ABSTRACT

This application note covers the use of the National Semiconductor HPC46083 High-Performance microController as a front-end processor to collect and block data from RS-232 (serial) and Centronics (parallel) ports for a Host CPU (a typical application being an intelligent graphics-oriented printer). This application note builds on Application Note AN-550 (UPI Port); the result being a program that implements a versatile front-end processor for a National NS32CG16 CPU.

1.0 INTRODUCTION

In Application Note AN-550, "A Software Driver for the HPC Universal Peripheral Interface Port", we saw how a National Semiconductor HPC46083 microcontroller can be connected and programmed to perform intelligent peripheral functions for a host CPU; our example being an application connecting an NS32CG16 CPU through the HPC to a typical front panel.

In this application note, we will expand on the hardware and the driver software presented there in order to implement a very useful function for a high-performance microcontroller: that of a front-end processor for data collection. To demonstrate a real-world application for this kind of function, we implement here an intelligent interface to a Centronics-style parallel input port and an RS-232 serial port, typical of a graphics-oriented printer.

2.0 THE FRONT-END PROCESSOR FUNCTION

As systems start to support higher data rates, one of the ever-present challenges is to minimize the interrupt processing load on the CPU, which can become intolerable if the CPU must process each character received in a separate interrupt. Since the character transfer task is typically so simple (reading a character from an input port and placing it into a memory buffer), it is often the case that the unavoidable context switch time associated with the interrupt outweighs the time spent processing the input character. In addition, the communication task may not be the CPU's highest priority: for example, in band-style laser printers the CPU must keep up with the paper movement; it can neither rerun an image nor stop the paper. The communication rate therefore suffers; even printers running from a Centronics-style parallel port are typically unable to accept data faster than 4k characters per second.

The traditional technique for overcoming this obstacle is to implement Direct Memory Access (DMA) for the communication ports. This is, however, quite a large investment in hardware, requiring an external DMA controller chip and more sophisticated bus structures to support it. In other words, it may be acceptable for a computer system, but it is overly expensive for an embedded controller application. Also, the response time required of the CPU can still be stringent, especially in implementing flow control to pace the character rate from the external system presenting the data.

The HPC46083 microcontroller, however, allows a much more cost-effective approach to the problem. As a peripheral, it interfaces to the CPU much as any peripheral controller

would. In the application documented here, it buffers up to 128 characters before interrupting the CPU, thus dropping the CPU input interrupt processing frequency by over two orders of magnitude, while allowing a character input rate of over 20 kb/sec.

2.1 Data Transfer Technique

The benefit provided by a front-end processor is derived from the efficiency it adds to the process of getting data into the CPU's data buffer; that is, how much of the CPU's processing time gets dedicated to this task.

The efficiency is provided by two means:

1. Reduction of interrupt overhead. By interrupting the CPU only once every 100 characters, the overhead per character becomes virtually negligible.
2. Elimination of error testing overhead. If the CPU were communicating with a UART directly, it would have to poll for error conditions on each character. In our implementation, there are two interrupt vectors for data transfer: one for good data (which transfers a block of data), and one for bad data (which transfers one character and its error flags). The good data interrupt routine, then, which is invoked almost exclusively, contains a very simple inner loop. After reading the character count from the HPC, all that the CPU needs to do is:

- Move a character from the HPC's OBUF register to the current destination address. No time is wasted polling the HPC status; the hardware synchronization technique described in Application Note AN-550 handles this.
- Increment the destination address. (Checking against buffer limits could be done here, but is more efficiently handled outside the inner loop.)
- Decrement the character count and test it; loop if non-zero.

The HPC firmware also supports this technique by guaranteeing that the reporting of character errors (and BREAK conditions) is synchronized with good data, so that the CPU can tell exactly where in the data stream the error occurred.

2.2 Logic Replacement

Front-end processing tasks by no means use up the HPC's capabilities in a system. In our application, the HPC also serves as the CPU's only interrupt controller, allowing a large number of vectors with no additional hardware. It performs additional control tasks such as dynamic RAM refresh request timing, front panel control and real-time clock functions given in Application Note AN-550 with inexpensive interfacing. In a single 4 kbyte program developed in our group, we were also able to add an interface to an inexpensive serial EEPROM device (connected directly to the MICROWIRE/PLUSTM port of the HPC) and to a laser-printer engine for non-imaging control functions, and we also implemented a higher-resolution event timing feature. (These are topics for future application notes, however, and are not dealt with here.)

To summarize, then, the HPC not only can provide front-end processing functions, but can pay for itself by replacing other logic in the system.

3.0 HARDWARE

The following sections refer to the schematic pages included. We will discuss here only the portions involving the Centronics Parallel and RS-232 Serial ports. See Application Note AN-550 for details of the other connections shown (the UPI port and front-panel functions).

3.1 The Centronics Parallel Port

The Centronics port was implemented on the connector designated J5. Most of the interface is diagrammed on Sheet 4 of the schematic.

3.1.1 Control Inputs

Pin 1 of the J5 connector receives the Data Strobe (**STROBE**) input, which signals the presence of valid data from the external system. On Sheet 4, in area C5, this signal appears from the connector. It is filtered using a Schmitt trigger (a spare 1488 RS-232 receiver chip), and is then presented to the HPC (Sheet 3) as interrupt signal I4.

Pin 31 is the Input Prime signal (**PRIME**), which is asserted low by the external system in order to reset the interface. It appears on Sheet 4 in area D5, and is filtered in a similar manner. It is then gated with the signal **ENPRIME** from the Centronics Control Latch, and the resulting signal is presented to the HPC on pin *EXUI, which is the External UART Interrupt input. The gating is used to prevent confusion between **UART** and **PRIME** interrupts: while the Centronics port is selected, only **PRIME** causes interrupts, and while the RS-232 port is selected, this gating keeps **PRIME** interrupts from being asserted.

3.1.2 Data Inputs

Eight data bits, from J5 pins 2 through 9, appear in areas B8 and C8 of Sheet 4. They are latched into a 74LS374 latch on the leading edge of the **STROBE** signal (note the inversion through the Schmitt receiver on **STROBE**). The latch is enabled to present data to the HPC's Port D pins by the signal **ENCDATA**, which comes from HPC pin B12. Note that Port D is also used for inputting pushbutton switch data from a front panel.

3.1.3 Control Outputs

The Centronics control and handshake signals are presented by loading the Centronics Control Latch (Sheet 4, area B4) from the HPC's pins A8 through A15 (Port A Upper) using as a strobe the signal **CCTLCLK** from HPC pin P2.

Pin 10 of connector J5 is the Centronics Acknowledge (**CACK**) pulse, which is used to signal the external system that the HPC is ready for the next byte of data. This is one of the two handshake signals used to pace data flow. It is initialized high by the HPC, and is pulsed low when required.

Pin 11 is the Centronics Busy (**CBUSY**) signal, which is generated by the flip-flop on Sheet 4, area C3. It is set directly by a **STROBE** pulse, and is also loaded from the Centronics Control Latch whenever the HPC finishes reading a byte of data (rising edge of **ENCDATA**). This will clear **CBUSY** under normal conditions, allowing the external system to send another byte of data.

Five additional signals, whose functions vary significantly from printer to printer, are presented on connector J5 from the Centronics Control Latch. These are:

Pin 13, which generally indicates that the printer is selected.

Pin 12, which indicates that the printer needs attention (for example, that it is out of paper).

Pin 32, which indicates a more permanent or unusual problem (lamp check or paper jam).

Pins 33 and 35, which vary more widely in use.

These five pins are manipulated by commands from the CPU; the HPC simply presents them as commanded.

3.1.4 Other Signals

Pin 18 of the Centronics port connector receives a permanent +5V signal (area B2 of Sheet 4), and a set of other pins (middle of Sheet 2) are connected permanently to ground.

3.2 The RS-232 Serial Port

The serial port (on connector J6) makes use of the HPC's on-chip UART and baud rate generator; very little off-chip hardware is required. The entire RS-232 circuit appears on Sheet 3 of the schematic.

This port is implemented in a way typical of printers, and so there are no sophisticated handshaking connections. The interface looks like an RS-232 DTE device: Connector J6 pin 2 is transmitted data (out) and pin 3 is received data (in). The RS-232 data input appears in area B8 of Sheet 3, as signal **RXD**. After the RS-232 receiver, it is presented on the HPC's UART input pin (I6). Note that this pin can be monitored directly as a port bit; this enables the HPC to check periodically for the end of a **BREAK** condition without being subjected to a constant stream of interrupts for null characters.

The Data Set Ready signal (**DSR**) is received from pin 6 of J6, and presented on HPC pin I7, where it can be monitored by the HPC firmware.

The Request to Send signal (**RTS**) is a constant high level placed on J6 pin 4.

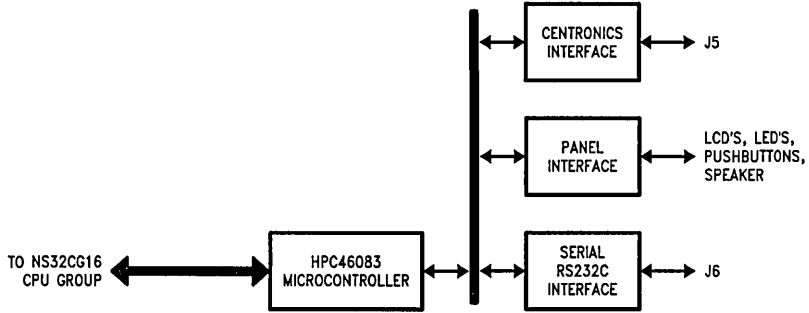

Transmitted data (**TXD**) is presented from the HPC's UART output pin (B0), through a buffering gate, to an RS-232 driver, and then out on J6 pin 3. The buffering gate would be unnecessary if the CMOS 14C88 driver were being used, but the gate was a spare and allowed cost savings using the less expensive TTL 1488 chip.

Data Terminal Ready (**DTR**) is simply presented from a programmable port pin of the HPC (pin B1). It is buffered through a spare inverter, and then presented to RS-232 connector J6 pin 20 through an RS-232 driver. As with the UART output, the buffering would be unnecessary with the 14C88 type of RS-232 driver; however, note that the HPC firmware would have to be modified slightly due to the resulting polarity difference on the pin.

J6 pins 1 (Frame Ground) and 7 (Signal Ground) are, of course, grounded, as shown in this sheet also.

4.0 PROTOCOL

The command and interrupt protocol is a superset of that implemented for Application Note AN-550. The two commands SELECT-CENT and SELECT-UART are added to select and initialize each of the communication ports (Centronics or RS-232). The CPU can exercise control over data buffering by the commands FLUSH-BUF, CPU-BUSY, CPU-NOT-BUSY and SET-IFC-BUSY. It can set Centronics port error flags and status using SET-CENT-STS, and it can test for RS-232 status using the TEST-UART command. The HPC also allows the CPU to send characters out on the RS-232 port using the SEND-UART command.

New interrupts presented by the HPC are !DATA, which transfers up to 128 bytes of buffered data to the CPU, IPRIME and !UART-STATUS, which inform the CPU of port status changes, and !DATA-ERR, which reports in detail any error occurring in characters received. The interrupt !ACK-UART is presented to the CPU to acknowledge that the SEND-UART command has been completed.

Note that the command codes for the front panel functions have been changed. Their formats, however, have not changed, nor have their functions, except that the INITIALIZE command now performs a disconnection function on the RS-232 and Centronics ports.

4.1 Commands

The first byte (command code) is sent to address FFFC00, and any argument bytes are then written to address FFFE00. The CPU may poll the UPIC register at address FD0000 to determine when the HPC can receive the next byte, or it can simply attempt to write, in which case it will be held in Wait states until the HPC can receive it. Except where noted, the CPU may send commands continuously without waiting for acknowledgement interrupts from previous commands.

00 INITIALIZE

This command has two functions. The first INITIALIZE command after a hardware reset (or RESET-HPC command) enables the !RTC and !BUTTON-DATA interrupts. Both data communication ports are set to their "Busy" states until a "SELECT" command is sent. The INITIALIZE command may be re-issued by the CPU to de-select both communication ports, and to either start or stop the !RTC interrupts. There is one argument:

RTC-Interval: One-byte value. If zero, !RTC interrupts are disabled. Otherwise, the !RTC interrupts occur at the interval specified (in units of 10 ms per count).

01 SELECT-CENT

Select the Centronics port and set it ready, using the timing sequence specified by the supplied ACK-Mode argument. Data from the port is enabled, and the IPRIME interrupt is also enabled. Arguments:

ACK-Mode: one byte in the format:

x	x	x	x	x	L	Timing
---	---	---	---	---	---	--------

where the Timing field is encoded as:
00 = BUSY falling edge occurs after ACK pulse.

01 = BUSY falling edge occurs during ACK pulse.

10 = BUSY falling edge occurs before ACK pulse.

and the L bit, when set, requests Line Mode. It suppresses the removal of BUSY and the occurrence of the ACK pulse when the buffer is passed to the CPU. To fully implement Line Mode, this mode should be used with Pass-Count = 1 and Stop-Count = 1, and the CPU must use the SET-CENT-STS command to acknowledge each character itself.

Pass-Count: Number of characters in buffer before the HPC passes them automatically to CPU. One byte.

Stop-Count: Number of characters in buffer before HPC tells the external system to stop. One byte.

Note that the buffer is a maximum of 128 bytes in length, in this implementation.

Requires INITIALIZE command first.

Select Serial port and set it ready, according to supplied arguments. Requires INITIALIZE command first. Arguments are:

Baud: Baud rate selection. One Byte containing.

0 = 300 baud

1 = 600 baud

2 = 1200 baud

3 = 2400 baud

4 = 4800 baud

5 = 9600 baud

6 = 19200 baud

7 = 38400 baud

8 = 76800 baud

Frame: One byte, selecting character length, parity and number of stop bits.

02 SELECT-UART

Value	Data Bits	Parity	Stop Bits
0	8	Odd	1
1	8	Even	1
2	8	None	1
3	8	None	2
4	7	Odd	1
5	7	Even	1
6	7	Odd	2
7	7	Even	2

Flow: One byte, bit-encoded for handshaking and flow control modes:

0	0	0	0	XON	DTR	DSR	
7	6	5	4	3	2	1	0

DSR: 1 = the HPC disables the UART receiver while the DSR input is inactive.

DTR: Polarity of DTR output, and whether it is used as a flow-control handshake.

00 = Permanently low (negative voltage).

01 = Permanently high (positive voltage).

10 = Handshaking: low means ready.

11 = Handshaking: high means ready.

XON: 1 = the HPC performs XON/XOFF flow control.

Pass-Count: Number of characters in buffer before the HPC passes them automatically to CPU. One byte.

Stop-Count: Number of characters in buffer before HPC tells the external system to stop. One byte.

Note that the buffer is a maximum of 128 bytes in length, in this implementation.

Requires INITIALIZE command first.

03 (reserved)

04 FLUSH-BUF

No arguments. Flush HPC data communication buffer to CPU. Any data in the buffer is immediately sent to the CPU (using the !DATA interrupt). This command triggers the !DATA interrupt only if the buffer contains at least one byte. Requires INITIALIZE command and SELECT command first.

05 CPU-BUSY

No arguments. Indicates that the CPU cannot accept any more data (the CPU's data buffer is full). This suppresses the !DATA and !DATA-ERR interrupts. Requires INITIALIZE command and SELECT command first.

06 CPU-NOT-BUSY

No arguments. This undoes a previous CPU-BUSY command, and indicates that the CPU can now accept more data from the HPC. Requires INITIALIZE command and SELECT command first.

07 SET-IFC-BUSY

"Set Interface Busy". No arguments. Commands the HPC to immediately signal the external system to stop

sending characters. This status is removed only by performing a SELECT command. Requires INITIALIZE command and SELECT command first.

08 SET-CENT-STS

"Set Centronics Port Status". Loads Centronics latch from the supplied argument byte. Argument is eight bits, which must be encoded as follows:

ENPRIME	CX2	FAULT	CALL	SELECT	BUSY	CX1	ACK
---------	-----	-------	------	--------	------	-----	-----

The $\overline{\text{ACK}}$ bit should always be a "1". The CPU must use the BUSY bit to generate an $\overline{\text{ACK}}$ pulse: if the BUSY bit is zero, the $\overline{\text{ACK}}$ signal will be automatically pulsed low, then high, (regardless of the previous states of BUSY and $\overline{\text{ACK}}$).

Requires INITIALIZE command and SELECT-CENT command first.

09 SET-CONTRAST

The single argument is a 3-bit number specifying a contrast level for the LCD panel (0 is least contrast, 7 is highest contrast). There is no response interrupt. Does not require INITIALIZE command first.

0A SEND-LCD

This writes a string of up to 8 bytes to the LCD panel. Arguments are:

flags: A single byte, containing the RS bit associated with each byte of data. The first byte's RS value is in the least-significant bit of the FLAGS byte.

#bytes: The number of bytes to be written to the LCD display.

byte[1]-byte[#bytes]: The data bytes themselves.

The HPC determines the proper delay timing required for command bytes (RS = 0) from their encodings. This is either 4.9 ms or 120 μ s.

The response from the HPC is the !ACK-SEND-LCD interrupt, and this command must not be repeated until the interrupt is received. This command does not require an INITIALIZE command first.

0B SEND-LED

The single argument is a byte containing a "1" in each position for which an LED should be lit.

There is no response interrupt, and this command does not require the INITIALIZE command first.

0C BEEP

No arguments. This beeps the panel for approximately one second. No response interrupt. If a new BEEP command is issued during the beep, no error occurs (the buzzer tone is extended to one second beyond the most recent command). Does not require INITIALIZE command first.

0D SEND-UART	The single one-byte argument is sent on the UART port. An acknowledgement interrupt !ACK-UART occurs on completion. This command must not be repeated until the interrupt is received. Requires INITIALIZE and SELECT-UART commands first.	Vector 00–0F (none)	(Reserved for CPU internal traps and the NMI interrupt.)
0E TEST-UART	Triggers a !UART-STATUS interrupt. This command must not be repeated until the interrupt is received. No arguments. Requires INITIALIZE and SELECT-UART commands first.	10 !DATA	Buffer data is being transferred to CPU. This will happen either automatically, at a point defined by the most recent SELECT command, or as the result of a FLUSH-BUF command. It is followed by a one-byte Length (number of characters: current HPC firmware has a range of 1–128), then that number of characters. Enabled by SELECT command after at least one INITIALIZE command.
A5 RESET-HPC	Resets the HPC if it is written to address FFFC00. It may be written at any time that the UPI port is ready for input; it will automatically cancel any partially-entered command. The CPU's Maskable Interrupt must be disabled before issuing this command. After issuing this command, the CPU should first poll the UPIC register at address FD0000 to see that the HPC has input the command (the least-significant bit [Write Ready] is zero). It must then wait for at least 25 μ s, then read a byte from address FFFE00. The HPC now begins its internal re-initialization. The CPU must wait for at least 80 μ s to allow the HPC to re-initialize the UPI port. Since part of the RESET procedure causes Ports A and B to float briefly (this includes the CPU's Maskable Interrupt input pin), the CPU should keep its maskable interrupt disabled during this time. It also must not enter a command byte during this time because the byte may be lost.	11 !RTC	Real-Time Clock Interrupt. No data returned. Enabled by INITIALIZE command if interval value supplied is non-zero. Note: This version of HPC firmware issues a non-fatal !DIAG interrupt if the CPU fails to service each !RTC interrupt before the next one becomes pending.
		12 (reserved)	
		13 !PRIME	Centronics INPUT PRIME signal has become active. No data returned. Enabled by SELECT-CENT command after at least one INITIALIZE command.
		14 (reserved)	
		15 (reserved)	
		16 (reserved)	
		17 !ACK-SEND-LCD	This is the response to the SEND-LCD command, to acknowledge that data has all been written to Panel LCD display. No other data is provided with this interrupt. Always enabled, but occurs only in response to a SEND-LCD command.
		18 !BUTTON-DATA	Pushbutton status has changed: one or more buttons have been either pressed or released. The new status of the switches is reported in a data byte, encoded as follows: Any pushbutton that is depressed is presented as a "1". All other bit positions, including unused positions, are zeroes. The pushbuttons are debounced before being reported to the CPU. This interrupt is enabled by the first INITIALIZE command after a reset.

4.2 Interrupts

The HPC interrupts the CPU, and provides the following values as the interrupt vectors for the CPU hardware. The CPU then reads data from the HPC at address FFFE00. All data provided by the HPC must be read by the CPU before returning from the interrupt service routine, otherwise the HPC would either hang or generate a false interrupt. The CPU may poll the UPIC register at address FD0000 to determine when each data byte is ready, or it may simply attempt to read from address FFFE00, and it will be held in Wait states until the data is provided by the HPC.

Note: All CPU interrupt service routines, including the NMI interrupt routines, must return using the "RETT 0" instruction. Do NOT use "RETI".

19 IUART-STATUS UART status has changed. This interrupt occurs only while the UART is selected. A data byte shows the UART's new state:

Bit	Condition
0 (LSB)	New state of DSR signal. This causes an interrupt only if DSR monitoring was requested in the last SELECT-UART command. The UART receiver is automatically enabled and disabled by the HPC, so no CPU action is required on receiving this interrupt. If a SELECT-UART command is entered, requesting DSR monitoring, and DSR is inactive, a IUART-STATUS interrupt occurs immediately.
1	This bit is set if a UART BREAK has just ended.
2-7	(unused)

Note 1: If the CPU has issued a CPU-NOT-READY command, this BREAK interrupt may be seen before the IDATA-ERR interrupt that announces the start of the BREAK (and its position in the data stream).

Note 2: The DSR and UART input (BREAK) signals are sampled every 10 ms.

1A IDATA-ERR

An error has been encountered in data coming from the currently-selected communication port. It is enabled by the first SELECT command after the first INITIALIZE command. Two data bytes are returned:

errchr: One byte containing the character on which the error was seen (this character is NOT placed in the data buffer).

errfgs: Error flags, detailing the error seen:

Bit	Error Seen
0 (LSB)	(unassigned)
1	(unassigned)
2	UART BREAK condition detected. This may be preceded by one or two framing errors.
3	Error Overflow: More errors occurred than HPC could report (the HPC has no FIFO for error reporting).
4	Buffer Overflow: Flow control failed to stop the external system, and the buffer overflowed.

5	Parity Error: Serial Port only.
6	Framing Error: Serial Port only.
7 (MSB)	Data Overrun: Serial Port only.

If bit 2, 3 or 4 is set, the communication port has been automatically shut down by the HPC. The CPU must issue a new SELECT command to re-enable the port.

When a character is received with an error, all characters appearing before it in the buffer are automatically flushed before this interrupt occurs. This is done to preserve the error character's position in the data stream. If the CPU decides to ignore the presence of an error, the character may be simply appended by the CPU to the data already in its data buffer. Please note: If the CPU has issued a CPU-NOT-READY command, the flush cannot occur, and this interrupt will not be issued until the flush has occurred.

1B IACK-UART

A CPU character has been sent on the UART, and the UART is ready for another. No data is returned with this interrupt. It is always enabled, but occurs only in response to the SEND-UART command.

1C (reserved)

1D IDIAG

Diagnostic Interrupt. This interrupt is used to report failure conditions and CPU command errors. There are five data bytes passed by this interrupt:

Severity
Error Code
Data in Error (passed, but contents not defined)
Current Command (passed, but contents not defined)
Command Status (passed, but contents not defined)

The Severity byte contains one bit for each severity level, as follows:

X	X	X	F	X	X	C	N
---	---	---	---	---	---	---	---

N (Note): least severe. The CPU missed an event; currently only the IRTC interrupt will cause this.

C (Command): medium severity. Not currently implemented. Any command error is now treated as a FATAL error (below).

F (Fatal): highest severity. The HPC has recognized a non-recoverable error. It must be reset before the CPU may re-enable its Maskable Interrupt. In this case, the remaining data bytes may be read by the CPU, but they will all contain the value 1D (hexadecimal). The CPU must issue a RESET command, or wait for a hardware reset. See below for the procedure for FATAL error recovery.

The Error Code byte contains, for non-FATAL errors, a more specific indication of the error condition:

RTC = Real-Time Clock overrun: CPU did not acknowledge the RTC interrupt before two had occurred.

The other bits are reserved for details of Command errors, and are not implemented at this time.

The remaining 3 bytes are not yet defined, but are intended to provide details of the HPC's status when an illegal command is received.

Note: Except in the FATAL case, all 5 bytes provided by the HPC *must* be read by the CPU, regardless of the specific cause of the error.

Fatal Error Recovery:

When the HPC signals a IDIAG error with FATAL severity, the CPU may use the following procedure to recover:

1. Write the RESET command (A5 hex) to the HPC at address FFFC00.
2. By inspecting the UPIC register at address FD0000, wait for the HPC to read the command (the WRRDY bit will go low).
3. Wait an additional 25 μ s.

4. Read from address FFFE00. This will clear the OBUF register and reset the Read Ready status of the UPI port. The HPC will guarantee that a byte of data is present; it is not necessary to poll the UPIC register. This step is necessary because only a hardware reset will clear the Read Ready indication otherwise (HPC firmware cannot clear it).

5. Wait at least 80 μ s. This gives the HPC enough time to re-initialize the UPI port.

6. After Step 5 has been completed, the CPU may re-enable the Maskable Interrupt and start issuing commands. Since the HPC is still performing initialization, however, the first command may sit in the UPI IBUF register or a few milliseconds before the HPC starts to process it.

5.0 SOURCE LISTINGS AND COMMENTARY

5.1 HPC Firmware Guide

This section is intended to provide help in following the flow of the HPC firmware. Discussion of features already documented in Application Note AN-550 are abbreviated here; see that application note for details.

The firmware for the HPC is almost completely interrupt-driven. The main program's role is to poll mailboxes that are maintained by the interrupt service routines, and to send an interrupt to the CPU whenever a HPC interrupt routine requests one in its mailbox.

On reset, the HPC firmware begins at the label "start". However, the first routine appearing in ROM is the Fatal Error routine. This is done for ease of breakpointing, to keep this routine at a constant address as changes are made elsewhere in the firmware.

5.1.1 Fatal Error Routine

At the beginning of the ROM is a routine (label "hangup") that is called when a fatal error is detected by the HPC. This routine is identical to that documented in Application Note AN-550.

5.1.2 Initialization

At label "start", entered on a Reset signal or by the RESET-HPC command from the CPU, the HPC begins its internal initialization. It loads the PSW register (to select 1 Wait state), and then (at label "srfs"), it starts the Refresh clock pulses running for the dynamic RAM by initializing Timer T4 and starting it.

At "supi", the UPI port is initialized for transfers between the HPC and the CPU.

At label "sram", all RAM within the HPC is initialized to zero.

At "sskint", the stack pointer is initialized to point to the upper bank of on-chip RAM (at address 01C0). The address of the fatal error routine "hangup" is then pushed, so that it will be called if the stack underflows.

At "tminit", the timers T1-T3 are stopped and any interrupts pending from timers T0-T3 are cleared. This step arbitrarily initializes the UART baud rate to 9600, but this selection has no effect.

At "scent", the Centronics port is initialized and set up to appear busy to the external system.

At "suart", the HPC UART is initialized for serial data from the external system. The RS-232 DTR signal is arbitrarily set low, which generally means that the printer is not ready. The state of DTR is not actually valid until the first SELECT-UART command is received, which selects the handshaking mode.

At "sled", the LED control signals are initialized, and all LED indicators are turned off.

At "stmrs", all timers are loaded with their initial values, and timers T5-T7 are stopped and any interrupts pending from them are cleared.

At "slcd", the LCD display is initialized to a default contrast level of 5, then commands are sent to initialize it to 8-bit, 2-line mode, with the cursor visible and moving to the right by default. This section calls a subroutine "wrpn!" for each character; the subroutine simply writes the character in the accumulator out to the LCD display and waits for approximately 10 ms.

The program then continues to label "minit", which initializes the variables in the HPC's on-chip RAM to their proper contents.

At label "runsys", the necessary interrupts are enabled (from the timers, and from pin I3, which is the UPI port interrupt from the CPU), and the program exits to the Main Program at label "mainlp". Interrupts from the Centronics and UART ports are not enabled until the appropriate SELECT command is received.

5.1.3 Main Program (UPI Port Output to CPU)

The Main Program is the portion of the HPC firmware that runs with interrupts enabled. It consists of a scanning loop at label "mainlp" and a set of subroutines (explained below). It is responsible for interrupting the CPU and passing data to it; the HPC is allowed to write data to the CPU only after interrupting it. Unlike the simpler UPI/Front Panel interface described in Application Note AN-550, this main loop scans two separate variables in on-chip RAM that are set up by interrupt service routines: a word called "alert", and a byte called "bstat" (for "Buffer Status"). Both variables are used to determine whether any conditions exist that should cause an interrupt to the CPU.

The "alert" word contains one bit for each interrupt that the HPC can generate. If a bit is set (by an interrupt service routine), the Main Program jumps to an appropriate subroutine to notify the CPU. The subroutine checks whether the UPI interface's OBUF register is empty, and if not, it waits (by calling the subroutine "rdwait"). It then writes the vector number to the OBUF register. This has the effect of interrupting the CPU (because the pin \overline{URDRDY} goes low), and the CPU hardware reads the vector from the OBUF register.

If there is more information to give to the CPU, the HPC places it, one byte at a time, into the OBUF register, waiting each time for OBUF to be emptied by the CPU. This technique assumes that the CPU remains in the interrupt service routine until all data has been transferred: if the CPU were to return from interrupt service too early, the next byte of data given to it would cause another interrupt, with an incorrect vector.

(Note, however, that the CPU may be interrupted with a Non-Maskable interrupt from a separate source. This simply inserts a pause into the process of reading data from the HPC. Since the HPC is running its main program at this point, with interrupts still enabled, it will not lose data from its communication port under these circumstances.)

The "bstat" byte represents a special case involving the interrupt IDATA to the CPU. This byte shows the main program whether the data communication buffer (which holds data from the external system) is full enough to send its contents to the CPU. If so, the main program calls the subroutine "snddta", which interrupts the CPU, then sends one data byte containing the number of characters to be transferred (currently as many as 128 are possible), and then the characters themselves.

The CPU may, at any time, demand that the HPC transfer all characters that are within its communication buffer. (This is called a "flush" command, which sets one of the bits of the "alert" word, described above.) The HPC, in response, will empty the buffer to the CPU with a IDATA interrupt, even if only one character is left. If the buffer is completely empty, however, the flush command is ignored.

Subroutines called from the Main Program loop are:

- sndrtc: sends a Real-Time Clock interrupt to the CPU. No data is transferred; only the interrupt vector.
- sndlak: interrupts the CPU to acknowledge that a string of data (from a SEND-LCD command) has been written to the LCD display. No data is transferred for this interrupt.
- sndbtn: interrupts the CPU to inform it that a pushbutton has been pressed or released. A data byte is transferred from variable "swlsnt", which shows the new states of all the pushbuttons.
- sndfsh: performs a Flush operation. If there is data, it jumps to the "snddta" routine to send the contents of the buffer to the CPU. If there is no data, however, this subroutine simply returns without generating an interrupt.
- snddta: sends data from the communication buffer to the CPU. It may be entered for one of three reasons:
 1. the communication buffer is full enough that it must be sent automatically to the CPU.
 2. a Flush command has been received from the CPU. (The bit "aflush" in the ALERT word is set.)
 3. an error has been detected on a character received from the external system. This causes an internal Flush request, so that all good characters are sent to the CPU before the bad character is reported. This case is also different because it does not flush the entire buffer, but only up to the point of the error. The limit is held in the variable "fshlim".

The subroutine sends a "length" byte (from variable "numout", sampled from "numchr", which is maintained by the communication interrupt routines). This indicates how many characters will be transferred. The subroutine next sends the characters themselves. It then updates the buffer status variables in on-chip RAM, to indicate how many characters were removed.

Depending on other status of the selected communication port, this subroutine may re-enable communication on the port if it was stopped (for example, if the buffer was too full to accept more data until the "snddta" routine emptied it). This is done at label "sdstp".

- sndprm: interrupts the CPU because the INPUT PRIME signal on the Centronics parallel port was activated by the external system. No data is transferred by this interrupt.
- sndust: interrupts the CPU to report a change in UART status. This interrupt may also be triggered by the CPU using the TEST-UART command.

snderr: interrupts the CPU to inform it that a character with an error was received. The character and a byte containing error flags are transferred to the CPU.

snduak: interrupts the CPU in response to a SEND-UART command, to acknowledge that the requested character has been sent on the UART transmitter, and that it is ready to transmit another character.

sndiag: interrupts the CPU to inform it of a !DIAG interrupt condition, when it is of NOTE severity. (Other !DIAG conditions are handled at label "hangup".)

5.1.4 UPI Port Input from CPU (Interrupt I3)

This interrupt service routine, at label "upiw", accepts commands from the CPU. Apart from the existence of additional commands, the structure of this routine is identical to that of Application Note AN-550. We document here the labels and functions involved in this larger application.

Command Processing Routines

INITIALIZE	I3 interrupt labels:	State 1 = fcinit	State 3 = lcinlt
SELECT-CENT	I3 interrupt labels:	State 1 = fcsele	State 3 = lcselc
SELECT-UART	I3 interrupt labels:	State 1 = fcselu	State 3 = lcselu
FLUSH-BUF	I3 interrupt labels:	State 1 = fcflsh	State 3 = (none)
	At label "fcflsh", the "alert" word bit "aflush" is set, which requests that the main program flush the communication buffer.		
CPU-BUSY	I3 interrupt labels:	State 1 = fcbsy	State 3 = (none)
	At label "fcbsy", the buffer status byte "bstat" is set to indicate that the CPU is busy and cannot accept more data from the HPC. This disables the !DATA interrupt.		
CPU-NOT-BUSY	I3 interrupt labels:	State 1 = fcnbby	State 3 = (none)
	At label "fcnbby", the buffer status byte "bstat" is set to indicate that the CPU is ready to accept more data from the HPC. The !DATA interrupt is re-enabled.		
SET-IFC-BUSY	I3 interrupt labels:	State 1 = fcifby	State 3 = (none)
	At label "fcifby", the currently selected interface is set busy, in order to present an error indication.		
SET-CENT-STS	I3 interrupt labels:	State 1 = fcscst	State 3 = lcsrst
	At label "lcsrst", the Centronics Port status byte "cps" is loaded from the value supplied by the CPU, and the Centronics port control signals are updated to reflect these new settings. The subroutine "setcen" is used to set up the control signals, and it also pulses the Centronics ACK signal if appropriate.		
SET-CONTRAST	I3 interrupt labels:	State 1 = fcslcv	State 3 = lcslcv
	At label "lcslcv" (Set LCD Voltage), the LCD Contrast latch is loaded from the value supplied by the CPU.		
SEND-LCD	I3 interrupt labels:	State 1 = fcslcd	State 3 = lcslcd
	This command sends a string of up to eight bytes to the LCD display. Application Note AN-550 describes the implementation of this command in detail.		
SEND-LED	I3 interrupt labels:	State 1 = fcslcd	State 3 = lcsled
	At label "lcsled", the byte provided by the CPU is written to the LED latch.		
BEEP	I3 interrupt labels:	State 1 = fcbeep	State 3 = (none)
	This command sends a one-second beep tone to a speaker.		
SEND-UART	I3 interrupt labels:	State 1 = fcsndu	State 3 = lcsndu
	At label "lcsndu", the single argument (the character to be sent) is placed in variable "uschr", and the bit "schr" is set in variable "ups" (UART Port Status). By doing this, the character has been queued for transmission. The transmission is performed by the subroutine at label "setuar", which is also responsible for performing the XON/XOFF flow control protocol. If a character is already being sent (the transmitter interrupt is enabled), then this is the only action required, since the transmitter interrupt automatically invokes the "setuar" subroutine. However, if the transmitter is idle, this routine must itself call "setuar" to transmit the character.		
	The subroutine "setuar" itself calls another subroutine at label "uecsnd", which formats the character to be transmitted into the frame selected by the current UART framing mode. It then sends the character. Note that the UART framing mode applies to output as well as input characters.		
TEST-UART	I3 interrupt labels:	State 1 = fcusts	State 3 = (none)
	At label "fcusts", the HPC sets the "austat" bit of the ALERT word, requesting the Main Program to send a !UART-STATUS interrupt to the CPU.		

5.1.5 Centronics Communication

This task is triggered by each edge of the Centronics port STROBE signal. This signal is detected by the HPC on the I4 interrupt line. On the leading edge of STROBE, the character is input to the data communication buffer. This edge also sets the BUSY signal, by hardware action. On the trailing edge, the BUSY flag is affected by the HPC firmware. If the HPC is ready to receive more characters, the BUSY signal is cleared and the ACK signal is pulsed. If the HPC is not ready to receive more data, it leaves the BUSY signal high, which prevents the external system from sending more characters.

The Centronics port STROBE handler is at label "cenint". It first determines whether a falling or rising edge was detected on the STROBE signal. If the leading (falling) edge was detected, then it jumps to label "cstrbl"; otherwise it jumps to label "cstrbt" to process a trailing edge.

At label "cstrbl", the character is placed in the next available position of the communication buffer, if the buffer is not already full. (If it is already full, then it is processed as an error, as discussed below.) Then some tests are performed:

If the buffer is not full enough to pass data to the CPU, then the routine exits by jumping to label "cenlex", where it prepares to detect the trailing edge of STROBE. Otherwise, it sets the "pass" bit in the variable "bstat", which requests the main program to send data to the CPU, and then it continues.

If the buffer is not full enough to tell the external system to stop sending characters, then the routine exits by jumping to "cenlex". Otherwise, it sets the "stop" bit in variable "bstat", indicating that the external system has been stopped, and it also sets the "cbusy" flag in variable "cps", which will prevent the Centronics BUSY and ACK signals from being changed when the STROBE pulse ends. The routine continues.

If the buffer has become completely full, then the "full" bit in "bstat" is set, indicating that any more characters received will trigger an error. Character processing then continues at label "cenlex".

At "cenlex", the Centronics Control Latch is set (temporarily) to force the BUSY signal high, because it should not become low until the STROBE pulse ends. The I4 pin, which detects the STROBE signal, is then re-programmed to detect the trailing edge (rising edge at the Centronics connector, but falling edge at pin I4 due to an inverting buffer). If the trailing edge already has occurred, then this reprogramming will set another interrupt pending immediately. There is, however, a possibility that the strobe edge could occur simultaneously with the reprogramming, with unknown results. For this reason, the STROBE signal is sampled by the firmware, and if the pulse has already completed, then instead of returning from the interrupt it jumps immediately to interrupt routine "cstrbt", which processes the trailing edge.

The code at label "cstrbt" is entered whenever either a trailing edge interrupt is detected on pin I4 (STROBE), or the leading edge interrupt routine jumps to it. It reprograms the I4 pin to detect a leading edge again, clears the I4 interrupt

(which is automatically cleared only on interrupt service), then jumps to the "setcen" subroutine, which manipulates the BUSY and ACK signals appropriately, according to the contents of the "cps" variable and the selected ACK timing mode in variable "ackmd".

5.1.5.1 Centronics Error Handling

A buffer overrun error is processed at label "cenerr". This is the only kind of character error that can happen on a Centronics interface, and it would be due to an incorrect connection or a software error.

For internal firmware debugging purposes, the "cps" variable bit "cbusy" is again set to ensure that the Centronics interface will keep the BUSY signal set.

If an error is already waiting to be reported (bit "aerr" of variable "alert" is already set), then this is a "multiple error" condition, and cannot be fully reported. Instead, at label "cenmer", the bit "errorfl" in variable "errfgrs" is set. This variable is sent to the CPU when the error is reported. Also, the I4 interrupt is disabled, to prevent any further STROBE interrupts until a new SELECT-CENT command is received from the CPU.

If no error is waiting to be reported, then bit "aerr" of variable "alert" is set, requesting the main program to generate an IERROR interrupt to the CPU. Further data is provided to be passed to the CPU:

variable "errfgrs" is initialized to indicate only a buffer overrun error.

variable "errchr" is loaded with the character that was received and could not fit in the buffer.

Because the received character is reported with the error interrupt, and because no data is lost yet, the Centronics port is not disabled by this condition.

5.1.6 UART Communication

UART communication is performed by the UART interrupt routine at label "uarint". After pushing the required registers onto the stack, the routine determines which interface is selected. If it is the Centronics port, the only cause of the interrupt is the INPUT PRIME signal, and the HPC jumps to label "uarprm" (see Background Processing/Monitoring Tasks, below). If the UART port is selected, then it is due to either a receiver or a transmitter interrupt (and the INPUT PRIME is gated so that it cannot be presented).

5.1.6.1 UART Output

At label "uarout", a transmitter interrupt has been received. If the bit "icpu" in variable "ups" is set, this means that the character just transmitted was a character sent by a CPU SEND-UART command, and the CPU is notified by requesting the !ACK-UART interrupt from the Main Program.

The subroutine "setuar" is now called, to determine whether any more characters need to be sent, either for XON/XOFF handshaking or because the CPU has requested the HPC to send another character. If so, another character is sent by "setuar", and the UART transmitter interrupt remains enabled. If not, the "setuar" routine disables the transmitter interrupt.

5.1.6.2 UART Input

At label "uartin", an interrupt has been generated by the UART receiver. This means that a character is available to be placed into the Communication Buffer.

The first action taken by the HPC is to read the receiver status register ENUR (which contains the 9th data bit and the Data Overrun and Framing Error error flags), then it reads the character itself from the RBUF register. The ENUR register is saved temporarily in variable "enring" for future processing, but is also held in the Accumulator, which is used here to "accumulate" error flags. The HPC then prepares to check for a parity error.

Parity checking is not a hardware feature of the HPC's UART, so a bit-table lookup is performed using the "X,[B].b" addressing mode of the IFBIT instruction. This addressing mode is similar to NS32000 bit addressing, in that it allows one to address up to 64 kbits (addressed from the contents of the X register) from a base address given in the B register. By placing the character to be checked into the X register, and pointing the B register at a properly constructed table (labels "evntbl" and "oddtbl"), a parity error can be detected in a single IFBIT instruction (see for example label "u8dopr").

After loading the X and B registers, a multi-way branch is performed (jid), which branches to one of 8 labels depending on the character framing mode variable "uframe" (which is loaded by the SELECT-UART command). Each mode handles parity differently: labels "uiod8" and "uiev8" check for odd or even parity, respectively, including 9 character bits (8 data plus 1 parity) to make the test. Labels "uiod7" and "uiev7" include only 8 bits (7 data plus 1 parity). Label "nopar" handles the cases where no parity is included in the character frame. Also within these routines, a decision is made whether a Framing Error seen in the character is also a Break condition: if two consecutive characters are seen with framing errors with all zeroes in their parity and data fields, then the second character is reported as a Break character as well as having a framing error. If, at label "uinpok", no errors have been flagged in the Accumulator, the routine branches to label "uingd" to place the character into the Data Communication Buffer for the CPU. If errors have been discovered, then the character is instead reported to the CPU using the !DATA-ERR at label "uiner".

The "uingd" portion of this routine is very similar to the portion of the Centronics input routine that places characters into the buffer for the CPU. A different mechanism is used for flow control, of course, to stop the external system if the buffer becomes full.

At label "uiner", a check is made to determine whether the CPU has received the last character error reported. If not, this is a "multiple error" condition, handled at label "uinmce". If so, then this is reported as a new error at label "uin1ce". The error character and its error flags are provided to the Main Program in the mailboxes "errchr" and "errfgs", and the bit "aerr" in variable "alert" is set to request that a !DATA-ERR interrupt be sent to the CPU.

On a multiple-error condition, the new error flags are ORed with the old ones, handshaking is used to stop the external

host system from sending more characters, and the UART receiver is automatically disabled. The CPU must issue a new SELECT-UART command to re-enable it.

Another pair of routines report an error if the buffer overflows. This error is reported at label "uin1e" if no other error report is pending, or at label "uinme" if this is a multiple error condition. On a multiple error, an attempt is made to stop the external host system from sending characters, and the UART receiver is disabled until the CPU issues a SELECT-UART command. (A single error does not disable the receiver, because no data has been lost yet: the !DATA-ERR interrupt reports the character with the error report.)

5.1.7 Buffer Status Reporting

For internal debugging purposes, four unassigned signals from the LCD Contrast Latch are updated to show the status of the buffer. While the buffer is full enough to pass to the CPU, one bit of the latch (IC 25G, pin 12) is high. While the buffer is full enough that the external system should stop, pin 15 is high. While the CPU is not ready to receive data from the CPU, pin 16 is high. If a buffer overrun condition occurs, and data is lost, or if any fatal error occurs (with a hexadecimal code appearing on the LCD display), then pin 19 goes high. The code that handles these bits is flagged with the word "DEBUG" in the comment field.

5.1.8 Background Processing/Monitoring Tasks

These are tasks that are not triggered directly by CPU commands.

Real-Time Clock (T1) Timer T1 is loaded with a constant interval value which is used to interrupt the HPC at 10 ms intervals. When the Timer T1 interrupt occurs (labels "tmrint", "t1poll", "t1int"), and the real-time interrupt is enabled, the variable "rtccnt" is decremented to determine whether a !RTC interrupt should be issued to the CPU. If so, the bit "artc" in the "alert" word is set, requesting the main program to send a !RTC interrupt to the CPU. The main program, at label "sndrtc", interrupts the CPU. No other data is passed to the CPU.

At label "kbdchk" the panel pushbutton switches are also sampled. This process is described fully in Application Note AN-550.

At label "dsrchk", the state of the UART DSR flag is checked if the UART is selected and DSR monitoring mode has been requested by the CPU. If it has changed, this routine requests the Main Program to issue a !UART-STATUS

interrupt to the CPU. The UART receiver is also enabled and disabled by the state of this signal if DSR monitoring has been requested. (The CPU does not have to react to the interrupt for normal operation, but might wish to record its occurrence.)

At label "brkchk", if the UART is selected, and a BREAK has been detected, the UART data input pin is polled to determine whether the BREAK condition has ended. If a BREAK has ended, then this routine requests the Main Program to issue a !UART-STATUS interrupt to the CPU.

Centronics INPUT PRIME When the $\overline{\text{EXU}}$ pin on the HPC is activated, and the Centronics port is selected rather than the UART, the UART service routine (at label "uarprm") sets bit "aprime" in the "alert" variable, requesting the main program to send a !PRIME interrupt to the CPU. The Centronics port is internally flagged (in the "cps" variable) as being "busy", and the Centronics Control Latch is updated to set the BUSY signal high. The UART interrupt is then disabled until a SELECT-CENT command is received from the CPU. In the main program, the !PRIME interrupt is sent to the CPU at label "sndprm". No other data is sent.

5.2 HPC Firmware Listing

```

# Centronics Port input / checksum calculation / LCD output.
#   Accepts up to 1024 characters on Centronics port,
#   accumulates 8-bit checksum, and on receiving Ctrl-D,
#   displays checksum on LCD display.

Interfacing A Serial EEPROM to the National HPC16083

National Semiconductor
Application Note 552
Brian Marley

ABSTRACT

This application note describes how to interface the HPC16083 High-Performance microController to a MICROWIRE™ serial EEPROM (Electrically Erasable Programmable Read-Only Memory) device. The technique uses interrupt-driven scheduling from one of the eight on-chip timers, and so can run in the "background", sharing the HPC gracefully with other control applications running at the same time. Source code is included.

1.0 INTRODUCTION

It is often the case in control-oriented applications that a piece of equipment, on being installed, must be set up with certain semi-permanent configuration mode settings. In the past, jumpers and switches have been the methods used, but in recent years these have been largely supplanted by EEPROM devices, which hold more information and are not prone to mechanical problems. In addition, the presence of an EEPROM allows certain information about the status of the equipment (for example, in printers, a page or character count for monitoring the "age" of the cartridge or print head) to be stored to assist in maintenance.

The most cost-effective type of EEPROM device is one with a serial interface, such as the 256-bit NMC9306 (COP494) or the 1024-bit NMC9345 (COP495). These reside in an

8-pin DIP package, and require only four connections (besides V_{CC} and Ground). These connections are provided by the HPC family of High-Performance Microcontrollers, on a serial port called the MICROWIRE/PLUSTM Interface.

Because one of the HPC's strong suits is Concurrent Control applications (applications in which several control tasks are executing simultaneously, scheduled by interrupts), the code given in this exercise is written to be completely interrupt-driven as well. Instead of timing events with software loops, interrupts from HPC Timer T5 are used both to signal the end of each MICROWIRE transfer and to time the ERASE and WRITE pulse durations for the EEPROM.

2.0 CONNECTIONS AND COMMANDS

The connection between the HPC and the EEPROM device is a completely traditional MICROWIRE connection, as shown in Figure 1. The SI (Serial Input), SO (Serial Output) and SK (Serial Clock) signals of the HPC connect directly to the DO, DI and SK pins of the EEPROM, respectively. The EEPROM's required Chip Select signal (CS: active high) could come from any port bit of the HPC, but the P1 pin of Port P was chosen because Port P pins present zeroes on reset (instead of floating), and this will automatically deselect the EEPROM.

FIGURE 1. MICROWIRE/PLUS Connections

TL/DD/9978-1

To communicate with the EEPROM, the signal CS (pin P1) is set high, and then each 8-bit serial transfer is triggered by writing a value to the HPC's eight-bit SIO register, which is effectively just a shift register. The data placed into the SIO register is shifted out, most-significant bit first, and eight clock pulses are presented on the SK pin corresponding to each shift. Serial data is simultaneously accepted from the SI pin, and at the end of the eight clock pulses the SIO register has been changed to reflect the value presented by the EEPROM (if any). The timing involved in a single MICROWIRE transfer is shown in Figure 2.

While reading from the EEPROM, the value written to SIO doesn't matter, since it is ignored by the EEPROM. The CS signal must be active throughout a command (which may involve more than one eight-bit transfer), and it must be set inactive between commands for at least one microsecond. Also, the time between an ERASE or WRITE command and the following command (as measured by the amount of time the CS signal remains low between them) determines the length of the corresponding ERASE or WRITE pulse within the EEPROM chip. These pulse widths have strict limits which, if exceeded, can damage some EEPROMs.

EEPROM commands are 8-bit values. However, they must start with an additional "1" bit (the Start bit), and READ commands require a trailing "pad" bit, to provide timing

control for the access. Since HPC MICROWIRE transfers must consist of integral numbers of 8-bit transfers, at least two such transfers must be used per command.

Note that the formats shown below (with 6 address bits) support an EEPROM with up to 1K bits (64 16-bit words). To use a 256-bit EEPROM, one would not specify an address greater than binary 001111, because the two most-significant address bits are ignored by the EEPROM.

2.1 Read Commands

Reading a 16-bit word from the EEPROM is accomplished with a single READ command. For the READ command, the format is:

where the bits marked "A" constitute the address of the EEPROM word to be accessed. These two command transfers are followed by two additional 8-bit transfers, in which the 16 bits of data from the addressed EEPROM word are read by the HPC (most significant bit first).

TL/DD/9978-2

*This bit becomes valid immediately when the transmitting device loads its SIO register. The HPC guarantees it to be valid for at least 1 full SK period before the rising edge of the first SK pulse presented.

† Arrows indicate points at which SI is sampled.

FIGURE 2. MICROWIRE/PLUS Transfer

Master presents eight pulses on SK pin; each pulse transfers one bit in and out.

2.2 Write Commands

To write data into the EEPROM, a sequence of commands is entered:

```

an EWEN command (Erase/Write Enable):
    0 0 0 0 0 0 0 1   0 0 1 1 1 0 0 0 0
an ERASE command:
    0 0 0 0 0 0 0 1   1 1 A A A A A A
    ("A" = Address bits,
     most-significant bit first)
a pause of 16 to 25 milliseconds, with CS
low,
a WRITE command:
    0 0 0 0 0 0 0 1   0 1 A A A A A A
    D D D D D D D D   D D D D D D D D
("A" = Address bits,
 "D" = Data bits,
 most-significant bit first)
a pause of 16 to 25 milliseconds, with CS
low,
and, finally, an EWDS command (Erase/Write
Disable):
    0 0 0 0 0 0 0 1   0 0 0 0 0 0 0 0
  
```

3.0 LISTING AND COMMENTARY

The listing provided shows three necessary segments of a program to access the EEPROM device:

- 1) initialization of the MICROWIRE/PLUS port on the HPC,
- 2) two program fragments of a Main Program which would initiate a Read or a Write operation,
- 3) an interrupt service routine (attached to Timer T5) which actually performs the transfers.

3.1 Initialization

On receiving a Reset signal, the HPC begins execution at the label "start". It loads the PSW register (to select 1 Wait state), and then removes all interrupt enables.

At label "sram", all RAM within the HPC is initialized to zero.

At "suwire", the MICROWIRE/PLUS interface pins are initialized. The MICROWIRE/PLUS interface is then set to the CKI/128 bit rate (125 KHz clocking at 16 MHz crystal frequency). The internal interface is not completely cleared by the Reset signal, so the firmware must set it up and wait (at label "suwlp") for the interface to become ready. Once this has been done, a byte of all zeroes is sent to the EEPROM to terminate any Write operation that might have been in progress when the Reset was received.

At "tminit", the timers T1–T7 are stopped and any interrupts pending from timers T0–T7 are cleared. The individual timer interrupt enables are then cleared.

The program then continues to label "minit", which initializes the variables in the HPC's on-chip RAM to their proper contents.

At label "runsys", the necessary interrupt is enabled (from the timers), and execution continues to the body of the Main Program.

There follow now two fragments of illustrative main program code which can be used to trigger the process of reading and writing the EEPROM.

3.2 Reading

The main program and interrupt routines given here enable reading from one to eight bytes from the EEPROM, starting at the beginning of any word.

At label "rnvr", an EEPROM READ command is constructed from the EEPROM starting address and placed in the variable "nvr cmd". The number of bytes to be transferred is placed in the variable "nvr num". Control is then transferred to the label "nvr x", where Timer T5 is set up to generate scheduling interrupts for reading data from the EEPROM.

The variable "nvr s" indicates the state of an EEPROM access from one interrupt to another: its top bit ("nvravl") shows whether the EEPROM is already being used, bit 6 ("nvrwr") shows whether it is being written or read, and the low-order 4 bits hold a state number, which is used to transfer control to the appropriate code within the Timer T5 interrupt service routine.

On each Timer T5 interrupt (see labels "tmrint", "t5poll", "t5int"), the timer is stopped, a check is made to determine whether the EEPROM is being read or written (T5 interrupts are used for both), and then a multiway branch (jidw) is performed based on the state number in the variable "nvrs". The state number is incremented on each interrupt. On a Read transfer, five states are entered, at the following labels:

- t5rd0 activates the chip select to the EEPROM and initiates the MICROWIRE transfer to send the first byte of a READ command. Timer T5 is started to time out the MICROWIRE transfer.
- t5rd1 sends the second byte of the READ command. Timer T5 is started to time out the MICROWIRE transfer.
- t5rd2 initiates the MICROWIRE transfer to read the first byte of data from the current EEPROM word. Timer T5 is started to time out the MICROWIRE transfer.
- t5rd3 accepts the first byte of the data into the high-order byte of the variable "nword", and initiates the transfer to read the second byte of the current EEPROM word. Timer T5 is started to time out the MICROWIRE transfer.
- t5rd4 accepts the second byte from the EEPROM into the low-order byte of the variable "nword", and then moves the word into the EEPROM string buffer, called "nvrbuf", using a pointer called "nvrptr". It then checks whether the requested number of bytes has been read (by decrementing the "nvrnum" variable). If so, it leaves Timer T5 stopped, disables its interrupt and returns. This would also be the proper place to set a semaphore flag to acknowledge to the main program that the reading is complete. (Code for this is not included here; it would vary from system to system.) If the requested number of bytes has not yet been read, it increments the address field of the READ command in "nvrcmd", resets the state field in "nvrs" to zero, leaves Timer T5 interrupts enabled, and jumps directly to the "t5rd0" routine to continue.

3.3 Writing

At label "wnvr", an EEPROM ERASE command is constructed from the word address supplied by the CPU. The 16-bit value to be written is placed in the variable "nword". As in the READ-NVR command above, the "nvrs" variable is initialized to select the first state of an EEPROM write operation, and Timer T5 is used to provide the interrupts

that schedule the steps. There are 13 states involved in writing a word to the EEPROM, at the following labels:

- t5wr0 activates the chip select signal to the EEPROM, and sends the first byte of an EWEN command to enable ERASE and WRITE commands. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr1 sends the second byte of the EWEN command. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr2 removes the chip select signal briefly (to signal the beginning of a new command), then sends the first byte of an ERASE command. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr3 sends the second byte of the ERASE command, from the variable "nvrcomd". Timer T5 is started to time out the MICROWIRE transfer.
- t5wr4 removes the chip select signal, then sets up the Timer T5 interval to 20 milliseconds, to time the duration of the EEPROM's internal Erase pulse.
- t5wr5 (entered 20 milliseconds after "t5wr4") re-asserts the chip select signal to the EEPROM, and transfers the first byte of a WRITE command. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr6 alters the command in "nvrcmd" to a WRITE command, then transfers it as the second command byte to the EEPROM. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr7 transfers the first byte of data to be written. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr8 transfers the second byte of data to be written. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr9 removes the chip select signal, then sets up the Timer T5 interval to 20 milliseconds, to time the duration of the EEPROM's internal Write pulse.
- t5wr10 (entered 20 milliseconds after "t5wr9") re-asserts the chip select signal to the EEPROM, and transfers the first byte of an EWDS command (Erase/Write Disable). Timer T5 is started to time out the MICROWIRE transfer.
- t5wr11 transfers the second byte of the EWDS command. Timer T5 is started to time out the MICROWIRE transfer.
- t5wr12 removes the chip select signal to the EEPROM, keeps Timer T5 stopped, disables its interrupt, and returns. This would also be the proper place to set a semaphore flag to acknowledge to the main program that the writing is complete. (Code for this is not included here; it would vary from system to system.)

I²C-Bus—Interface with HPC

National Semiconductor
Application Note 561
Hubert Utz

INTRODUCTION

There are many applications in which microcontrollers are used as a central processor. These systems are designed with the following aspects:

- reduce and minimize system costs
- provide system flexibility
- simple connections to other peripheral devices
(no high speed requirements)

A serial bus structure fulfills the above subjects.

The National Semiconductor microcontroller family provides the MICROWIRE/PLUSTM interface as a synchronous serial line to communicate with peripherals.

Another important serial bus is the I²C-Bus (Inter IC-Bus) which was developed by Valvo/Philips. It is mainly used in the customer area. This article describes a simple I²C-Bus interface with National's microcontroller family HPC 16xxx and two different software routines to work the interface:

- a. Softwarepolling
- b. Using the MICROWIRE™ shift register

THE I²C-Bus

The I²C-Bus is a bidirectional two line serial communication bus. The two wires, SDA (serial data) and SCL (serial clock) carry information between the different devices connected to the bus.

The devices can operate either as a receiver or a transmitter, depending on their functions.

The I²C-Bus also supports multimaster mode. Each device has its own 7-bit address.

This address consists commonly of a fixed hardwired part (4 Bits chip intern) and a variable address part (3 Pins of the device).

The I²C-Bus is based on the following definitions:

- TRANSMITTER: the device which sends the data to the serial data line
- RECEIVER: the device which receives the data from the serial data line
- MASTER: the device which starts a transfer, supplies the clock signals and terminates a current transfer cycle
- SLAVE: the device which is addressed by the master
- MULTIMASTER: more than one device can get the master to control the serial data bus and the serial clock bus
- ARBITRATION: if more than one device simultaneously tries to control the bus, a simple arbitration procedure takes place, so that only one device can get the master
- SYNCHRONIZATION: procedure to synchronize the clock signals of two or more devices (slow slaves)

The maximum transmission rate is 100 kbit/s.

The maximum number of devices connected to the bus is limited by the maximum bus capacitance of 400 pF (typical device capacitance 10 pF).

Start-and Stop Conditions

The bus is not busy if both data- and clock lines remain HIGH because there are only two lines available, the start- and stop conditions have special timing definitions between these two lines:

- start conditions: HIGH-to-LOW transition of the data line, while the clock line is in a HIGH state.
- stop conditions: LOW-to-HIGH transition of the data line, while the clock line is in a HIGH state.

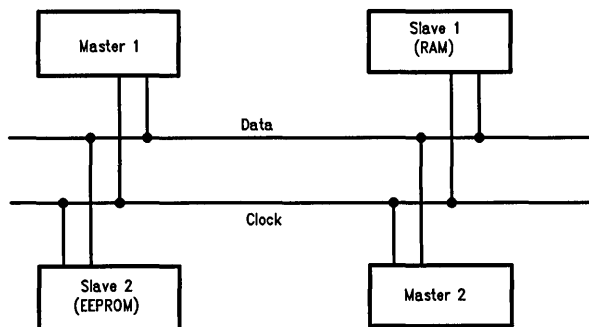

FIGURE 1. I²C-Bus Configurations

TL/DD/10080-1

TL/DD/10080-2

Startcondition

- Clock-, Dataline high (Bus free)
- change Dataline from high to low level
- after $t_{HS} \text{ Min} = 4 \mu\text{s}$ the master supplies the clock

Acknowledge

- transmitting Device releases the Dataline
- the receiving Device pulls the Dataline low during ACK-clock if there is no error
- if there is no ACK the master will generate a Stopcondition to abort the transfer

Stopcondition

- clockline goes high
- after $t_{HP} \text{ Min} = 4.7 \mu\text{s}$ datalines goes high
- the master remains the Data-, Clockline high
- next Startcondition after $t_{FB} \text{ Min} = 4.7 \mu\text{s}$ possible

FIGURE 2. I²C-Bus Timing

The master always generates the start and stop conditions. After the start condition the bus is in the busy state. The bus becomes free after the stop condition.

DATA BIT TRANSFER

After a start condition 'S' one databit is transferred during each clock pulse. The data must be stable during the HIGH-period of the clock. The data line can only change when the clock line is at a LOW level.

Normally each data transfer is done with 8 data bits and 1 acknowledge bit (byte format with acknowledge).

ACKNOWLEDGE

Each data transfer needs to be acknowledged. The master generates the acknowledge clock pulse. The transmitter releases the data line (SDA = HIGH) during the acknowledge clock pulse. If there was no error detected, the receiver will pull down the SDA-line during the HIGH period of the acknowledge clock pulse.

If a slave receiver is not able to acknowledge, the slave will keep the SDA line HIGH and the master can then generate a STOP condition to abort the transfer.

If a master receiver keeps the SDA line HIGH, during the acknowledge clock pulse the master signals the end of data transmission and the slave transmitter release the data line to allow the master to generate a STOP- condition.

ARBITRATION

Only in multi master systems.

If more than one device could be master and more than one wants to access the bus, an arbitration procedure takes place: if a master transmits a HIGH level and another master transmits a LOW level the master with the LOW level will get the bus and the other master will release the bus and the clockline immediately and switches to the slave receiver mode. This arbitration could carry on through many bits (address bits and data bits are used for arbitration).

FORMATS

There are three data transfer formats supported:

- master transmitter writes to slave receiver; no direction change
- master reads immediate after sending the address byte
- combined format with multiple read or write transfers (see ...)

ADDRESSING

The 7-bit address of an I²C device and the direction of the following data is coded in the first byte after the start condition:

TL/DD/10080-3

A "0" on the least significant bit means that the master will write information to the selected Slave address device; a "1" means that the master will read data from the slave.

Some slave addresses are reserved for future use. These are all addresses with the bit combinations 1111XXX and 0000XXX. The address 00000000 is used for a general call address, for example to initialize all I²C devices (refer to I²C bus specification for detailed information).

—Master Transmits to Slave, No Direction Change

TL/DD/10080-4

—Master Reads Slave Immediately after First Byte

TL/DD/10080-5

The master becomes a master receiver after first ACK

—Combined Formats

TL/DD/10080-6

FIGURE 3. I²C-Bus Transfer Formats

TIMING

The master can generate a maximum clock frequency of 100 kHz. The minimum LOW period is defined with 4.17 μ s, the minimum HIGH period width is 4 μ s, the maximum rise

time on SDA and SCL is 1 μ s and the maximum fall time on SDA and SCL is 300 ns.

Figure 4 shows the detailed timing requirements.

Symbol	Parameter	Min	Max	Units
f _{SCL}	SCL Clock Frequency	0	100	kHz
t _{BUF}	Time the Bus Must Be Free before a New Transmission Can Start	4.7		μ s
t _{HD} : STA	Hold Time Start Condition. After This Period the First Clock Pulse Is Generated	4.0		μ s
t _{LOW}	The LOW Period of the Clock	4.7		μ s
t _{SU} : STA	Setup Time for Start Condition (Only Relevant for a Repeated Start Condition)	4.7		μ s
t _{HD} : DAT	Hold Time DATA for CBUS Compatible Masters (See Also NOTE, Section 8.1.3.) for I ² C Device	5 0*		μ s μ s
t _{SU} : DAT	Setup Time Data	250		ns
t _R	Rise Time of Both SDA and SCL Lines		1	μ s
t _F	Fall Time of Both SDA and SCL Lines		300	ns
t _{SU} :STO	Setup Time for Stop Condition	4.7		μ s

All values referred to V_{IH Min} = 3.0V and V_{IL Min} = 1.5V levels at 5V supply voltage

*Note that a transmitter must internally provide at least a hold time to bridge the undefined region (max. 300 ns) of the falling edge of SCL.

FIGURE 4. I²C-Bus Timing Requirements

- Two Wire Serial Bus with
 - *Data line
 - *Clock line
- Features:
 - *Multimaster Bus (Master/Slave)
 - *Busarbitration
 - *Transfer rate up to 100 kbits/s
 - *Bytetransfers
 - *Protocols with
 - Start Condition
 - Address
 - Ackn.
 - Data
 - Ackn. (Each Byte)
 - Stop Condition
- *Read, Write, Multiple R/W

FIGURE 5. I²C-Bus Features

The I²C test hardware uses the following components:

- 2 x PC F 8570: 256 x 8-Bit RAM
 - RAM 1: Address: 1010000X
 - RAM 2: Address: 1010010X
- 2 x PC F 8582: 256 x 8 Bit EEPROM
 - EEPROM 1: Address: 1010001X
 - EEPROM 2: Address: 1010011X
- 2 x PC F 8574: Remote 8-Bit I/O Expander
 - I/O 1: Address: 0100000X Used as 8-Bit LED Output Port
 - I/O 2: Address: 0100001X Used as 8-Bit Input Port
- 1 x HCT04: Inverter
- 1 x LS05: Inverter, Open Collector
- 8 x LEDs: Connected Via Pull Up Resistors to Output Pins of PCF 8574
- 2 x Rp: Pull Up Resistors for Clock Line and Data Line
- 8 Switches: Connected Via Pull Up Resistors to Input Pins of PCF 8574
- 1 x Pin Grid Socket: Socket for MOLE™ Connection
- 1 x Power Connector: 5V Power Supply

Four I/O lines of the HPC are used to connect a HPC-MOLE or a HPC-Designer Kit to the I²C-board: SO, SI, P0, and SK. SO drives the data bus line; SDA and P0 drive the clock bus line SCL.

The data on the SDA line is monitored by the input SI and the I²C-bus clock is available at input SK.

SI, SO and SK are μ Wire interface lines.

P0 is used as a continuous timer output during the transfer. All rise and fall times meet the I²C-bus specification. The highest I²C-clock frequency you can get with a 17 MHz HPC oscillator/4 Waitstates is ca. 20 kHz.

I²C-Bus Software HPC

- *Master only Mode
- *Tested I²C-Clock Frequency 16 kHz–20 kHz
- *3 Possible Formats Supported
 - Read
 - Write
 - Multiple Read or Write
- *Two Program Versions
 - Programmed I/O
 - Interrupt Driven I/O
- *Demo Loop:
 - Write Output
 - RAM test
 - Read Input
 - Increment Output or Set Output = Input
- *IRQ Driven Program Uses μ Wire Shift register
- *Message Field:

Extended Memory Support for HPC

National Semiconductor
Application Note 577
Raja Gopalan

INTRODUCTION

HPC™ family of microcontrollers have maximum addressing capability of 64 kbytes directly by the CPU. If an application requires more than 64k of address space, then the HPC address space can be expanded in terms of banks of memory, using an I/O port to select the memory banks. For example one can use PORTB pins 8, 9, 13 and 14 to select up to 16 banks of memory (which the MOLE development system also supports currently for debugging purposes). Please refer to the application note AN-497 "Expanding the HPC Address Space" by Joe Cocovich for hardware details.

The current version of HPC software package (Compiler, Assembler and Linker) however, does not directly support more than 64k of address space. This is mainly due to the Linker, which currently can handle only 64k of address space.

This report describes a method to handle more than 64k of address space from a software point of view. In order to do this, the user has to do multiple linking of modules in different banks and resolve the inter-bank symbol references.

The rest of the report describes the following:

1. Compiler generated selections (of code and data).
2. Programming conventions for bank switching.
3. Switch function to support bank switching.
4. Linking for bank switching.

SECTIONS GENERATED BY THE COMPILER

The compiler generates sections of relocatable assembly code which can be positioned in absolute address using the Linker in two ways:

1. Using the /SECT directive.
2. Using the /RANGE directive.

The following are the sections generated by the compiler for a source file named "MODULE":

1. MODULE_code,rom8	Code.
2. MODULE_code,rom16	
3. MODULE_ram8_bss,ram8	Data area for uninitialized static variables.
4. MODULE_ram16_bss,ram16	
5. MODULE_ram8_data,ram8	Data area for initialized static variables.
6. MODULE_ram16_data,ram16	
7. MODULE_ram8_strdata,ram 8	Data area for string literals.
8. MODULE_ram16_init,rom8	Initial value for static variables.
9. MODULE_ram8_init,rom8	
10. MODULE_ram8_strinit,rom8	Initial values for string literals.
11. MODULE_base16_bss,base	Base page area for uninitialized static variables.
12. MODULE_base8_bss,base	
13. MODULE_base16_data,base	Base page area for initialized static variables.
14. MODULE_base8_data,base	
15. MODULE_base16_init,rom16	Initial values for Base page initialized variables.
16. MODULE_base8_init,rom8	
17. MODULE_rom16_data,rom16	Area for constant storage type.
18. MODULE_rom8_data,rom8	
19. c_stack,ram16	Stack area in module containing main().
20. _init_info_	for each module which has any static variables defined.

PROGRAMMING CONVENTIONS TO BE USED FOR BANK SWITCHING

As far as the bank switching hardware is concerned, the HPC addressing space is divided into banks of memory. The Fixed Address space is referred to as shared bank and the switchable address space is called as switchable bank. Any mechanism for bank selection can be used, as long as the conventions mentioned below are strictly followed:

1. All static variables must be placed in the shared memory. Basepage must go in basepage (which is shared).
2. If string literals are not in ROM, they must be placed in the shared memory.
3. Initialization values for static variables or string literals in RAM must be in the shared memory. This includes basepage initializers and `__init_info__` sections.
4. If string literals for a bank are in ROM, and are never used as an argument to an inter-bank function call, the literals for that bank can be in the switchable bank.
5. If constants for a bank are never used by passing their address as an argument to an inter-bank function call, the constants for that bank can be in the switchable bank.
6. If the addresses of constants or string literals for a bank are used as arguments to an inter-bank function call, the constants or literals must be in the shared memory.
7. The stack must be in the shared memory.
8. Interrupt vectors must point to routines in the shared memory.
9. Only code and qualified ROM data can be placed in switchable banks.
10. A call to a function placed in the shared memory is always direct.
11. A function call from one switchable bank to another switchable bank must use a switching routine in the shared memory. Such a call cannot pass arguments which are addresses of functions, constants, or string literals in the calling bank. All pointers passed must be to objects in the shared memory.
12. A function which returns a structure cannot be used in an inter-bank function call if the returned structure is in memory in the calling bank. If the returned structure is an argument to another function, has a member of it accessed, or is assigned to a static or local variable, it is legal. If it is placed into switchable memory, by assigning to what is pointed at by a pointer, the operation will fail for an inter-bank function call.
13. The `START` macro in `CRTFIRST` must initialize the bankswitching port as necessary, and select the bank containing `main()` if it is not in the shared memory.

FUNCTION IN ASSEMBLER TO HANDLE SWITCHING OF BANKS

When bank switching must occur, the stack is set up by the compiler generated code for a normal function call. Instead of calling the destination function directly, however, the inter-bank link for the destination is called, as a result of the special manipulations with the linker `LNHPC`. This routine must change banks and then transfer to the destination, and must receive the return from the destination function so as to switch back to the original caller. This must be done transparently—no registers may be modified, and the stack must appear the same.

Included is the code to support the actual switching of banks during inter-bank function calls. This code allows a routine in either the shared memory or one of the switchable banks to make an inter-bank call to a routine in another bank.

The inter-bank link for each destination is created by a macro, invoked for each required linkage. The inter-bank link is simply a subroutine call to a common switching routine, with in-line arguments giving the bank and address of the destination. The common switching routine does the necessary manipulation of the stack to execute the destination and receive the return. The excess information is saved off in a separate software stack; upon return this information is used to restore the situation as if a normal function call had occurred.

Since the inter-bank transfer is completely transparent, it is not limited to handling C function calls. Any subroutine call which does not pass pointers to objects in switchable banks, which does not have in-line arguments, which does not use the Carry bit as either input or return, and which does not use a Return And Skip instruction, can be used with an inter-bank function call. However, the macro generates names using the C convention; an additional form is available for assembly subroutine names.

Also available is a version which allows the bank switching stack to be in 8-bit memory. It differs only in a few places from the 16-bit stack version.

The normal arrangement calls for the common switching routine and all the inter-bank links to be in shared memory. However, order of execution in the bank switching code is such that the inter-bank links for each destination that a bank needs can be in the switchable memory, and only the common routine needs to be in shared memory.

The software stack used by the bank switching is designed to grow downward, in contrast to the hardware stack, which grows upward. This allows the software stack to be placed in the same memory area as the hardware stack, but above it, and the two stacks will share their memory.

LINKAGE PROCEDURE FOR BANK SWITCHING

The actual linking of a multibank program is a series of individual linkages. The result will be a load module representing each bank's code, plus that bank's contribution to the shared memory area. It is essential that command files be used as inputs to `LNHPC` because each module must be linked several times, and changes would be ruinous:

First, each bank's set of modules must be linked independently. The Map files from each bank's linkage will give the necessary information on:

1. Undefined references, both functions and data.
2. A list of library routines invoked to support the code.
3. The size of the `__init_info__` section for the bank.
4. The size of the total code.
5. The entry for the functions defined in that bank.
6. The address of the variables defined in the bank (which is applicable for shared bank only).

This information should be checked and validated. The undefined data references must be only to data which will be in the shared memory. The undefined function references should be for the function calls defined in other banks. The library routines invoked may be reduced by library routines which will be in the shared memory to support code there, or can be placed in shared memory to use the shared ver-

sion for several banks. The size of each bank's `__init_info__` section will be used to make dummy sections for the initial shared memory linkage (see next step below). Finally, the total size of the code, allowing for library routines which will be in the shared memory, must fit in the bank.

Second, an initial linkage of the shared memory is done to determine the addresses of routines and data which will be in there. This requires certain routines to be assembled:

1. The inter-bank switching routine and all the links needed for inter-bank function calls (their bank and address values are left out initially).
2. External references for any additional library routines to be forced into the shared memory.
3. Dummy `__init_info__` sections which are each as large as the corresponding bank's real `__init_info__` section (or one dummy section as large as all the bank's sections combined).

The shared memory is then linked with all of these items included, and the Map file will give valid addresses of data, functions, and sections.

Third, the banks can be linked to produce actual modules. All entry points in the shared memory are now defined, and need to be provided to the linkages of each bank. Assembly files providing the definitions is the simplest way to go. One file can provide the addresses of all user functions, library routines, and data variables in the shared memory, from the Map of the shared memory. Individual files need to be made to provide the addresses of the inter-bank links, because the links for a bank cannot be given to that bank. Additionally, the next available addresses need to be figured for each memory area. This provides linkage and layout by creating the new names and values to resolve the undefined references in the linkage; the linker will do the work of substituting the link address for the undefined function address. Then each bank can be linked, with the addresses for memory areas given to the linker, and the additional files defining shared memory and the other banks inter-bank links being linked in. After each bank, the next available addresses must be updated. Note that the `__init_info__` sections must be contiguous and in the exact space created by the dummy routines.

Finally, the shared memory can be linked to produce the actual module. The banks and addresses must be provided for each inter-bank link and that module reassembled. The external references for additional library routines remains the same, and the dummy section for `__init_info__` are unchanged. The Map of this linkage must be checked against the Map of initial linkage and/or against all addresses fed to the bank switched modules.

EXAMPLE CODE DISTRIBUTION

The example is a skeleton for a realtime program which accumulates time data into tables, then processes those tables by regression fit into a table of coefficients. The system then monitors further events and uses the coefficient to predict behavior as it occurs. The following files are to be in a system with two banks, from 0x4000 to 0x7fff.

TABLES.H	Data structure
MAIN.C	Main program, for shared bank
TABLES.C	Table accumulation and processing
MONITOR.C	Monitor external events and predict
ERRORS.C	Error routines
TIMERS.C	Timer initialization and interrupt service
UART.C	UART processing and interrupt service

CRTFIRST.ASM	Modified to set up Port B for Bankswitching
CRTFIRST.INC	<Standard module, unchanged>
BANKSWIT.ASM	<Standard module, unchanged>
BANKLINK.INC	Modified for inter-bank linkages
BANKDEFS.INC	Macro definitions to simplify linkages

The distribution shown in Table I is intended as an initial starting point. The monitor and prediction code is very large, and fills the bank. The table processing code has room left so the error routines (which are seldom called) are fit in there. This bank has RAM in it, which is not known to the compiler but is managed by the program. Main is in shared memory because it is the major loop of the program. Timers and UART are in shared because they contain the Interrupt Service Routines.

Shared	Bank 0	Bank 1
Main	Tables	Monitor
Timers	Errors	Strings
UART	Strings	Constants
Crtfirst	Constants	
Statics	Table RAM	
Initialization		
Printf		
Stack		
Bank Stack		
Crtinit		

All statics will be in shared memory. Initialization data is in shared memory. The string literals are all in ROM, and will be in banks; since these are passed as arguments to `printf()`, `printf()` must either be in both banks or in shared memory in this case, to avoid duplication of memory usage and to save room in Bank 1. Constants are in banks, since inter-bank calls can be avoided when using constants and string literals. The stack and the bank stack are in the shared memory. The `crtfirst` routine is modified, and `crtinit` is with it in shared memory (although it may be possible to have `crtinit` in the bank selected by the `START` macro, this would require more manual linkage for the call in `crtfirst`).

LINKAGE PROCEDURE

Each bank load module is created by linking the banks separately. The linking is done in two steps. The first step is trial linkage and the parameters are specified in `BANK0_1.CMD`, `BANK1_1.CMD` and `SHARED_1.CMD` for linker. The information from this trial linkage is used in the second attempt where the load module is actually created. The command files used are `BANK0_2.CMD`, `BANK1_2.CMD` and `SHARED_2.CMD`.

Initial linker command files are:

```
SHARED_1.CMD
BANK0_1.CMD
BANK1_1.CMD
```

describing memory as

```
0000-01ff  shared: onchip RAM & I/O
0200-0fff  shared: offchip RAM
1000-3fff  shared: ROM
4000-7fff  banks
           bank 0: 4000-5fff  ROM
           6000-7fff  RAM, private
           bank 1: 4000-7fff  ROM
8000-ffff  shared: ROM
```

where the private RAM is not mentioned to the linker. The private RAM is defined to the compiler using constants; another alternative would have been to define an assembler module of the proper size allocating the space, and place it with the linker. This would require another piece of assembly code, but would limit the address information to the linker command files.

During the trial linkage Bank 0 links but contains `printf()`, which was desired to be in shared memory so it can be passed string literals; `putchar()` will also be there. This leaves only the variable `live`, which is just fine, will be placed in shared bank. The size of `__init_info__` is 0x4136 to 0x4147 or 18 bytes (this information is best taken from the Section Table of the map). The code is not present; it is assumed to fit. For Bank 1, `printf()` will again be defined in shared; `putchar()` will not be referenced. The undefined for `live`, `capture_table()`, and `error()` are correct. The size of `__init_info__` is 0x409A to 0x409F or 6 bytes. The code is assumed to fit.

The initial linkage of the shared memory requires the creation of the linkage files. The linkages have to be put into `BANKLINK.INC` for all inter-bank entry points, including from shared to a bank. The sizes for the `__init_info__` sections and the library access forcing requests are put in a file, using `BANKDEFS.INC` to make things easier. These are linked together, with the C stack and the switch stack in the off-chip RAM, with the switch stack on top so that they can share the same memory. There are few inter-bank calls, so the `SWITCH_STACK_DEPTH` used is 10. Linking this finishes the initial sequence, and the values are now available for the real second attempt of linking whereby the actual modules will be created.

Now the definitions to complete each bank are created. The module `BANKDEFS.INC` makes this easier. Each bank defines the linkages to entry points within that bank. The shared defines publics within the shared memory. (These values are best taken from the Symbol Table portion of the map.) Then the linker command files need to be modified (in the example new file names are used, but the user will probably not use new files, rather simply modify the existing files). The definition files needed for each bank will be added; these are the file for shared memory and for every other bank but this one. The No Output option is changed to giving a name for the object file, if desired, and the Ignore Errors is added because there is still no reset vector for a bank.

Finally, the memory addresses have to be determined from the shared load map and put into the command file (these values are best taken from the Memory Order Map, Memory Type Map, or the Section Table). The positioning of `__init_info__` is critical, the others can have gaps. A trial linkage shows where the linker places modules, and final adjustments are required to ensure such placements meet the requirements. Bank 0 requires only that the initialization data be moved to shared memory. The updated addresses from Bank 0 are used in Bank 1. Bank 1 is placed acceptably by the linker.

The final linkage of the shared memory can now be done. Address and bank information is added to the linkage list. The remaining parts don't change. This linkage must be checked against the first linkage of shared to be certain no addresses have changed. Finally, the addresses used in each bank or shared should be checked against other banks to check for overlaps, and the types of sections in each memory should be checked to make sure all conventions have been met.

If everything is correct, you have load modules for the system.

The code listed in this Application Note is available on Dial-A-Helper.

Dial-A-Helper is a service provided by the Microcontroller Applications Group. The Dial-A-Helper system provides access to an automated information storage and retrieval system that may be accessed over standard dial-up telephone lines 24 hours a day. The system capabilities include a MESSAGE SECTION (electronic mail) for communicating to and from the Microcontroller Applications Group and a FILE SECTION mode that can be used to search out and retrieve application data about NSC Microcontrollers. The minimum system requirement is a dumb terminal, 300 or 1200 baud modem, and a telephone.

With a communications package and a PC, the code detailed in this Application Note can be downloaded from the FILE SECTION to disk for later use. The Dial-A-Helper telephone lines are:

Modem (408) 739-1162
Voice (408) 721-5582

Information obtained from BANK0_1.MAP are:

1) The `_INIT_INFO` section size for Bank0 linkage is 18 bytes, ie from 0x4136 to 0x4147.

2) The entry address for functions obtained here as follows:

Function	Address
<code>initialize_table_memory</code>	0x4000
<code>build_tables</code>	0x404b
<code>capture_table</code>	0x404e
<code>compute_coefficients</code>	0x40ab
<code>error</code>	0x4136
<code>fatal_error</code>	0x4159

These addresses will be used by the `SWITCH_TO_FUNCTION` assembly macro calls in the file `BANKLINK.INC`.

3) The undefined external reference for the variable `live` is expected, which will be defined in the `SHARED` bank. The undefined function `putchar` will also be defined in the shared bank.

The informations derieved from this file are:

1) The `_INIT_INFO` section size for Bank0 linkage is 6 bytes.
ie, from `0x409a` to `0x409f`.

2) The entry address for functions obtained here as follows:

Function	Address
----------	---------

monitor	0x4000
---------	--------

These addresses will be used by the `SWITCH_TO_FUNCTION` assembly macro calls in the file `BANKLINK.INC`.

3) The undefined external reference for the variable `live` is expected, which will be defined in the `SHARED` bank. The undefined function `putchar` will also be defined in the `shared` bank. The undefined external references for functions defined in `Bank0` and `Shared` will be taken care by proper link addresses during second pass of linkage.

TL/DD/10131-12

Contents of the Linker command file SHARED_1.CMD:

```

```

Notice that there is entry for each function that is actually placed in switchable bank being called from other banks. These entries are used as link addresses for the respective functions when linking the banks individually. Refer the files shared.asm, bank0.asm and bank1.asm.

TL/DD/10131-17

Contents of the linker command file BANK0_2.CMD:

```
/Echo
/libfile=\hpc\library
/Format=lm
/Map=bank0_2.map
/Table
/Cr
/Range=BASE=(0x0004:0x00BF)
/Range=RAM16=(0x0B00:0x0FFF,0x01C0:0x01FF,BASE)
/Range=RAMB=RAM16
/Range=ROM16=(0x4000:0x5FFF,0x8740:0xFFAE,0x1000:0x3FFF)
/Range=ROMB=ROM16
tables,
errors,
shared, bank1
/Sect=_init_info_=0x804A:0x8061
/Sect=errors_ram16_init=0x8740
/Output=bank0
/Ignore
```

Notice the ROM address is space defined as 0x4000:0x5fff for the BANK0 space. In shared memory address range 0x8740:0xffae is available, which is obtained from shared_1.map. Also `_init_info_` goes into the range 0x804a:0x8061 which was reserved by the `init_dummy` macro and the address is obtained from shared_1.map. Also the section `errors_ram16_init` goes to address 0x8740 onwards. The link addresses for the functions and variables are specified in shared.asm and bank1.asm.

TL/DD/10131-18

```

Notice that there is no undefined external references errors.

TL/DD/10131-21

Since the function Main is not defined in this bank there is no reset vector address defined and hence the Linker gives the 'no end address specified' error message, which can be ignored.

Contents of the Linker command file BANK1_1.CMD:

```
/Echo
/libfile=\hpc\library
/Format=lm
/Map=bank1_2.map
/Table
/Cr
/Range=BASE=(0x0004:0x00BF)
/Range=RAM16=(0x0C00:0x0FFF,0x01C0:0x01FF,BASE)
/Range=RAM8=RAM16
/Range=ROM16=(0x4000:0x7FFF,0x8742:0xFFAE,0x1000:0x3FFF)
/Range=ROM8=ROM16
monitor,
shared, bank0
/Sect=_init_info_=0x805C:0x8061
/Output=bank1
/Ignore
```

Notice the `_init_info_` section is placed in address space 0x805c to 0x8061. This is basically the rest of the space after `Bank0_init_info_usage`. Also the Link addresses for BANK0 and SHARED are appropriately mentioned in the assembly files `bank0.asm` and `shared.asm` and they are also linked. The shared address (ROM16 and RAM16) space is properly updated with the information from `bank0_1.map`.

; This routine provides the standard C RunTime Routine for starting a
; compiled and linked program. It initializes the stack pointer and
; RAM memories, and enters the compiler generated code in function
; "main()" with no arguments.
;
; Four macros are used to allow the end user to have control of the start
; process at key moments, before the C code begins execution. The macros
; used are ORIGIN, START, READY, and HALT, in the following fashion:
;
; ORIGIN
; PROGRAM_start:
;   |d sp,<stack>
;   START
;   jsrl initialize_memories
;   READY
;   jsrl _main
; PROGRAM_exit:
;   HALT
;
; Code size is tested to ensure that the code does not overwrite any
; dedicated addresses (e.g., subroutine jump table), and optionally to

```

TL/DD/10131-32

```

;ensure that no space is wasted between the end and the dedicated area.
;The dedicated address is defined as ADDRESS_limit, and the check for
;waste space is controlled by ORIGIN_check being non-zero. Either of
;these may be redefined by the user in the ORIGIN macro.

```

```

;ORIGIN macro
;Must declare the section and set the absolute origin for the startup
;code. Code must end before any dedicated addresses (ADDRESS_limit),
;and should not waste any space. If any of the other macros here are
;lenghened, this must be adjusted. Might optionally redefine values
;of ADDRESS_limit or ORIGIN_check.
;

```

```

;START macro
;Code to execute after the stack pointer is initialized, and before the
;memories are initialized. Must enable the appropriate configuration
;options for the chip, so that memories can be accessed. Since all
;memories can be accessed, the list of RAM memories can be accessed
;where ever it may be.
;

```

```

;READY macro
;Code to execute after memory is initialized, but before the C code is
;entered.
;

```

```

;HALT macro
;Code to execute when the C code terminates.
;

```

```

;Limit address of code for this routine (first dedicated address)

```

```

;Whether to check that the origin provided is exactly correct

High Performance Controller in Information Control Applications

National Semiconductor
Application Note 585
Steve McRobert

ABSTRACT

This paper describes National Semiconductor's HPC™ family of High Performance microControllers. Included are two examples showing how the devices are used in actual Information Control applications.

The architecture, technology, and instruction set of the HPC family are presented, with emphasis on how these features are appropriate for use in microcontroller based information control systems. Two example applications are given, the first being the use of a single chip mode HPC as an I/O processor and interrupt handler in a laser beam printer. In this case the HPC acts as a slave to the main 32-bit CPU in the printer, freeing it from the many tasks which require fast interrupt response and thus improves system throughput. The second example shows the HPC used in expanded mode as the sole microprocessor in an ESDI to SCSI bridge adapter card. The operations performed by the HPC in this application are used as an example of how the instruction set and addressing modes work together to achieve high throughput. The paper concludes with a brief discussion of the future of the HPC family of devices.

INTRODUCTION

The HPC (High Performance Controller) family of microcontrollers was designed by National Semiconductor as the first of a new generation of 16-bit CMOS microcontrollers.

The intention was to start afresh, using the experience gained from earlier device families and, without software

compatibility constraints, to create an architecture sufficiently advanced to be competitive for 10 years or more. Other design goals were to minimize device complexity, thus allowing for dependable, economical, high volume production, and to make HPC easy to understand so that system designers could readily convert designs to use the new family's advanced features.

These goals have been met, and, since the first device was sampled in early 1986, the HPC family has developed into a well proven solution to many design problems.

ARCHITECTURE

The HPC family is based on a core concept. All devices share a common core including the CPU and a base set of peripherals such as timer/counters etc. *Figure 1* shows a block diagram of the HPC16083 with the core emphasized at left. HPC uses a memory-mapped Von Neuman architecture, in which all registers, I/O ports, peripherals etc. are assigned memory locations in one uniform address space.

This includes the CPU registers (*Figure 1*), allowing all HPC instructions to operate on every register in the programmer's model. Such uniformity simplifies the work of the assembly language programmer and the writer of the C compiler, making the HPC a particularly efficient microcontroller for running programs written in "C".

FIGURE 1. HPC16083 Block Diagram

TL/DD/10346-1

The core is connected to peripherals and on-chip memory by a 16-bit address/data bus, which is multiplexed to reduce die size. This bus is brought out on the A port when the device is used in expanded and/or ROMless modes, allowing off-chip devices to be accessed in exactly the same fashion as on-chip memory or peripherals.

When writing assembly language or C instructions the programmer perceives no difference between on-chip and off-chip memories, but both assembler and compiler take account of two key differences. When the HPC is run at high oscillator frequencies (up to 30 MHz on current production devices) a wait state must be applied for accesses to external memories or peripherals, but are never applied to on-chip RAM or registers. The other difference is that accesses to on-chip locations with addresses below 100 hexadecimal (called basepage accesses) require only a one byte address, so are thus shorter and faster than accesses to non-basepage locations (Figure 2).

FFF:FFF0	INTERRUPT VECTORS	HPC16083 ON-CHIP ROM SPACE
FFEF:FFD0	JSRP VECTORS	
FFCF:E000	GENERAL PURPOSE ROM	
DFFF:0200	EXPANDED MODE ADDRESS SPACE	EXTERNAL USER MEMORY
01FF:01C0	ON-CHIP RAM	ON-CHIP RAM AND REGISTERS
01BF:00C0	ON-CHIP REGISTERS	
00BF:0000	ON-CHIP RAM	

FIGURE 2

The programmer must choose which variables to put into on chip RAM or the basepage to achieve maximum performance and code efficiency.

Basepage RAM, because it is very fast and efficient to use, provides many of the benefits of the register file architecture used on some other microcontrollers. The HPC is different, however, in that it has a small set of registers: Accumulator, B pointer, X pointer and K (or limit) register. These registers all have addresses and can be used as general purpose memory locations, but are best used for their special func-

tions. Many HPC instructions have two operands, the source and the destination. If the Accumulator (A) register is used as the destination, this is implied in the opcode and the address of A need not be included in the instruction, thus making it shorter and faster than instructions using another memory location as the destination. If the address of the source is contained in the B register then this too can be implied from the opcode and the whole instruction becomes one byte long.

Most HPC instructions thus have a single-byte form, using the B or X register as a pointer to the memory location being accessed.

The use of the K register will be discussed in the next section.

The primary objective when designing the architecture and instruction set of HPC was to minimize code size, an approach which can reduce throughput if unlimited bus bandwidth is available. In typical microcontroller applications the use of external memory is undesirable for board space and cost reasons. If the code is too large for mask ROM, the best solution in terms of space and cost is a single, relatively slow, EPROM.

In this situation of low bus bandwidth, the high byte efficiency of the HPC goes hand-in-hand with good performance.

ADDRESSING MODES

In keeping up with the HPC philosophy of being simple and quick to understand, the HPC instruction set (Figure 3) has relatively few mnemonics. This is because for those instructions with one or two addressable operands the same mnemonic is used regardless of the addressing mode, operand size (byte or word) or address size (depending upon whether each operand is in the basepage or not). Each individual memory location may be addressed using one of the following addressing modes:

Direct: The 8- or 16-bit address is included in the series of bytes that make up the instruction.

Indirect: The 8-bit address of a word in the base page is included in the instruction. The contents of this word are used as a pointer to the variable to be accessed.

Mnemonic	Description	Action
ARITHMETIC INSTRUCTIONS		
ADD	Add	MA + Mem1 → MA carry → C
ADC	Add with carry	MA + Mem1 + C → MA carry → C
ADDS	Add short imm8	MA + imm8 → MA carry → C
DADC	Decimal add with carry	MA + Mem1 + C → MA (Decimal) carry → C
SUBC	Subtract with carry	MA - Mem1 + C → MA carry → C
DSUBC	Decimal subtract w/carry	MA - Mem1 + C → MA (Decimal) carry → C
MULT	Multiply (unsigned)	MA * Mem1 → MA & X, 0 → K, 0 → C
DIV	Divide (unsigned)	MA / Mem1 → MA, rem. → X, 0 → K, 0 → C
DIVD	Divide Double Word (unsigned)	(X & MA) / Mem1 → MA, rem → X, 0 → K, carry → C
IFEQ	If equal	Compare MA & Mem1, Do next if equal
IFGT	If greater than	Compare MA & Mem1, Do next if MA > Mem1
AND	Logical and	MA and Mem1 → MA
OR	Logical or	MA or Mem1 → MA
XOR	Logical exclusive-or	MA xor Mem1 → MA
MEMORY MODIFY INSTRUCTIONS		
INC	Increment	Mem + 1 → Mem
DECSZ	Decrement, skip if 0	Mem - 1 → Mem, Skip next if Mem = 0

FIGURE 3. HPC Instruction Set Description

Mnemonic	Description	Action
BIT INSTRUCTIONS		
SBIT	Set bit	1 → Mem.bit
RBIT	Reset bit	0 → Mem.bit
IFBIT	If bit	If Mem.bit is true, do next instr.
MEMORY TRANSFER INSTRUCTIONS		
LD	Load	MemI → MA
ST	Load, incr/decr X	Mem(X) → A, X ± 1 (or 2) → X
X	Store to Memory	A → Mem
	Exchange	A ↔ Mem
	Exchange, incr/decr X	A ↔ Mem(X), X ± 1 (or 2) → X
PUSH	Push Memory to Stack	W → W(SP), SP + 2 → SP
POP	Pop Stack to Memory	SP - 2 → SP, W(SP) → W
LDS	Load A, incr/decr B, Skip on condition	Mem(B) → A, B ± 1 (or 2) → B, Skip next if B greater/less than K
XS	Exchange, incr/decr B, Skip on condition	Mem(B) ↔ A, B ± 1 (or 2) → B, Skip next if B greater/less than K
REGISTER LOAD IMMEDIATE INSTRUCTIONS		
LD B	Load B immediate	imm → B
LD K	Load K immediate	imm → K
LD X	Load X immediate	imm → X
LD BK	Load B and K immediate	imm → B, imm → K
ACCUMULATOR AND C INSTRUCTIONS		
CLR A	Clear A	0 → A
INC A	Increment A	A + 1 → A
DEC A	Decrement A	A - 1 → A
COMP A	Complement A	1's complement of A → A
SWAP A	Swap nibbles of A	A15:12 ← A11:8 ← A7:4 ↔ A3:0
RRC A	Rotate A right thru C	C → A15 → ... → A0 → C
RLC A	Rotate A left thru C	C ← A15 ← ... ← A0 ← C
SHR A	Shift A right	0 → A15 → ... → A0 → C
SHL A	Shift A left	C ← A15 ← ... ← A0 ← 0
SC	Set C	1 → C
RC	Reset C	0 → C
IFC	IF C	Do next if C = 1
IFNC	IF not C	Do next if C = 0
TRANSFER OF CONTROL INSTRUCTIONS		
JSRP	Jump subroutine from table	PC → [SP], SP + 2 → SP W(table #) → PC
JSR	Jump subroutine relative	PC → [SP], SP + 2 → SP, PC + # → PC (# is + 1025 to - 1023)
JSRL	Jump subroutine long	PC → [SP], SP + 2 → SP, PC + # → PC
JP	Jump relative short	PC + # → PC (# is + 32 to - 31)
JMP	Jump relative	PC + # → PC (# is + 257 to - 255)
JMPL	Jump relative long	PC + # → PC
JID	Jump indirect at PC + A	PC + A + 1 → PC then Mem(PC) + PC → PC
JIDW		
NOP	No Operation	PC + 1 → PC
RET	Return	SP - 2 → SP, [SP] → PC
RETSK	Return then skip next	SP - 2 → SP, [SP] → PC, & skip
RETI	Return from interrupt	SP - 2 → SP, [SP] → PC, interrupt re-enabled
<p>Note: W is 16-bit word of memory MA is Accumulator A or direct memory (8 or 16-bit) Mem is 8-bit byte or 16-bit word of memory MemI is 8- or 16-bit memory or 8 or 16-bit immediate data imm is 8-bit or 16-bit immediate data imm8 is 8-bit immediate data only</p>

FIGURE 4. Word Block Move

- Indexed:** As indirect, but with an 8- or 16-bit immediate offset added to the pointer.
- Register Indirect:** As indirect, but the B or X registers are used as pointers, with their addresses implied in the opcode.
- Immediate:** Only for the source in two-operand instructions. An 8- or 16-bit immediate value is included in the instruction.

The first four addressing modes are used both for single operand instructions e.g. bit set, bit clear, bit test, increment, decrement, and two operand instructions such as ADD and LD.

Direct and immediate modes can be used in combination, allowing operations to be performed directly on memory or registers without using the accumulator.

Two variables, each byte or word, each located anywhere in memory, can be compared, added, divided or have any of the other two-address instructions performed on them. This improves the byte-efficiency of the HPC, and enhances the power of the instruction set in that it takes less lines of assembly code to perform a given function than it would for earlier, completely accumulator-based CPUs.

An important benefit provided by the indirect and indexed modes is that any of the 96 words of RAM or the basepage registers, such as port A or the accumulator, may be used as pointers.

There are two special addressing modes which are used only with the LD and X (exchange) instructions. These modes are called auto increment/decrement and auto increment/decrement with conditional skip, and their use is illustrated by the example shown in *Figure 4*.

This example uses the B pointer, the X pointer and the K register to move a block of data one word at a time. Some points to note are that the LD BK instruction initializes both registers with one instruction, and that both the LD and XS instructions increment the pointer by two because two bytes (one word) are moved. The S in XS signifies the conditional

skip. After A has been exchanged with the word pointed to by B, B is incremented, then compared with K. If B is greater than K (or, for an XS A, [B-] instruction, if B is less than K) the next statement is skipped over, thus terminating the loop. This example epitomizes the approach taken in designing the HPC family.

String operations are built up from simple data movement instructions, allowing them to be interrupted at any time with no need for complex re-start or recovery schemes.

INSTRUCTION SET

The HPC instruction set is noticeably different from other 16-bit controllers, in that many of its instructions are single byte. How this is achieved can be seen by looking at the opcode map (*Figure 5*).

Instructions such as bit manipulation operations and single byte jumps (JP) use many opcodes for the same mnemonic. This is because information, such as the jump length for JP, is coded into the opcode.

This makes these instructions very efficient, and enhances the performance of the HPC in information control applications, where decision making and bit manipulation operations tend to be important.

All of the arithmetic, comparison, logical and data movement instructions have a single byte form using register indirect addressing mode. The opcode space "used up" by having many opcodes for a few instructions is restored by using addressing mode prefixes for the less commonly used addressing modes. These make instructions using these modes one byte longer, but the use of these prefixes allows all of the two address instructions to use all of the addressing modes. Without the prefixes the HPC would run out of opcode space and restrictions would have to be placed on some instructions, making the assembly language much harder to use and the C compiler harder to write. Examples are given in *Figure 6* of several combinations of instructions and addressing modes, with execution times for systems using low cost external memories.

There are many more powerful features of the HPC instruction set, but space does not permit describing them here. For more information see the documents listed in the references section.

TECHNOLOGY

The HPC family and nearly all other new National Semiconductor analog and digital VLSI devices are fabricated in an advanced double metal process called M2CMOS. This is a very high speed process, as shown by the current production two micron (drawn) HPC46083, which is available as a 30 MHz version.

The HPC family has been migrated to a 1.5 micron (drawn) process for the first part with an analog to digital converter on chip, the HPC46164.

National Semiconductor already manufactures the NS32532 microprocessor in 1.25 micron M2CMOS, and will shrink this process still further in the future. The HPC devices will be migrated to these smaller geometries and will benefit from other process developments such as on chip EPROM.

INFORMATION CONTROL APPLICATIONS

Laser Beam Printer Front End Processor

This section describes a customer's application for an HPC46083 used in single chip mode. It makes use of the Universal Peripheral interface (UPI) port which is a feature of all HPC devices with on-chip mask ROM.

FIGURE 7

TL/DD/10346-2

The UPI port allows an HPC device to be used as a peripheral to a host processor, connected to the host via its data bus. The HPC in UPI mode appears to the host to be a peripheral device such as a UART, but provides additional processing power, relieving the host of interrupt-intensive tasks and thus improving the host's performance.

The UPI port of the HPC provides status signals to both the HPC CPU and that of the host which ensure that no data is lost when the CPUs communicate.

In the laser beam pointer (LBP) application (Figure 7), the HPC handles the serial and Centronics interfaces of the printer, buffering received characters and interrupting the host CPU when a block of up to 128 characters has been received. When the host CPU (a National Semiconductor NS32CG16 printer/display controller) is interrupted it then transfers the whole block of data into its own memory very rapidly.

This approach reduces the number of interrupts received by the 32CG16 by a factor of over 100 compared to a solution using a conventional UART while being simpler, cheaper and offering higher system performance than using a DMA approach. These overhead reductions are very important in LBP systems, because the main CPU must keep up with the paper movement, otherwise image data will be lost.

In addition to improving printer performance, the HPC reduces the system cost by providing functions that would otherwise need extra devices. The HPC acts as the interrupt controller for the 32CG16, generating an interrupt signal to it and then placing the interrupt vector on the UPI port when the 32CG16 acknowledges the interrupt. Another function provided by the HPC is an intelligent interface to the printer front panel displays and push buttons controlling such functions as LCD contrast. Finally, the HPC implements a serial interface to the electronic subsystem of the printer engine itself, providing diagnostic capability to the 32CG16. For all of these functions, the HPC performs first-level error checking, further relieving the main CPU of minor tasks.

The LBP is at one extreme of the range of HPC applications, where the HPC uses virtually nothing but its on-chip peripherals and memories.

The next section deals with an application towards the other end of the range.

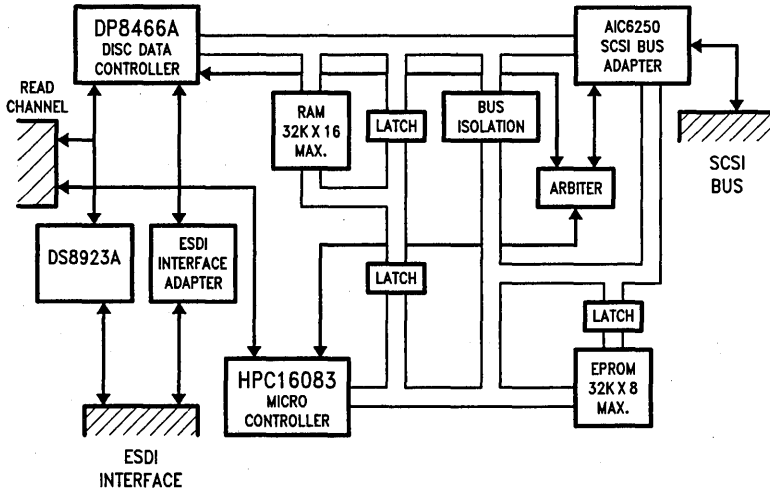

FIGURE 8

TL/DD/10346-3

SCSI Bridge Adapter

The fast growing usage of Winchester disk drives in the Small Computer System Interface (SCSI) environment has provided another important market for the HPC family.

The HPC architecture is well suited for use in embedded SCSI systems, as the peripherals such as the SCSI interface device may be memory mapped into the HPC address space, allowing bit and byte manipulation operations to be performed directly on the registers of the peripheral using single assembly language instructions. Many SCSI interface devices are relatively unintelligent, requiring the CPU to perform many bit test, set, and clear operations to set up a data transfer operation. Most other microcontrollers need up to three instructions to set a bit in one of these peripherals, thus reducing drive performance.

National Semiconductor has produced an ESDI-to-SCSI bridge adapter board, which demonstrates the use of the HPC46003 and the DP8466A disk data controller in a real synchronous SCSI system. A software package has been written in HPC assembly language which implements the SCSI common command set and is available in source code form to companies wishing to use the HPC in embedded SCSI or host adapter designs.

The code was written in HPC assembly language because for very high volume, cost sensitive designs, like a disk drive, the extra development cost of writing in assembler is outweighed by the advantages of reduced code size and improved performance.

The adapter board design (Figure 8) uses the HPC46003 running in 8-bit mode with a single EPROM providing program memory. Data memory is provided by the 256 bytes of on-chip RAM which provides fast scratch pad and stack space.

One important function in embedded SCSI disk drives is logical to physical address conversion, in which a logical address (typically 24 bits) is divided twice by constants, the result and the two remainders being the head, cylinder and sector numbers.

The HPC is capable of dividing a 32-bit number in under four microseconds, thus providing a dramatic improvement in logical to physical address conversion time compared to earlier 8-bit microcontroller solutions. As a final point in this necessarily brief discussion, the HPC uses very little power due to its advanced CMOS manufacturing technology. This is important in disk drive applications, where low power consumption is an important performance parameter for the end product.

CONCLUSION AND FUTURE DEVELOPMENTS

This paper has discussed the design of the HPC family and described two actual applications in important market areas. The development work performed for these and other projects has shown that the HPC architecture provides very high performance in embedded control applications.

The plans for future products are to take the high performance core and add various combinations of peripherals, thus allowing the family to reach a wide range of markets. *Figure 9* shows some of the current and future devices.

Pulse Width Modulation Using HPC

As the use of MicroControllers in embedded control applications grows in popularity, we find more use of width modulated pulse trains. Typical applications that use Pulse Width Modulation are automotive engine control, motor speed control, display intensity control, and sound generation.

PWM DEFINITION

Pulse width modulation is simply a method of communicating information to a device. It can be viewed as an analog signal provided in digital form. *Figure 1* shows a typical timing diagram of a PWM signal. The duty cycle is expressed as the duration of T_{on} over the sum of T_{on} and T_{off} . A signal has a constant duty cycle if T_{on} and T_{off} are uniform. If T_{on} is equal to T_{off} , the signal has a 50% duty cycle.

$$\text{Duty Cycle} = \frac{T_{on}}{T_{on} + T_{off}}$$

TL/DD/10347-1

FIGURE 1. A Typical PWM Signal

TYPICAL APPLICATIONS THAT REQUIRE PWM

One element of an automotive engine control system is the spark ignition. In a distributorless ignition system, spark control signals are required to appear in sequence, with a time delay between each of them. Typical signals for a four spark plug system are shown in *Figure 2*. The generation of these signals will be explained further in the timer synchronous output section.

TL/DD/10347-2

FIGURE 2. HPC Based Spark Ignition Control

Another element of an automotive system is the carburetion and idle speed control. When no pressure is applied to the

National Semiconductor
Application Note 586
Alvin Chan, Bill Miller,
Bob Moeckel, Bob Hanrahan

accelerator pedal, the throttle is completely shut off. The idle speed control utilizes a stepping motor to operate an auxiliary fuel valve. *Figure 3* shows the control signals that have to be generated for a four phase stepper motor. Each of the PWM signals should have a phase lag of one quarter of a cycle from the previous one.

PWM is applied to motor speed control. The speed of a dc motor is directly proportional to the voltage applied.

TL/DD/10347-3

FIGURE 3. Stepper Motor Control Signals

PWM is used selectively to switch full supply power on and off to the motor at some frequency and duty cycle. The bigger the duty cycle, the more power is supplied to the motor. Hence the speed is higher. Motor speed can be controlled by adjusting the ON time of the signal. *Figure 4* depicts the relationship of motor speed and the applied signal.

TL/DD/10347-4

FIGURE 4. Using PWM to Control Motor Speed

The same manipulation also applies to controlling the intensity of light emitting diodes. The brightness of the LED can be varied by using different duty cycles.

Sound synthesis can be achieved by uniting the process of sinusoidal signal generation and envelope generation.

A sinusoidal signal can be generated by a variety of methods. A common technique is to use Walsh functions. Walsh functions are the digital equivalent of Fourier Series. They are essentially pulse signals with varying duty cycles. The individual Walsh components are generated by the microcontroller and combined with the proper weighting factors to form the sinusoids.

Envelope generation can be done by using PWM to build a D/A converter. The envelope will give the composite sinusoidal signal the characteristic sharp attack followed by slow decay. The amplitude of the envelope function is altered by changing the duty cycle of the PWM input to the D/A converter. This function is performed by another timer.

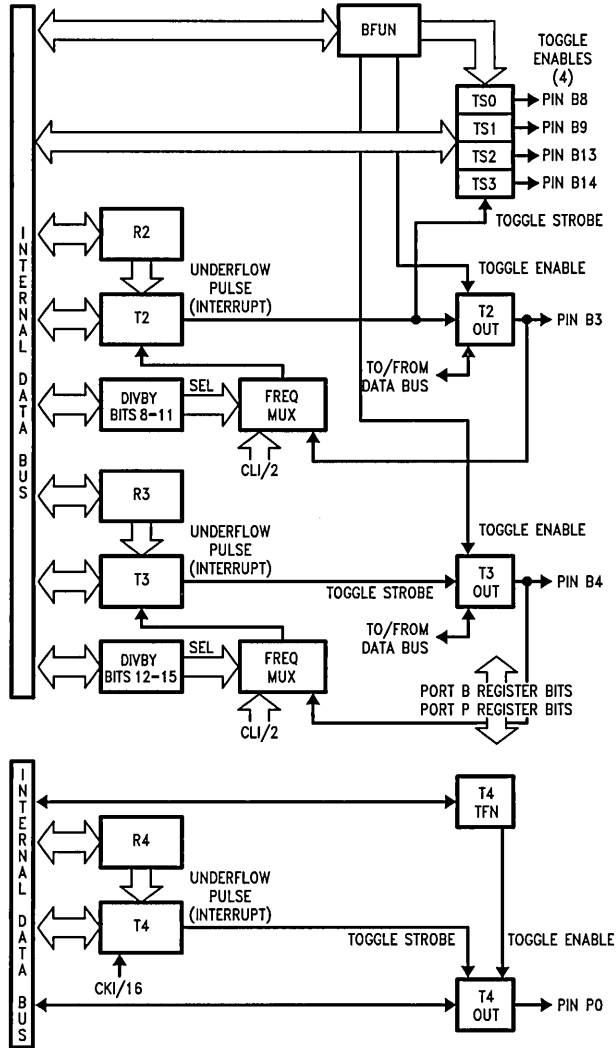

HPC Implementation

National Semiconductor's HPC, High Performance Micro-Controller, provides a simple method for generating width modulated pulse trains, with little or no software overhead, by use of the device's 9 on-chip timers, T0 through T8.

SETTING UP HPC TO DO PWM

PWM Outputs in the HPC

Timers T1 through T7 are down-counters with associated input registers R1 through R7. The value in the registers is loaded automatically into the timers when the timers underflow. Timers T2 through T7 have individual output signals which toggle when the timers underflow. Interrupts are generated at the time of underflow *Figure 5* shows the structure of these timers.

Note: Only Time 4 is Shown. T5, T6, and T7 are identical.

FIGURE 5. HPC Timers T2-T7

TL/DD/10347-5

Timers T2 through T7 can be separated into 2 groups. Different procedures and registers are used to set up the two groups of timers. In one group is timers T4 through T7, which are dedicated to PWM applications. They count down at a constant rate of $\frac{1}{16}$ of the input clock (CKI/16) while enabled to do so. In the other group are the more versatile timers, T2 and T3. The clock input to timers T2 and T3 may be independently selected as coming from one of 14 available prescaled versions of the CKI clock, or from an external pin, as specified in the DIVBY register. Timer T2 can also be specified to be clocked on underflows from timer T3 by appropriate selection in the DIVBY register; the pair then form, in effect, a single 32-bit counter.

With timers T4 through T7, the maximum PWM frequency that can be achieved is half of CKI/16. The associated register provides a 16-bit resolution for the duration of the pulse width.

To use T2 and T3 as PWM timers, the clock must come from an internal source. By configuring the DIVBY register and selecting a value for the counter, the maximum frequency that can be achieved is half CKI/16 and the minimum frequency is half (CKI/131072)/65536.

50% Duty Cycle PWM

On underflow of the timers T2 through T7, the value in the corresponding input register is automatically reloaded into the counters. Therefore a 50% duty cycle PWM can be generated without software intervention once the timer is set up.

Listings 1 and 2 illustrate the use of T4 and T2 in generating PWM outputs. The PWM frequency to be generated is 20 kHz. By using a 16 MHz crystal and CKI/16 as the input clock, the counter value to be loaded into the registers is 24 so that an underflow occurs and the output toggles every 25 μ s.

Non 50% Duty Cycle PWM (Software/Interrupts)

Timers T1 through T7 will generate an interrupt on underflow. For non-50% duty cycle PWM, software has to be involved in controlling the duty cycle. The same software for the 50% duty cycle is used to set up the timers for counting down. On interrupt from the timers, the interrupt service routine loads the other half of the cycle time into the timer register.

On each interrupt from the timer the user software alternately loads T_{on} and T_{off} into the register. The result is a constant duty cycle output. Examples of programming the interrupts are shown in listings 3 and 4.

TIMER SYNCHRONOUS OUTPUTS OF TIMER T2

Timer T2 has in addition to the normal output pin, four output pins which can be independently selected. These pins are referred to collectively as the "Timer Synchronous" outputs. *Figure 2* shows the synchronous output being applied

to engine control in spark ignition. The signals TS0 to TS3 are synchronous outputs derived from timer T2. By enabling each pin in sequence, the spark control signals SP1 to SP4 can be generated.

SOFTWARE INTERVENTION

Another problem facing the designer of a MicroController based system is that software overhead must be kept to a minimum. Interrupt latency and changing input registers can use a significant portion of the time which would otherwise be available for processing of sensor data.

The conventional way of generating non-50% duty cycle was discussed earlier. That involves software changing the value of the auto-reload register every time the timer counts down and interrupts. Two timers can be used to generate two synchronized and offset 50% duty cycle pulses. By EXCLUSIVE-ORing them, a non-50% duty cycle PWM is generated.

Figure 6 shows the result of EXCLUSIVE-ORing the two timers. The duty cycle depends only on the phase shift between the timer outputs. In can be seen that the resulting frequency is actually twice the frequency of the original timers. Therefore, in order to generate a 20 kHz result, two 10 kHz timers must be used. The code is shown in listing 5. By varying the initial delay in the second timer, different duty cycles can be chosen. In the example given, a one digit difference in the counter value results in a 2% difference in the duty cycle.

CONCLUSION

PWM is easily generated by the HPC 16083 with its abundant source of timers. With a 30 MHz crystal, the maximum PWM frequency that can be achieved is 937.5 kHz. The timers run by themselves once the proper setup is performed. A method of obtaining non-50% duty cycle PWM without software intervention was presented.

C in Embedded Systems and the Microcontroller World

National Semiconductor
Application Note 587
David LaVerne

ABSTRACT

C is becoming the higher-level language of choice for microcontroller programming. Traditional usage of C depends on assembly language for the intimate interface to the hardware. A few extensions to ANSI C allow embedded systems to connect directly and simply, using a single language and avoiding detailed knowledge of the compiler and hardware connections.

HIGHER-LEVEL LANGUAGE USAGE

The desires leading to the greater use of higher-level languages in microcontrollers include increased programmer productivity, more reliable programs, and portability across hardware. Few such languages have served well when required to manipulate hardware intimately because most have been for mathematical computation. The C language has always been close to machine level. Indeed Kernighan and Ritchie^[1] refer to it as not really a higher-level language; one view of C is as a higher-level syntax expressing PDP-11 assembly language.

C has gained a great deal of its reputation and popularity associated with its use for operating systems, specifically UNIX[®][2] and similar systems. Many languages will do well enough for the application and utility programs of such a system, but being appropriate for the kernel indicates C can probably do the job of hardware control in an effective manner.

The needs of an embedded system, however, are not identical to the environment from which C has come. This warrants looking at C as it is and comparing it to the needs of C for the microcontroller world.

Operating Systems vs Embedded Systems

In most non-embedded programs, it is the processing which is important, and the Input/Output is only to get the data and report the results. In embedded or realtime applications, it is the Input/Output which is vital, and the processing serves only to connect inputs with outputs.

Operating systems are actually not as closely tied to the hardware as they might appear initially, and those portions which are close are not very portable. Operating systems manipulate hardware registers primarily for memory management (to map tasks), task process switching (to activate tasks), interrupt response (to field requests), and device drivers (to service requests). Because memory management hardware is so different between systems; because task process changing is so contingent on processor operations and compiler implementations; because interrupt system behavior is so varied; and because device control is so dependent on architecture and buses, these particular aspects of the operating system are not concerned with portability. As a result, they are generally kept separate, use a less convenient form of C depending on constants, and frequently are implemented in assembly language. This is not a major problem, since they comprise only a small portion of the total system, and have to change anyway each time the system is ported.

Embedded systems, by their very nature, are closely tied to the hardware throughout the system. The system consists of manipulating the hardware registers, with varying amounts of calculation and data transformations interspersed with the manipulations. As the system gets larger, the calculations may get more complex and may become a larger share of the program, but it is still the hardware operations which are the purpose of the system. Because the system in which these hardware pieces reside consists mostly of these hardware pieces, it is reasonable to hope for portability across processors or controllers for an application or product. Attempting to isolate all of the hardware operations is often impractical; using inconvenient forms of C is troublesome throughout the system and throughout its life-cycle; and implementing them in assembly language defeats the advantages of higher-level language usage and eliminates portability for those (and related) portions. For embedded systems, conveniently accessing hardware registers while doing calculations is essential.

Computer Systems vs Embedded Systems

Computational systems generally can be down the cable, and thus down the hall, from where they are used and can be whatever size is necessary to get the performance; production quantities are measured in hundreds and thousands, so price is a price/performance issue. Embedded systems end up tucked away in some of the strangest and tiniest places, so size can be a success or failure issue; quantities are often tens of thousands to millions of units, so additional chips or costs are multiplied ferociously and become a bottom-line issue.

The computer systems for which C was originally developed were relatively small and not especially sophisticated. However, as systems have grown, C and its implementation has grown right along with them. Most computer systems for which C is used now involve high-speed processors with large memory caches to huge memory spaces, backed by virtual memory. Many have large register sets. Such linear memory with heuristic accelerators allow for very large programs and fast execution. A major effort in optimization is in the allocation and usage of the registers, which tend to be general purpose and orthogonally accessible. Such systems, processor chips, and compilers compete almost exclusively in the field of speed.

Embedded systems, and most especially microcontrollers, have a different nature. While some applications may add external devices and memories to the controller, many are meant to be fully self-contained on one chip or have at most a few I/O chips. Microcontroller systems are small, are often required to fit in a physically small space, and are usually fed small amounts of power. Even when the system is externally expanded, the memories provided on-chip are significantly faster than the external memories because of buss driving. The total addressing space is usually very limited (32k, 64k) with expansion not linear. The registers in microcontrollers are usually a limited number of special pur-

pose registers, thus eliminating orthogonal usage. Speed is only one of many considerations in the microcontroller competition. Cost, package size, power consumption, memory size, number of timers, and I/O count are very important considerations.

Embedded Systems

Higher-level languages will achieve the goals of programmer productivity, program reliability, and application portability only if they fit the target environment well. If not, productivity will disappear into work-arounds and maintenance, reliability will be lost to kludges, and portability will not exist.

DESIRED TRAITS IN C FOR MICROCONTROLLERS

The environment in which C has developed is not the same as the embedded microcontroller world. What changes or extensions or implementations of C will provide the means to adapt the language? National Semiconductor Microcontroller Division has a compiler^[3] developed for the 16-bit High Performance Controller (HPCTM[4]) which has led to some exploration of these issues. The needs can be summarized as:

- Compatibility
- Direct Access to Hardware Addresses
- Direct Connection to Interrupts
- Optimization Considerations
- Development Environment
- Re-Entrancy

Compatibility

The first consideration for any such adaptation MUST be compatibility. Any attempt to create a different language, or another dialect of C, will create more problems than using C will solve. Dialects create problems in portability, maintenance, productivity, and possibly reliability. A programmer used to working in C will be tripped up by every little gotcha in a dialect; everyone will be tripped up by a different language.

Providing extensions to the language, while maintaining compatibility and not creating a new dialect, is accomplished by using the C Pre-Processor. By carefully choosing the extensions and their syntax, the use of the preprocessor's macro capability allows them to be discarded for normal C operation with non-extended compilers. By carefully choosing their semantics, the elimination of the extensions does not render the program invalid, just less effective.

Within these considerations there should be no unnecessary additions. An extension should not be made to avoid the optimizer's having to work hard. An extension should be made only to give the user an ability he would not have without it, or to tell the compiler something it cannot figure out by itself.

Direct Access to Hardware Addresses

Access to hardware addresses is improper in computation programs, is unusual in utility programs, is infrequent in operating systems, and is the *raison d'etre* of microcontrollers. The normal means of accessing hardware addresses in C is via constant pointers. This is adequate, if not great, when the accesses are minimal. For example

```

struct HDLC_registers
{
    ....
};
#define HDLC_1(*(struct HDLC_registers*)
    0x01a0)

```

allows reference to a structure of HDLC device registers at address 0x01a0, but never actually creates the entity of such a structure. If a debugger were asked about HDLC_1, it would not recognize the reference. If many registers and devices are involved, it becomes a problem to be handled by the programmer, not his tools. If the debugger tries to read the source for preprocessor statements, it adds significant complexity.

Another way of doing it is

```

struct HDLC_registers
{
    ....
};
extern struct HDLC_registers HDLC_1;

```

and providing an external file defining the address of HDLC_1, written in assembly language. This is clean, and does create the actual entity of a structure at the address, but has required an escape to assembly language for the system (although only at the system definition level). This was the first choice at National, and retains merit because the use of macros in the definition file allows the simple creation of a table exactly like the table in the hardware manual.

What is desirable, so that the user can do his own definitions without resorting to two languages, is a means to create the entities and define the addresses of those entities, a simple means of saying that this variable (or constant) is at a specific absolute address. The syntax

```

struct HDLC_registers HDLC_1 @ 0x01a0;

```

would be excellent as an official enhancement to the language, since the @ parses like the = for an initialization (and the program shouldn't initialize a hardware register this way like a variable). However, this violates the compatibility rule for an extension, since the preprocessor cannot throw away the address following the @ character. Therefore,

```

struct HDLC_registers HDLC_1 At (0x01a0);

```

is a much more practical form as an extension—and can be made to expand to the previous (or any other) form if it is ever added as an enhancement to the language. The resulting forms

```

volatile struct HDLC_registers HDLC_1 At
    (0x01a0);
volatile struct HDLC_registers HDLC_2 At
    (0x01b0);
volatile const int Input_Capture_3 At
    (0x0182);

```

are straightforward, simple, readable, and intuitively understandable, and provide the data item definitions as desired.

Direct Connection to Interrupts

Operating systems attach to interrupts in one centralized, controlled location and manage them all in that module. Embedded systems attach to varied interrupts for a variety of purposes, and frequently the different interrupt routines are in different modules with associated routines for each purpose. It is possible to do this with another escape to assembly language, but this requires that the system be maintained and enhanced in two languages.

The solution chosen for the National compiler is to provide an identifier for functions which are to service interrupts.

These functions obviously take no arguments and return no values, so they are worth considering as special. The syntax chosen was simply

```
INTERRUPT2 timer_interrupt ( )
```

although a more desirable form as an official enhancement would be

```
INTERRUPT(type)
interrupt_service_routine( )
```

because the chosen syntax can be preprocessed into whatever might be the final form. The semantics of the interrupt function were more difficult to guarantee for the future—should an interrupt function be callable by the other functions? Prohibiting it allows eventually permitting it if necessary; for improved efficiency, the National compiler does not allow an interrupt function to serve as anything other than an interrupt service routine, although one function can be attached to several interrupts.

Because the functions are special purpose, the function entry and exit code can be dedicated to interrupt entry and exit, rather than having to hide it in a separate library module. The National compiler actually generates the interrupt vector to point directly to the interrupt function; the function saves and restores the registers which it may destroy. Latency is minimized.

Interrupt response speed (latency) and interrupt system performance are important characteristics of a microcontroller. It is one thing (inconvenient or embarrassing) for a multi-MIPS machine to choke on long 9600 baud transmissions and drop a character or two because of inefficient interrupt response. It is another thing entirely—lethal, a total failure—for an embedded system's interrupt response to be so poor as to miss even one critical interrupt.

Optimization Considerations

Computer systems compete on speed (or at least MIPS ratings); compilers for them must be speed demons. Microcontrollers compete on size and costs; compilers for them must be frugal. Embedded systems are limited in their memory and different memories frequently have significantly different behavior.

The major concern of optimization comes down to code size. In most controller systems, as generated code size decreases speed usually increases. The effort in the code generation and optimization should be directed towards reducing code size. Claims for exactly how close the generated code gets to hand-written assembly code depend on specific benchmarks and coding techniques. An acceptance criterion for the National HPC compiler was code size comparison on a set of test programs. A level slightly below 1.4 times larger than assembly was reached.

In addition to the implementation of the optimization, other concerns of microcontrollers affect the way code can be generated. An example is the different forms of memory. Many controllers have memories which can be accessed by faster or shorter code. Certain variables should be placed in these memories without all the variables of a module going there (which is a linker process). There is no possible way for the optimizer to guess which variables should go there,

especially in a multiple module program, so it must be told. The syntax used is

```
static BASEPAGE int important_variable;
```

because the special memory in National's HPC is the first page of RAM memory. Several other possibilities offer themselves, including using for an official enhancement

```
static register int important_variable;
```

because currently static register variables are specifically prohibited. This cannot be an extension, because the register word could not be redefined to the preprocessor. If some variables need to be accessed by fast code, and some need to be accessed by short code, and if the two were mutually exclusive, it would be desirable to have two separate extension words. Since such hardware is unlikely, the single word BASEPAGE is probably sufficient.

Additional savings can be achieved by reconsidering string literals. The ANSI C requires that each string literal is a separate variable, but in actual usage they are usually constants and therefore need not be separate nor variables. The National compiler provides an invocation line switch to indicate that all string literals (but not string variables) can be kept in ROM rather than being copied to RAM on system start-up. Such strings can be merged in the ROM space to eliminate duplication of strings.

An extension to the language to identify functions which will not be used recursively is

```
NOLOCAL straight_forward_function( );
```

which causes all local variables to be converted to static variables, which are easier and faster to access and use. If the function has no arguments, the compiler can even eliminate the use and creation of the Frame Pointer for the function, saving additional code and time.

The particular processor, the HPC, has a special form of subroutine call. Since the optimizer cannot guess across modules which functions should be called with the special form, the extension

```
ACTIVE specially_called_function(arg);
```

was added. This may or may not be appropriate for other processors, but is a good example of why the language needs careful extensions to take advantage of different processors.

One command extension was added to the language because it allows the programmer to guarantee something the optimizer cannot usually determine. The form

```
switchf(value) {...}
```

provides for a switch/case statement without a default case. When speed and size become critical, the extra code required to validate the control value and process the default is highly undesirable when the user's code has already guaranteed a good value.

The National compiler has one extension which violates the issues stated under compatibility. It remains for historical reasons. It is a command

```
loop(number) {...};
```

which produces a shortened form of the for loop, without an accessible index. This does not provide the user with any new ability, it merely allows the compiler optimizer to know, without figuring out, that the index is not used inside nor outside the loop, and can therefore be a special counted form. The preprocessor cannot produce an exact semantic equivalent for the statement. This is a perfect example of a poor extension and will eventually be eliminated.

Development Environment

Languages developed for large or expensive systems can usually depend on large systems for development support, either self-hosted or with a large system host providing cross-development tools. Microcontrollers are often price sensitive, are frequently in the laboratory or the field, and are not always supported by a large system as a development host. Personal computers provide an excellent platform for the entire suite of development tools.

National Semiconductor currently provides its compiler and associated cross-development programs on the IBM PC and clone type of computer. The software is all very portable, and can be run under VAX/VMS, VAX/Ultix, or VAX/BSD4.2, and on the NSC 32000-based Opus add-in board for the PC running UNIX V.3, and some other versions of UNIX. The demand has been for the PC version; the PC is a very good workstation environment for microcontrollers. Other environments may be desirable, but the PC is first.

Re-Entrancy

Even with all these other considerations handled, there is a time bomb lurking in C on microcontrollers. C is a single thread, synchronous language as it is usually implemented. Since most utilities are strictly single-thread and the UNIX kernel forces itself into a single-thread, this is not a big problem for them. Embedded systems involving controllers are inherently asynchronous; the language in which they are implemented must be multi-thread without special rules and exception cases.

The passing of arguments on the stack and the returning of values in registers allow for complete re-entrancy and thus asynchronous multi-threading, but this breaks down when structures are returned. Most implementations of C use a static structure to contain the returned value and actually return a pointer to it; the compiler generates the code to access the returned structure value as required. This cannot

be used in a microcontroller environment, because if an interrupt occurs during the time the static structure is being used, it cannot re-enter the function. On an operating system level such conflicts can be managed with gates, semaphores, flags, or the like, but that solution is completely inappropriate on the language level. Turning the interrupts off is similarly not a language level concept, and is impossible on a system with a NonMaskable Interrupt. Telling users not to get themselves into that situation is crippling at best, impossible to enforce, and extremely difficult to track down and correct.

The solution should be at the language level, and should allow the return of a structure without hindering re-entrancy. The author's solution, developed with National, has been to have the code calling the function provide the address of a structure in which to build the return value. Since this is frequently on the caller's stack, and is never invisibly static, the program has no hidden re-entrancy flaws.

The HPC C Compiler

The HPC C Compiler (CCHPC) is a full and complete implementation of ANSI Draft Standard C (Feb 1986) for free-standing environment. Certain additions take advantage of special features of the HPC (for the specific needs of microcontrollers). The extensions include the support of two non-standard statement types (loop and switch), non-standard storage class modifiers and the ability to include assembly code in-line. The compiler supports enumerated types, passing of structures by value, functions returning structures, function prototyping and argument checking.

Symbol Names, both internal and external, are 32 characters. Numerics are 16-bit for **short** or **int**, 32-bit for **long**, and 8-bit for **char**, all as either **signed** or **unsigned**; floating point are offered as **float** or **double**, both using 32-bit IEEE format.

All data types, storage classes and modifiers are supported. All operators are supported, and anachronisms have been eliminated (as per the standard). Structure assignment, structure arguments, and structure functions are supported. Forward reference functions and argument type checking are supported.

Assembly code may be embedded within C programs between special delimiters.

See Table I.

Embedded Assembly Code

CONCLUSIONS

With the right extensions, the right implementations, and the right development environment, National is providing its customers with a C compiler tool which allows effective higher-level language work within the restrictive requirements of embedded microcontrollers. Productivity increases do not have to come at the expense of larger programs and more memory chips. No strangeness has been added to the language to cause reliability problems. Portability has been retained. Assembly language code has been eliminated as the chewing gum and baling wire trying to hold it all together, further increasing reliability and portability.

HPC16400

A Communication Microcontroller with HDLC Support

National Semiconductor
Application Note 593
Nick Burd

INTRODUCTION

The HPC16400 is a communications microcontroller for HDLC based applications and is the latest in the range of High Performance microcontrollers (HPC™) from National Semiconductor Corporation. HPC is a family of 16-bit CMOS microcontrollers which feature a common core to which are added peripherals for a specific application area. In the case of the HPC16400, these include dual HDLC channels and a four channel DMA controller which make the HPC16400 ideally suited to embedded protocol processing, such as X.25/LAPB. In addition, the HPC16400 also contains an on-chip serial decoder which allows the HDLC channels to be time multiplexed onto common transmit and receive lines as used by the ISDN (Integrated Services Digital Network) Basic Rate interface. This means that together with Nationals' ISDN line interface and COMBO™ circuits, and a software

package which implements the generic ISDN protocols (Q.921 and Q.931) a complete system solution for ISDN Basic Rate applications is possible.

The HPC16400 is capable of running at a maximum clock frequency of 20 MHz, and each of its HDLC channels can operate up to a maximum 4.65 Mbps data rate. A photograph of the HPC16400 chip is shown in *Figure 1*.

This article describes the features of the HPC16400, and in particular the operation of the HDLC/DMA channels and the serial decoder. As an example of how the HPC16400 would be used in an ISDN application, an ISDN terminal is described together with the features of the ISDN software package which can be used to minimize the time and effort in developing such equipment.

FIGURE 1. Block Diagram of the HPC16400

TL/DD/10361-2

THE HPC CORE

Figure 1 shows the block diagram of the HPC16400 in which the functions within the dotted line form the HPC core which is common to all HPC family members. It can be seen that the core contains the CPU as well as several peripherals. Those functions outside the dotted line are the peripherals specific to the HPC16400.

The CPU contains a 16-bit ALU and a 16-bit accumulator which acts as the source and destination for most operations. Two 16-bit address pointer registers, B and X, are intended to be used for indirect addressing of data with auto increment and decrement of the register. The K register is used to set a limit for the B register when it is either incremented or decremented with successive execution within program loops. A specific feature of the instruction set of the HPC CPU is that conditional execution of an instruction is based on a skip structure instead of the traditional conditional branch or jump. This is best illustrated through an example using the B, K and X registers described above. The example listed in Figure 2 swaps the contents of two areas of memory in the ranges 0x4000 to 0x4FFF and 0x5000 to 0x5FFF. A single instruction is used to load the B and K registers which define the boundaries of the lower memory area, and the X register is loaded to point to the

beginning of the upper memory area. The first instruction within the loop loads the accumulator with the memory word pointed to by the X register, and the X register is then incremented. The fact that a word value has been specified here means that the X register will automatically be incremented by two. If a byte value had been specified, it would be incremented by one. The second instruction in the loop is an exchange with a conditional skip which exchanges the contents of the 16-bit accumulator with the memory word pointed to by the B register, and the B register is then incremented by two. If the new value of the B register now exceeds the value in the K register, the following jump instruction will be skipped and program execution will exit the loop. If the value of the B register is less than the K register, then the next instruction is executed and the loop is continued. Judicious encoding of the opcodes for the HPC instruction set has resulted in a very efficient implementation of common constructs such as the loop just described. The register indirect instructions are encoded as single-byte instructions as well as the short jump instruction where a six bit offset is included within the opcode. The loop described above therefore generates only three bytes of program code. In total, the HPC has 54 instructions and nine addressing modes.

```

LD BK, #4000, #4FEE ;load B and K with start and end of 1st. memory block.
LD X, #5000 ;load X with start of second memory block.
LOOP: LD A, [X+].W ;get word from second block, increment X.
XS A, [B+].W ;exchange with word from first block, increment pointer,
;skip if B>K.
JP LOOP ;do loop again

EXIT: ↓ Continue program

```

FIGURE 2. An Example HPC Program to Swap Two Memory Areas

The HPC core contains several peripheral features. The MICROWIRE/PLUS™ is an inter-chip serial communication port which consists of an 8-bit shift register and a clock. Writing data to the microwire port when configured as a master causes the data to be loaded into the shift register and eight clock pulses generated to shift the data out. At the same time, these clock pulses can be used to clock data in from a microwire slave device such as the ADC0834 A/D converter or the NMC93C46 EEPROM.

The HPC core also contains a number of timers. A purpose of one of these timers, T0, is to provide a means for accurate time interval measurements, and when configured in this mode, it is associated with up to three capture registers which can be triggered by external interrupt inputs. Timer T1 provides a dual function as it can operate as a normal timer, or its registers can be used as two of the capture registers for T0. The timer T0 also drives the Watchdog™ logic which causes the Watchdog output to trigger whenever it is not serviced before a timeout of T0. The remaining two timers can be used to generate a variety of timing outputs.

Interrupt logic provides enabling circuitry for the numerous sources of interrupt on the HPC, and an interrupt pending register eases the processing of multiple interrupts. The HPC can be placed into one of two power saving modes by programming the Processor Status Word (PSW) register and the Halt Enable register. In the Halt mode, all processor activities, including the clock and timers, are stopped thereby reducing the power requirements of the HPC to a minimum. Recovery from the Halt Mode can either be from a Reset or from the NMI. In Idle mode, all processor activity apart from the on-board oscillator and timer T0 is stopped so that recovery from the Idle mode can be achieved with the timer T0 overflow as well as the reset or NMI functions as in the Halt mode (except that in the Halt mode recovery is not immediate as the oscillator will take time to stabilize).

HPC MEMORY

All functions on the HPC chip are memory mapped. The on-chip peripherals, core registers, and on-chip user RAM (16-bit) occupy an address area between 0 and 0x1FF as shown in the memory map of *Figure 3a*. The area of user on-chip RAM in the range 0–0xBF is in the BASEPAGE (0–0xFF) of the address space, and in addition to being used as general purpose storage locations for variables, the indirect addressing mode of the HPC allows memory words in this area to be used as pointers containing the effective address of the operand. This allows many additional pointers to be created in addition to the B and X register and significantly eases the programming of many tasks.

The memory requirements in telecom applications are generally large for both program and data areas, and so the HPC16400 does not have a single-chip configuration with

on-chip ROM. Instead, a 16-bit multiplexed address and data bus is brought external to the chip and is used to add program memory and additional data memory to the system in the address range 0x200 to 0xFFFF.

FFFF	External User Memory

FIGURE 3a. The Basic 64k Memory Map of the HPC16400

The 64 kbyte address space can be expanded further by the use of bank switching. Four lines from Port B may be used to select one of sixteen banks of 32 kbytes in the address range 0–0x7FFF as shown in *Figure 3b*. In this way, the upper 32 kbytes of memory are common to all of the banks and allows a program in one bank to jump or call subroutines in other banks via this common area where the banks can be safely switched (see reference 1 for a more in-depth discussion of bank switching on the HPC). The common memory also provides storage area for global variables and stack locations when operating in a bank-switched environment. The total memory addressing capability of the HPC16400 amounts to just over 500 kbytes as the section of on-chip RAM in the range 0–0x1FF is common to all banks.

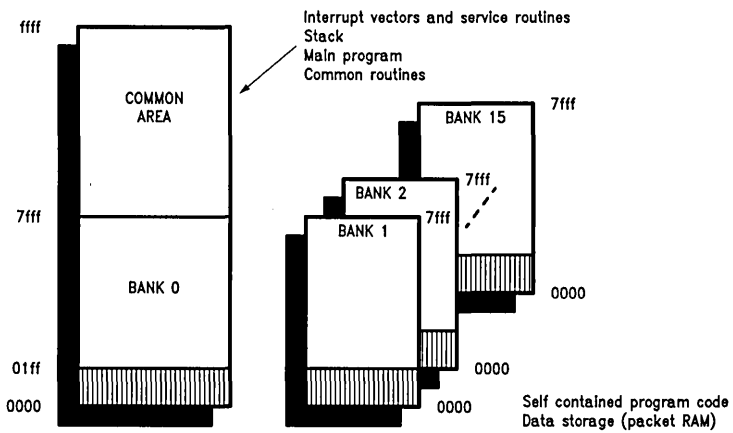

FIGURE 3b. HPC Extended Memory Addressing by Bank Switching

TL/DD/10361-3

When the HPC fetches program from memory, it does so one byte at a time because the opcode encoding is byte oriented. This allows the HPC to be configured with either 16-bit external memory, 8-bit external memory for more cost sensitive applications, or a mixture of both. When operating with 16-bit memory, the HPC can access both odd and even bytes, and words on an even boundary. In 8-bit mode the HPC makes only byte accesses to external memory, and although the registers in the BASEPAGE memory of the HPC are 16 bits, they may also be addressed individually as high and low bytes thereby enabling the 16-bit architecture of the CPU to be used.

Selection of 8- or 16-bit bus mode for the HPC is achieved on reset of the processor when the "high byte enable" control line is sampled by the CPU. If this line is detected in a high state, the HPC enters 8-bit mode. However, if the line is detected as high impedance, as a result of it being used as a control output to select low and high 8-bit memory banks, then the HPC enters 16-bit bus mode.

THE HDLC AND DMA CHANNELS

The HPC16400 contains two identical on-chip HDLC channels, each capable of transmitting and receiving HDLC frames transparently to the operation of the CPU. The format of an HDLC frame is shown in Figure 4. The frame is delimited by an identical opening and closing flag which is a

unique bit pattern consisting of a zero followed by six consecutive ones and then a final zero. This pattern must not occur anywhere else within the frame and is guaranteed by a zero insertion mechanism which, after the transmission of five consecutive ones in the data stream between flags, will insert a zero before continuing to transmit data. A reverse procedure is adopted at the receiver to delete the additional zeroes. Immediately following the opening flag is an address field which identifies which equipment on the network is to receive the frame. The control field contains information, such as handshake control, which is used to control the flow of frames between communicating devices. This is followed by the application specific data, a frame check sequence which validates the integrity of the frame with a cyclic redundancy check (CRC) code, and the closing flag. The HPC HDLC channels provide automatic framing functions such as opening and closing flag insertion and deletion, zero bit insertion and deletion (also known as bit-stuffing), CRC16 or CCITT implementations of CRC checking, and abort sequence transmission and recognition. The abort sequence in this case is a modified flag consisting of a zero followed by seven ones. In addition, the transmitters can be programmed to generate flags, abort sequences, or just idle (transmitting consecutive ones) between the transmission of consecutive frames.

FIGURE 4. The HDLC Frame Format

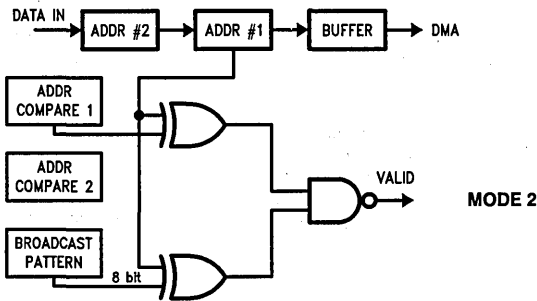

A feature which helps to reduce the CPU overhead in protocol processing is the address recognition logic. Each channel has two address recognition registers that can be programmed with a byte which can be compared in a number of different ways with the first two bytes received by an HDLC channel. The different comparison modes are intended to cope with a range of different communication network addressing modes. *Figure 5* shows the logical operation of three of the four possible modes. In mode one, the second byte received after the opening flag of the frame is com-

pared with both address registers and a seven bit broadcast address pattern (0x7F). If any of the registers match the incoming address, then the HDLC channel will continue to receive the complete frame. If no match is detected, the HDLC channel will stop receiving the frame, discard the address already received, and start to look for the opening flag of the next frame. This particular address recognition mode is useful in ISDN communications because the second byte received will be the address of the terminal equipment, such as a telephone or perhaps a PC, on the ISDN network.

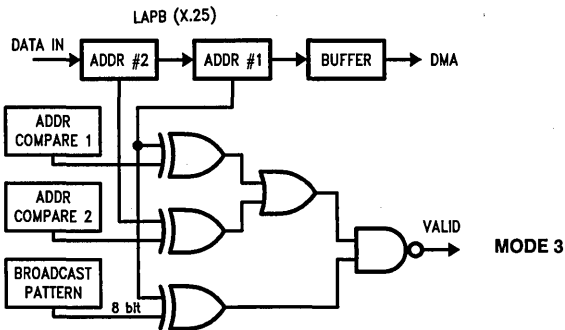

MODE 1

TL/DD/10361-4

MODE 2

TL/DD/10361-5

MODE 3

TL/DD/10361-6

FIGURE 5. The Address Recognition Logic for the HDLC Receivers

Mode two matches the first byte received with the first address register and an 8-bit broadcast address which could be used in X.25/LAPB applications. Mode three compares a 16-bit address field so that the contents of the first comparison register must match the first address byte received, and the contents of the second comparison register must match the second address byte received. Or, if the first byte corresponds to the 8-bit broadcast pattern, an address match will also be signalled to the CPU. The last mode, Mode zero, is the "transparent mode" in which all frames are received by the HDLC controller regardless of the address field contents. This mode would be used, for example, in a device which had to gather all information from the communications network and compute statistics about its communications loading.

Both HDLC channels are capable of implementing bit oriented protocols, such as IBMs SDLC, by programming the number of bits to be transmitted in the last byte of the information field. Further flexibility is achieved with a bypass mode which disables all of the HDLC framing functions allowing designers to implement their own byte-oriented synchronous protocols.

As mentioned earlier, all programmable features of the HPC are memory mapped, so the HDLC registers are mapped to an area of on-chip RAM above the BASEPAGE section in the range 0x1A0 and 0x1B8. Each HDLC channel has an identical set of registers, and each set contains receiver status, control, address comparison, and error status registers. In addition, there are two global registers which handle the enabling and servicing of interrupts from the HDLC channels. An interrupt can be generated whenever an HDLC channel signals an "End of Message" (EOM) which indicates that an HDLC frame has just been received or an HDLC frame has just finished being transmitted. Should a transmitter or receiver generate an EOM before the previous EOM has been serviced, then an overrun interrupt may be generated. All of these interrupt sources have a single interrupt service vector, and so the global registers contain bits which allow the source of the interrupt to be uniquely identified. Additional error conditions, such as reception of a bad CRC, reception of an abort sequence, or a framing error, cause bits to be set in the error status register which

may also generate an interrupt, although this may lead to the generation of multiple interrupts. A more straightforward approach would be to test the condition of the error status register once an EOM interrupt has been received.

The HPC16400 contains an on-chip four channel DMA controller. The operation of the DMA controller is closely linked to the HDLC channels because they are responsible for interfacing them to the memory. Hence, as each byte is received by an HDLC channel, it signals the DMA controller which requests and gains control of the processor bus and writes the received byte to a predetermined area of memory. Similarly, when an HDLC channel is transmitting a frame, it requests data from the DMA controller which transfers a byte from an area in memory to the HDLC channel. During DMA accesses the CPU loses control of the memory bus. However, for the HPC16400 running at 20 MHz, the CPU bus occupancy is only expected to decrease by 10% for an aggregate HDLC data rate of 2 Mbps. For typical Basic Rate ISDN applications the decrease is expected to be less than 2%.

The DMA channels contain several addressing features which allow convenient transmit and receive buffers to be created in memory. Each DMA channel supports a split-frame mode which allows the transmitted or received frame to be split into two sections with each section being stored in a different area of memory. In HDLC, it may be convenient to have all the address and control fields in one area of memory, and all the information fields in another. (The CRC and flag fields are stripped off or appended by the HDLC channels, and so are not present in the memory area.) In the DMA receiver, there are two pairs of address pointers, each pair pointing to the two sections of the same frame as shown in *Figure 6*. As the HDLC controller starts to receive data, the DMA channel places the first received byte in the memory pointed to by the first address pointer, and the pointer is then incremented. This continues until the number of bytes for the first segment, which can be programmed up to a maximum of 7 bytes in the DMA receiver control-status register, has been reached, at which point the contents of the second address pointer becomes the destination for the remainder of the received frame.

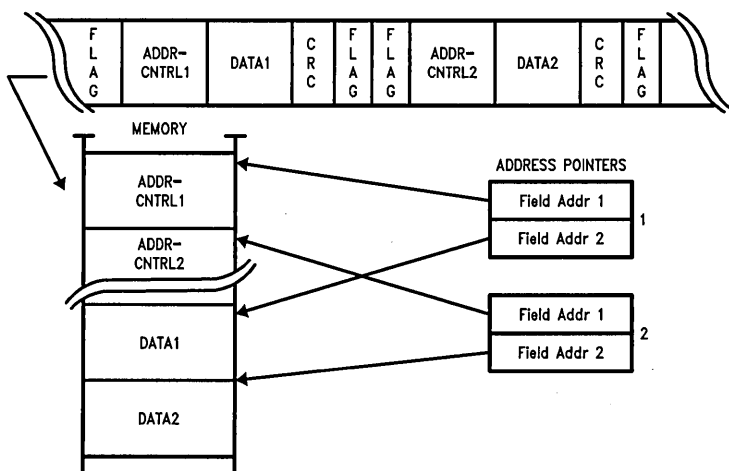

FIGURE 6. Split-Frame Operation for HDLC/DMA Receiver

TL/DD/10361-7

For the DMA channel which supports the HDLC transmitter, each pair of registers contains a single pointer and a byte counter which holds the number of bytes to be transmitted, as illustrated in Figure 7. When the split-frame mode is not used, each pair of registers in the transmit DMA, and each address pointer in the receive DMA, refers to a separate complete frame. This means that the HDLC receiver can receive four frames before the DMA address pointer registers need to be updated, provided the EOM is serviced after each frame to prevent an overrun interrupt.

In the previous section, the extended memory configuration of the HPC16400 using bankswitching was described. The DMA channels are capable of taking full advantage of this extended memory by a programmable field in the control-status registers whose value is written to the external bank-switch control lines during a DMA cycle. This allows the extended memory banks to be used for storing frame information.

The DMA controller is only capable of taking control of the processor bus when the CPU has finished executing the current instruction. When the HPC16400 executes long instructions, such as the Multiply or Divide instructions, and the HDLC channels are being used at very high data rates (in excess of 2.2 Mbps with a 20 MHz HPC), it may be possible that the DMA cannot gain control of the processor bus in time to service the HDLC channels. In this situation, the receiver is forced to overwrite the last byte received and a receiver overrun is flagged in the error status register. When this occurs during transmission, the transmitter no longer has any valid information to send and so it transmits an abort character and sets a transmitter underrun bit in the error status register. Programming the HDLC/DMA controllers is relatively straightforward, both for their initialization and interrupt servicing. Because the DMA controllers have two sets of registers, it means that the pointers to the next message to be received or transmitted can be set up while reception or transmission is in progress, thereby maximizing the throughput of the HDLC channels.

THE SERIAL DECODER—BASIC RATE ISDN AS AN EXAMPLE

As already described, the HDLC channels of the HPC16400 can be used in general purpose communications and networking applications. To enhance their capabilities, and provide on-chip support for ISDN, a serial decoder has been implemented to time division multiplex the two HDLC channels onto common transmit and receive lines.

Each HDLC channel can be enabled and disabled both internally by the serial decoder, and externally by individual receiver and transmitter enable pins. The internal enable signals are generated by the serial decoder according to six time division multiplexing (TDM) formats. The framing of these TDM formats, or modes, is synchronized by an externally generated frame sync. pulse which will normally be derived from an external clock signal used to clock the HDLC channels. With these inputs, the serial decoder generates the internal enable signals for the HDLC channels at the correct time within the frame according to mode that has been selected. The serial decoder can also be programmed to generate enable signals for the HDLC channels based on combinations of both the external enable signals and those generated internally by the serial decoder, thereby giving the designer a wide choice of possibilities.

As an example of the use of the serial decoder, we shall look at Basic Rate ISDN. Basic Rate ISDN specifies that a terminal equipment, such as a telephone or computer, should have two general purpose B channels (Bearer channels) for voice data or perhaps computer packet switched data, and a D channel which is used specifically for control of the ISDN network, such as setting up a call to another user. These 2B + D channels are time division multiplexed within a 125 μ s frame on a bus which interconnects functional blocks within a piece of equipment. The time slot for each B channel is the transmission time for 8 bits at a data rate of 64 kbps, and the D channel time slot is 2 bits at 16 kbps.

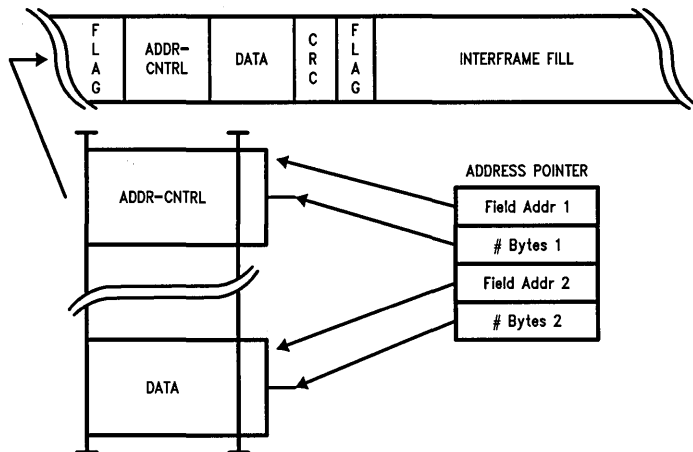

FIGURE 7. Split Frame Operation for HDLC/DMA Transmitter

TL/DD/10361-8

The overall scheme is shown in *Figure 8*. Now the HPC16400, having two HDLC channels, could be set up so that one HDLC channel is a B channel, and the other HDLC channel is the D channel. The serial decoder therefore has to be programmed so that its mode corresponds to the format shown in *Figure 7*, and that the enable signals are chosen internally such that the D time slot is assigned to one of the HDLC channels, and the correct B channel is assigned to the other HDLC channel. The remaining B channel could be occupied by any other device capable of generating a 64 kbps data stream within its time slot, such as a voice COMBO. The frame sync. signal and the HDLC clock will be generated externally to the HPC16400, typically by the ISDN line interface circuit as described in the next section.

AN ISDN TELEPHONE

Figure 9 shows the block diagram of an ISDN telephone. The three main components of the system are the HPC16400 microcontroller, the TP3420 "S" Interface Device (SID) which is the line interface to the ISDN subscriber

(S) link, and the TP3057 COMBO which provides the interface to the system for a handset. The inter-chip data bus, whose timing format was used as an example in the previous section, is called the Digital System Interface (DSI) bus, and combines the B and the D channels into common transmit and receive lines. Hence, the HDLC Tx outputs are tied together with the Dx output of the COMBO and are input to the SID DSI input pin Bx, and the HDLC Rx pins are combined with the Dr input from the COMBO and are driven by the SID DSI output pin Br. The SID, when configured in master mode, generates the frame sync. and clock signals which are derived from the received signal on the S bus. These signals are both connected to the HPC16400 and the COMBO so that the correct multiplexing format for the DSI bus as shown in *Figure 9* can be achieved. An additional output from the SID, DENx, indicates the presence of D channel bits on the DSI bus, and is used to enable the HDLC channel of the HPC16400 which has been assigned to handle the D channel communications, in this case HDLC channel 1.

FIGURE 8. The Serial Decoder Format for ISDN

TL/DD/10361-9

FIGURE 9. Block Diagram of an ISDN Telephone

TL/DD/10361-10

The SID is a programmable device with various modes and functions that conform to the CCITT I.430 specification for the physical layer of ISDN. Programming of the SID is achieved with the MICROWIRE/PLUS interface which is also used to drive the display for the telephone using a COP472-3 liquid crystal display controller. Selection of either the SID or the display driver is achieved with port lines from one of the general purpose I/O ports on the HPC16400 so that the chip selects for each device are software driven.

The Halt power saving mode can be used whenever the telephone is not active. This is indicated by the on/off hook signal from the handset which is interfaced to the NMI input of the HPC. When a telephone conversation is finished and the handset placed on-hook, the HPC can be put into Halt mode by software. When the handset is subsequently picked up for another call, and so goes off-hook, it will generate an NMI which will wakeup the HPC.

THE ISDN SOFTWARE

The control of end-to-end communications in a telephone system can be a complex procedure. Many things have to be taken into consideration, such as procedures for establishing a call, dial-plans, disconnecting calls, and so on. All of these procedures amount to the protocols which are part of ISDN. In particular, the control protocols for ISDN are those which are used on the D channel to establish and disconnect physical links between two (or more) users of the telephone network. *Figure 10* shows the three protocol layers of ISDN according to the ISO seven layer reference model for Open Systems Interconnection.

At the physical layer, the CCITT standard I.430 is used to specify the requirements of the ISDN S-Bus interface device. The TP3420 SID conforms to this specification, and in fact exceeds it in some aspects such as its ability to drive longer cable lengths. (The DSI bus is not part of this standard as it refers to the equipment side of the network.)

The data link layer protocol is responsible for the safe delivery of frames across the network. Here, ISDN uses the

CCITT standard Q.921 which is more commonly known as LAPD, or "Link Access Protocol on the D Channel". LAPD defines the "HDLC" frame format and a set of procedures to control the flow of information on the network, and recovery from errors. It is similar to the LAPB link access protocol used in X.25 and true HDLC networks, but defines an expanded set of procedures to cope with communications on a telephone network instead of a typical computer network.

Finally, in Layer 3, the CCITT Q.931 standard specifies a series of procedures for establishing, maintaining, and disconnecting calls between users on the network. Part of these services are application dependent, so in order to make the ISDN standard generic as possible, the Layer 3 is split into two parts. The generic part of Layer 3 executes the "protocol control procedures" and the application dependent part performs the "Call Control Procedures".

Figure 10 also shows how the ISDN protocols are mapped onto the hardware components. The SID is the Layer 1 device and the HPC16400 provides hardware support, by means of its HDLC channels, for the Layer 2 protocol. The clear boundary between the Layer 1 and Layer 2 devices results in a well structured system architecture, with the DSI bus creating the physical interface between these two layers. The remaining parts of Q.921 and Q.931 are implemented as a software package which includes drivers for the SID and HDLC/DMA channels, and tools which aid the debugging of application tasks that interface to the software at the Layer 3 call control level.

Within the software, the individual layers and drivers are implemented as tasks which run under a multi-tasking executive. The operation of the executive has been optimized to work with layered tasks, and includes features such as a mail manager, timer manager, and memory manager. The entire software package is written in "C" so that application tasks can be developed, run with the layer software (excluding the drivers), and debugged on a PC before being ported to the target hardware.

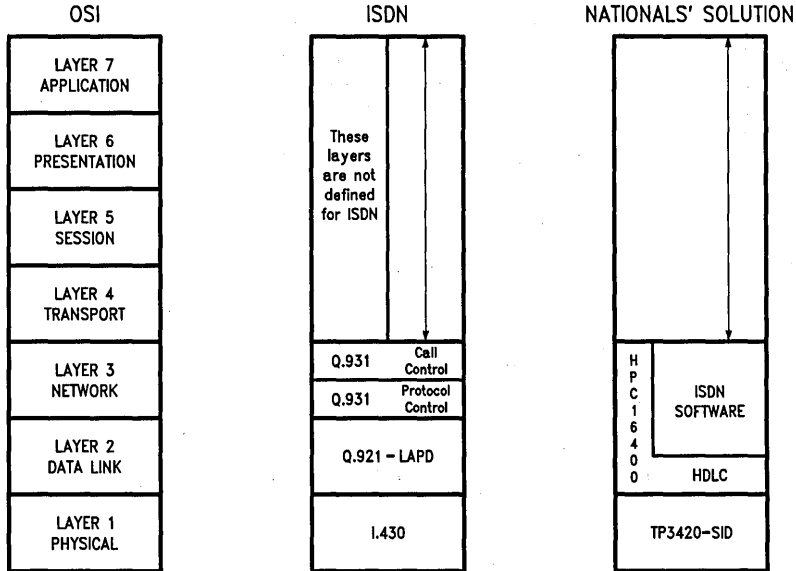

FIGURE 10. National's Solution to ISDN

CONCLUSIONS

The HPC16400 is a versatile high performance 16-bit CMOS microcontroller for embedded communications applications. Its fast CPU together with dual HDLC channels provides an ideal platform for implementing proprietary or standard communication protocols that use the HDLC framing structure.

Signed Integer Arithmetic on the HPC™

National Semiconductor
Application Note 603
Raj Gopalan

This report describes the implementation of signed integer arithmetic operations on the HPC. HPC hardware support for unsigned arithmetic operation. In order to support signed integer arithmetic operations on the HPC, the user can represent negative numbers in two's complement form and perform the signed arithmetic operations explicitly through software.

The following signed integer arithmetic routines are implemented in the package:

Multiplication:

16 by 16 yielding 16-bit result
32 by 32 yielding 32-bit result

Division:

16 by 8 yielding 16-bit quotient and 16-bit remainder
32 by 16 yielding 16-bit quotient and 16-bit remainder
32 by 32 yielding 16-bit quotient and 16-bit remainder

Addition:

16 by 16 yielding 16-bit

Subtraction:

16 by 16 yielding 16-bit

Comparison:

16 by 16 for greater to, less than or equal to.

REPRESENTATION OF NEGATIVE NUMBERS:

For binary numbers, negative numbers are represented in two's complement form. In this system, a number is positive if the MSB is 0, negative if it is 1.

The decimal equivalent of two's complement number is computed the same as for an unsigned number, except that weight of the MSB is $-2^{**n} - 1$ instead of $+2^{**n} - 1$. The range of representable numbers is $-(2^{**n} - 1)$ through $+(2^{**n} - 1 - 1)$.

The two's complement of a binary number is obtained by complementing its individual bits and adding one to it.

The advantage of representing a negative number in two's complement form is that addition and subtraction can be done directly using unsigned hardware.

        .endsect

```

MULTIPLICATION**Method 1:**

Signed multiplication can be achieved by taking care of the signs and magnitudes of the multiplicand and multiplier separately.

Perform the multiplication on the magnitudes alone.

The sign of the result can be set based on the signs of the multiplier and the multiplicand.

Method 2:

This method does not require finding the magnitude of the operands. Multiplication can be done using unsigned hardware on the two's complement numbers. The result will be signed based on the signs of the operands.

```

        .title      SIMULL
        .sect       code,rom8,byte,rel
;Multiply (Signed or Unsigned are the same)
;32 bit
;
;   K:A           Multiplicand
;   -4:8[SP]      Multiplier
;   K:A           return
;
        .public multiply_32
        .local
multiply_32:
    push        x                ;(Argument now at -6:8[SP])

    ld         a,k                ;Multiply hi reg* lo stack
    mult       a,-8[sp].w
    x         a,0.w                ;hold, retrieve lo reg
    push       a                ;(argument now at -8:10[SP])
    mult       a-8[sp].w        ;Multiply lo reg* hi stack
    add        0.w,a            ;add into hi partial
    pop        a                ;(Argument now at -6:8[SP])
    mult       a,-8[sp].w        ;Multiply lo reg* lo stack
    add        x,0.w            ;add in hi partial
    ld         k,x                ;Position
    pop        x                ;Restore
    ret

        .endsect

```

The algorithm is as follows:

Step 1. Result = op1 * op2

Step 2. If op1 < 0 then subtract op2 from upper half of the result.

Step 3. If op2 < 0 then subtract op1 from upper half of the result.

Now the Result will yield the correct value of the multiplication on two's complement numbers.

Method 3:

By sign extending the multiplier and multiplicand to the size of the result one can always obtain the correct result of signed multiplication using unsigned multiplication.

DIVISION

Similar to multiplication method 1, one can perform the division on the magnitudes of the dividend and divisor.

The sign of the quotient can be set based on the signs of the dividend and the divisor.

The sign of the remainder will be same as the dividend.

ADDITION

Two's complement numbers can be added by ordinary binary addition, ignoring any carries beyond the MSB. The result will always be the correct sum as long as the result doesn't exceed the range.

If the result is the same as for the subtrahend, then overflow has occurred.

SUBTRACTION

Subtraction can be achieved by negating the subtrahend and perform the addition operation.

Overflow can be detected as mentioned before by checking the signs of minuend and the negation of the subtrahend and that of the sum.

```

COMPARISON

To do signed comparison on n bit two's complement numbers first add $2^{**}(n - 1)$ to the numbers. This will basically shift the numbers from $-(2^{**}n - 1)$ to $+(2^{**}n - 1 - 1)$ range to 0 to $2^{**}n - 1$.

Now comparison operations on the numbers will produce the correct result.

EMI/RFI Board Design

National Semiconductor
Application Note 643
Joe Cocovich

INTRODUCTION

The control and minimization of Electro-Magnetic Interference (EMI) is a technology that is, out of necessity, growing rapidly. EMI will be defined shortly but, for now, you might be more familiar with the terms Radio Noise, Electrical Noise, or Radio Frequency Interference (RFI). The technology's explorations include a wide frequency spectrum, from dc to 40 GHz. It also deals with susceptibility to EMI as well as the emissions of EMI by equipment or components. Emission corresponds to that potential EMI which comes out of a piece of equipment or component. Susceptibility, on the other hand, is that which couples from the outside to the inside.

In HPC designs to date, we have looked at noise situations ranging from 2 MHz to 102 MHz. EMI, in some cases, can affect radio reception, TV reception, accuracy of navigation equipment, etc. In severe cases, EMI might even affect medical equipment, radar equipment, and automotive systems.

This Application Note will define ElectroMagnetic Interference and describe how it relates to the performance of a system. We will look at examples of Inter-system noise and Intra-system noise and present techniques that can be used to ensure ElectroMagnetic Compatibility throughout a system and between systems.

We will investigate and study the sources of noise between systems through wire-harness and backplane cables and connectors. Active circuit components can be contributors of noise and be susceptible to it. The fast switching times of CMOS devices fabricated in today's technology can cause incredible noise in a system. This noise typically is made up of crosstalk, power supply spiking, transient noise, and ground bounce.

The minimization and suppression of EMI can be obtained by utilizing proper control techniques. Intra-system noise, noise within a single module, sometimes can be controlled with methods such as filtering, shielding, careful selection of components, and following good wiring and grounding procedures. Controlling noise between systems, Inter-system noise, uses subtler techniques such as frequency management and time management, etc.

Appropriate time and resources should be spent during the design of a system or systems to insure that no problems will be encountered due to effects of EMI. Design guidelines will be presented that can be used to increase ElectroMagnetic Compatibility between systems by reducing the effects of noise between them. Above all, don't forget that the development tools used are also systems and are important to consider in your planning.

A brief look will be taken at the environment and tools required for different levels of noise testing. Relative risk-costs between preparing for EMC or excluding EMI concerns from the project will be listed.

DESCRIPTION OF NOISE

ElectroMagnetic Interference

EMI is a form of electrical-noise pollution. Think of the time when an electric drill or some other power tool jammed a nearby radio with buzzing or crackling noises. Sometimes it

got so bad that it prevented you from listening to the radio while the tool was in use. Or the ignition of an automobile idling outside your house caused interference to your TV picture making lines across the screen or even losing sync altogether making the picture flip. These examples are quite annoying but not catastrophic.

More serious, how about a sudden loss in telephone communication caused by electrical interference or noise while you are negotiating an important business deal? Now EMI can be economically damaging.

The results of EMI incidences can be even farther reaching than these examples. Aircraft navigation errors resulting from EMI or interruption of air traffic controller service and maybe even computer memory loss due to noise could cause two aircraft to collide resulting in the loss of lives and property.

These were just a few examples to help you identify the results of EMI in a familiar context. To help understand an ElectroMagnetic Interference situation, the problem can be divided into three categories. They are the source, the victim, and the coupling path. Secondary categories involve the coupling path itself. If the source and victim are separated by space with no hard wire connection, then the coupling path is a radiated path and we are dealing with radiated noise. If the source and victim are connected together through wires, cables, or connectors, then the coupling path is a conducted path and we are dealing with conducted noise. Incidentally, both types of noise can exist at the same time.

TL/DD/10562-1

ElectroMagnetic Compatibility

If you think about the examples given, one can understand that EMI or electrical noise is of national concern. The Government and certain industry bodies have issued specifications with which all electrical, electromechanical, and electronic equipment must comply. These specifications and limitations are an attempt to ensure that proper EMC techniques are followed by manufactures during the design and fabrication of their products. When these techniques are properly applied, the product can then operate and perform with other equipment in a common environment such that no degradation of performance exists due to internally or externally conducted or radiated electromagnetic emissions. This is defined as ElectroMagnetic Compatibility or EMC.

Inter-System EMI

For the purpose of this Application Note, when the source of noise is a module, board, or system and the victim is a different and separate module, board, or system under the control of a different user, that is considered to be an inter-system interference situation. Examples of inter-system interference situations could be a Personal Computer interfering with the operation of a TV or an anti-lock brake module in a car causing interference in the radio. This type of interference is more difficult to contain because, as mentioned earlier, the systems are generally not under the control of a single user. However, design methods and control techniques used to contain the intra-system form of EMI, which are almost always under the control of a single user, will inherently help reduce the inter-system noise.

Intra-System EMI Manifestations

TL/DD/10562-2

This Application Note will address problems and solutions in the area of intra-system noise. Intra-system interference situations are when the sources, victims, and coupling paths are entirely within one system or module or PC board. Systems may provide emissions that are conducted out power lines or be susceptible to emissions conducted in through them. Systems may radiate emissions through space as well as be susceptible to radiated noise. Noise conducted out antenna leads turns into radiated noise. By the same token, radiated noise picked up by the antenna is turned into conducted noise within the system. A perfect example is ground loops on a printed circuit board. These loops make excellent antennas. The system itself is capable of degrading performance due to its own internal generation of conducted and radiated noise and its susceptibility to it.

Some results of EMI within a system: Noise on power line causing false triggering of logic circuits, rapidly changing signals causing "glitches" on adjacent steady state signal lines (crosstalk) causing erratic operation, multiple simultaneously switching logic outputs propagating ground bounce noise throughout system, etc.

Coupling Paths

The modes of coupling an emitter source to a receptor victim can become very complicated. Remember, each EMI situation can be classified into two categories of coupling, conducted and radiated. Coupling can also result from a combination of paths. Noise can be conducted from an emitter to a point of radiation at the source antenna, then picked up at the receptor antenna by induction, and re-conducted to the victim. A further complication that multiple

coupling paths presents is that it makes it difficult to determine if eliminating a suspected path has actually done any good. If two or more paths contribute equally to the problem, eliminating only one path may provide little apparent improvement.

Conducted Interference

In order to discuss the various ways in which EMI can couple from one system to another, it is necessary to define a few terms. When dealing with conducted interference, there are two varieties that we are concerned with. The first variety is differential-mode interference. That is an interference signal that appears between the input terminals of a circuit. The other variety of conducted interference is called common-mode interference. A common-mode interference signal appears between each input terminal and a third point; that third point is called the common-mode reference. That reference may be the equipment chassis, an earth ground, or some other point.

Let's look at each type of interference individually. In *Figure 1* we show a simple circuit consisting of a signal source, V_S , and a load, R_L . In *Figure 2* we show what happens when differential-mode interference is introduced into the circuit by an outside source. As is shown, an interference voltage, V_D , appears between the two input terminals, and an interference current, I_D , flows in the circuit. The result is noise at the load. If, for instance, the load is a logic gate in a computer, and the amplitude of V_D is sufficiently high, it is possible for the gate to incorrectly change states.

FIGURE 1

TL/DD/10562-3

TL/DD/10562-4

FIGURE 2. Differential-Mode Interference

Figure 3 shows what happens when a ground loop is added to our circuit. Ground loops, which are undesirable current paths through a grounded body (such as a chassis), are usually caused by poor design or by the failure of some component. In the presence of an interference source, common-mode currents, I_C , and a common-mode voltage, V_C , can develop, with the ground loop acting as the common-mode reference. The common-mode current flows on both input lines, and has the same instantaneous polarity and direction (the current and voltage are in phase), and returns through the common-mode reference. The common-mode voltage between each input and the common-mode reference is identical.

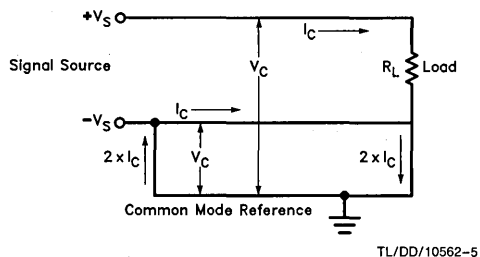

FIGURE 3. Common-Mode Interference

TL/DD/10562-5

FIGURE 4. Field-to-Cable Coupling

TL/DD/10562-6

Radiated Interference

Radiated coupling itself can take place in one of several ways. Some of those include field-to-cable coupling, cable-to-cable coupling, and common-mode impedance coupling. Let's look at those types of coupling one at a time.

The principle behind field-to-cable coupling is the same as that behind the receiving antenna. That is, when a conductor is placed in a time-varying electromagnetic field, a current is induced in that conductor. That is shown in *Figure 4*. In this figure, we see a signal source, V_S , driving a load, R_L . Nearby there is a current carrying wire (or other conductor). Surrounding the wire is an electromagnetic field induced by the current flowing in the wire. The circuit acts like a loop antenna in the presence of this field. As such, an interference current, I_N , and an interference voltage, V_N , are induced in the circuit. The magnitude of the induced interference signal is roughly proportional to the frequency of the incoming field, the size of the loop, and the total impedance of the loop.

Cable-to-cable coupling occurs when two wires or cables are run close to one another. *Figure 5* shows how cable-to-cable coupling works. *Figure 5a* shows two lengths of cable (or other conductors) that are running side-by-side. Because any two conducting bodies have capacitance between them, called stray capacitance, a time-varying signal in one wire can couple via that capacitance into the other wire. That is referred to as capacitive coupling. This stray capacitance, as shown in *Figure 5c* makes the two cables behave as if there were a coupling capacitor between them. Another mechanism of cable-to-cable coupling is mutual inductance. Any wire carrying a time-varying current will develop a magnetic field around it. If a second conductor is placed near enough to that wire, that magnetic field will induce a similar current in the second conductor. That type of coupling is called inductive coupling. Mutual inductance, as shown in *Figure 5b*, makes the cables behave as if a poorly wound transformer were connected between them. In cable-to-cable coupling, either or both of those mechanisms may be

responsible for the existence of an interference condition. Though there is no physical connection between the two cables, the properties we have just described make it possible for the signal on one cable to be coupled to the other.

FIGURE 5. Cable-to-Cable Coupling

TL/DD/10562-7

Either or both of the above-mentioned properties cause the cables to be electromagnetically coupled such that a time-varying signal present on one will cause a portion of that signal to appear on the other. The "efficiency" of the coupling increases with frequency and inversely with the distance between the two cables. One example of cable-to-cable coupling is telephone "crosstalk", in which several phone conversations can be overheard at once. The term crosstalk is now commonly used to describe all types of cable-to-cable coupling.

Common-mode impedance coupling occurs when two circuits share a common bus or wire. In *Figure 6* we show a circuit that is susceptible to that type of coupling. In that figure a TL092 op-amp and a 555 timer share a common return or ground. Since any conductor (including a printed circuit board trace) is not ideal, that ground will have a non-zero impedance, Z . Because of that, the current, I , from pin 1 of the 555 will cause a noise voltage, V_N , to develop; that voltage is equal to $I \times Z$. That noise voltage will appear in series with the input to the op-amp. If that voltage is of sufficient amplitude, a noise condition will result.

While not all inclusive, these coupling paths account for, perhaps, 98% of all intra-system EMI situations.

FIGURE 6. Common-Mode Impedance Coupling

TL/DD/10562-8

NOISE SOURCES

In this Application Note, we will look at sources of EMI which involve components that may conduct or radiate electromagnetic energy. These sources, component emitters, are different from the equipment and subsystems we have

been talking about. Component emitters are sources of EMI which emanate from a single element rather than a combination of components such as was previously described. Actually, these component emitters require energy and connecting wires from other sources to function. Therefore, they are not true sources of EMI, but are EMI Transducers. They convert electrical energy to electrical noise.

Cables and Connectors

The three main concerns regarding the EMI role of cables are conceptualized in *Figure 7*. They act as (1) radiated emission antennas, (2) radiated susceptibility antennas, and (3) cable-to-cable or crosstalk couplers. Usually, whatever is done to harden a cable against radiated emission will also work in reverse for controlling EMI radiated susceptibility. The reason for the word usually, is that when differential-mode radiated emission or susceptibility is the failure mode, twisting leads and shielding cables reduces EMI. If the failure mechanism is due to common-mode currents circulating in the cable, twisting leads has essentially no effect on the relationship between each conductor and the common-mode reference. Also cable shields may help or aggravate EMI depending upon the value of the transfer impedance of the cable shield. Transfer impedance is a figure of merit of the quality of cable shield performance defined as the ratio of coupled voltage to surface current in ohms/meter. A good cable shield will have a low transfer impedance. The effectiveness of the shield also depends on whether or not the shield is terminated and, if so, how it is terminated.

TL/DD/10562-9

FIGURE 7. Cables and Connectors

Connectors usually are needed to terminate cables. When no cable shields or connector filters or absorbers are used, connectors play essentially no role in controlling EMI. The influence of connector types, however, can play a major role in the control of EMI above a few MHz. This applies especially when connectors must terminate a cable shield and/or contain lossy ferrites or filter-pins.

Connectors and cables should be viewed as a system to cost-effectively control EMI rather than to consider the role of each separately, even though each offers specific interference control opportunities.

Components

Under conditions of forward bias, a semiconductor stores a certain amount of charge in the depletion region. If the diode is then reverse-biased, it conducts heavily in the reverse direction until all of the stored charge has been removed as shown in *Figure 8*. The duration, amplitude, and configuration of the recovery-time pulse (also called switching time or period) is a function of the diode characteristics and circuit parameters. These current spikes generate a broad spectrum of conducted transient emissions. Diodes with mechanical imperfections may generate noise when

physically agitated. Such diodes may not cause trouble if used in a vibration-free environment.

TL/DD/10562-10

FIGURE 8. Diode Recovery Periods and Spikes

Power Supply Noise

Power-supply spiking is perhaps the most important contributor to system noise. When any element switches logic states, it generates a current spike that produces a voltage transient. If these transients become too large, they can cause logic errors because the supply voltage drop upsets internal logic, or because a supply spike on one circuit's output feeds an extraneous noise voltage into the next device's input.

With CMOS logic in its quiescent state, essentially no current flows between V_{CC} and ground. But when an internal gate or an output buffer switches state, a momentary current flows from V_{CC} to ground. The switching transient caused by an unloaded output changing state typically equals 20 mA peak. Using the circuit shown in *Figure 9*, you can measure and display these switching transients under different load conditions.

TL/DD/10562-11

FIGURE 9

Figure 10a shows the current and voltage spikes resulting from switching a single unloaded ($C_L = 0$ in *Figure 9*) NAND gate. These current spikes, seen at the switching edges of the signal on V_{IN} , increase when the output is loaded. *Figures 10b*, *10c*, and *10d* show the switching transients when the load capacitance, C_L , is 15 pF, 50 pF, and 100 pF, respectively. The large amount of ringing results from the test circuit's transmission line effects. This ringing occurs partly because the CMOS gate switches from a very high impedance to a very low one and back again. Even for medium-size loads, load capacitance current becomes a major current contributor.

FIGURE 10

Although internal logic generates current spikes when switching, the bulk of a spike's current comes from output circuit transitions. *Figure 11* shows the I_{CC} current for a NAND gate, as shown in the test circuit, with one input switching and the other at ground resulting in no output transitions. Note the very small power-supply glitches provoked by the input-circuit transitions.

TL/DD/10562-16

TL/DD/10562-17

FIGURE 11

High-Speed CMOS Logic Switching

The magnitude of noise which can be tolerated in a system relates directly to the worst case noise immunity specified for the logic family. Noise immunity can be described as a device's ability to prevent noise on its input from being transferred to its output. It is the difference between the worst case output levels (V_{OH} and V_{OL}) of the driving circuit and the worst case input voltage requirements (V_{IH} and V_{IL} , respectively) of the receiving circuit.

Using *Figure 12* as a guide, it can be seen that for TTL (LS or ALS) devices the worst case noise immunity is typically 700 mV for the high logic level and 300 mV for the low logic level. For HCMOS devices the worst case noise immunity is typically 1.75V for high logic levels and 800 mV for low logic levels. AC high speed CMOS logic families have noise immunity of 1.75V for high logic levels and 1.25V for low logic levels. ACT CMOS logic families have noise immunity of 2.9V for high logic levels and 700 mV for low logic levels.

Logic Family Comparisons

Characteristic	Symbol	LS/ALS TTL	HCMOS	AC	ACT
Input Voltage (Limits)	V_{IH} (Min)	2.0V	3.15V	3.15V	2.0V
	V_{IL} (Max)	0.8V	0.9V	1.35V	0.8V
Output Voltage (Limits)	V_{OH} (Min)	2.7V	$V_{CC}-0.1$	$V_{CC}-0.1$	$V_{CC}-0.1$
	V_{OL} (Max)	0.5V	0.1V	0.1V	0.1V

FIGURE 12

To illustrate noise margin and immunity, *Figure 13* shows the output that results when you apply several types of simulated noise to a 74HC00's input. Typically, even 2V or more input noise produces little change in the output. The top trace shows noise induced on the high logic level signal and the bottom trace shows noise induced on the low logic level signal.

TL/DD/10562-18

TL/DD/10562-19

TL/DD/10562-20

FIGURE 13

Figure 14 shows how noise affects a 74HC74's clock input. Again, no logic errors occur with 2V or more of noise on the clock input.

TL/DD/10562-21

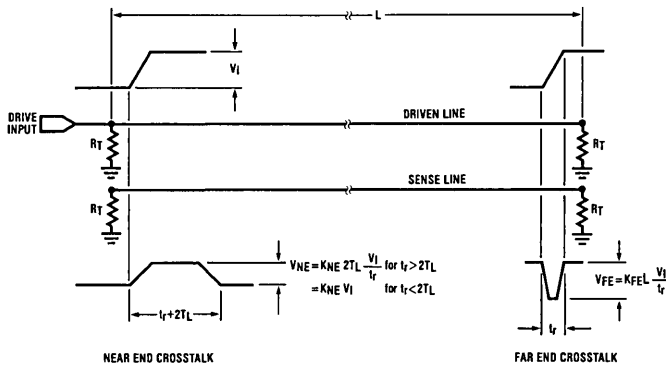

TL/DD/10562-22

FIGURE 14

Signal Crosstalk

The problem of crosstalk and how to deal with it is becoming more important as system performance and board densities increase. Our discussion on cable-to-cable coupling described crosstalk as appearing due to the distributed capacitive coupling and the distributed inductive coupling between two signal lines. When crosstalk is measured on an undriven sense line next to a driven line (both terminated at their characteristic impedances), the near end crosstalk and the far end crosstalk have quite distinct features, as shown in *Figure 15*. It should be noted that the near end component reduces to zero at the far end and vice versa. At any point in between, the crosstalk is a fractional sum of the near and far end crosstalk waveforms as shown in the figure. It also can be noted that the far end crosstalk can have either polarity whereas the near end crosstalk always has the same polarity as the signal causing it.

The amplitude of the noise generated on the undriven sense line is directly related to the edge rates of the signal on the driven line. The amplitude is also directly related to

TL/DD/10562-23

FIGURE 15. Crosstalk

the proximity of the two lines. This is factored into the coupling constants K_{NE} and K_{FE} by terms that include the distributed capacitance per unit length, the distributed inductance per unit length, and the length of the line. The lead-to-lead capacitance and mutual inductance thus created causes "noise" voltages to appear when adjacent signal paths switch.

Several useful observations that apply to a general case can then be made:

- The crosstalk always scales with the signal amplitude V_1 .
- Absolute crosstalk amplitude is proportional to slew rate V_1/t_r , not just $1/t_r$.
- Far end crosstalk width is always t_r .
- For $t_r < 2 T_L$, where t_r is the transition time of the signal on the driven line and T_L is the propagation or bus delay down the line, the near end crosstalk amplitude V_{NE} expressed as a fraction of signal amplitude V_1 is K_{NE} which is a function of physical layout only.
- The higher the value of ' t_r ' (slower transition times) the lower the percentage of crosstalk (relative to signal amplitude).

Although all circuit conductors have transmission line properties, these characteristics become significant when the edge rates of the drivers are equal to or less than about three times the propagation delay of the line. Significant transmission line properties may be exhibited, for example, where devices having edge rates of 3 ns are used to drive traces of 8 inches or greater, assuming propagation delays of 1.7 ns/ft for an unloaded printed circuit trace.

Signal Interconnects

Of the many properties of transmission lines, two are of major interest to the system designer: Z_{oe} , the effective equivalent impedance of the line, and t_{pde} , the effective propagation delay down the line. It should be noted that the intrinsic values of line impedance and propagation delay, Z_o and t_{pd} , are geometry-dependent. Once the intrinsic values are known, the effects of gate loading can be calculated. The loaded values for Z_{oe} and t_{pde} can be calculated with:

$$Z_{oe} = Z_o \cdot (1 + C_l/C_i) \cdot 0.5$$

$$t_{pde} = t_{pd} \cdot (1 + C_l/C_i) \cdot 0.5$$

where C_i = intrinsic line capacitance

C_l = additional capacitance due to gate loading.

These formulas indicate that the loading of lines *decreases* the effective impedance of the line and *increases* the propagation delay. As was mentioned earlier, lines that have a propagation delay greater than one third the rise time of the signal driver should be evaluated for transmission line effects. When performing transmission line analysis on a bus, only the longest, most heavily loaded and the shortest, least loaded lines need to be analyzed. All lines in a bus should be terminated equally; if one line requires termination, all lines in the bus should be terminated. This will ensure similar signals on all of the lines.

Ground Bounce

Ground bounce occurs as a result of the intrinsic characteristics of the leadframes and bondwires of the packages used to house CMOS devices. As edge rates and drive capability increase in advanced logic families, the effects of these intrinsic electrical characteristics become more pronounced. One of these parasitic electrical characteristics is the inductance found in all leadframe materials.

Figure 16 shows a simple circuit model for a CMOS device in a leadframe driving a standard test load. The inductor L1

represents the parasitic inductance in the ground lead of the package; inductor L2 represents the parasitic inductance in the power lead of the package; inductor L3 represents the parasitic inductance in the output lead of the package; the resistor R1 represents the output impedance of the device output, and the capacitor and resistor C_L and R_L represent the standard test load on the output of the device.

TL/DD/10562-24

FIGURE 16. Ground Bounce

The three waveforms shown represent how ground bounce is generated. The top waveform shows the voltage (V) across the load as it is switched from a logic HIGH to a logic LOW. The output slew rate is dependent upon the characteristics of the output transistor, and the inductors L1 and L3, and the load capacitance. In order to change the output from a HIGH to a LOW, current must flow to discharge the load capacitance. The second waveform shows the current that is generated as the capacitor discharges [$I = -C_L \cdot (dV/dt)$]. This current, as it changes, causes a voltage to be generated across the inductances in the circuit. The formula for the voltage across an inductor is $V = L(dI/dt)$. The third waveform shows the voltage that is induced across the inductance in the ground lead due to the changing currents [$V_{GB} = L1 \cdot (dI/dt)$]. This induced voltage creates what is known as ground bounce.

Because the inductor is between the external system ground and the internal device ground, the induced voltage causes the internal ground to be at a different potential than the external ground. This shift in potential causes the device inputs and outputs to behave differently than expected because they are referenced to the internal device ground, while the devices which are either driving into the inputs or being driven by the outputs are referenced to the external system ground. External to the device, ground bounce causes input thresholds to shift and output levels to change.

Although this discussion is limited to ground bounce generated during HIGH-to-LOW transitions, it should be noted that the ground bounce is also generated during LOW-to-HIGH transitions. This ground bounce though, has a much smaller amplitude and therefore does not present the same concern.

There are many factors which affect the amplitude of the ground bounce. Included are:

- Number of outputs switching simultaneously: more outputs results in more ground bounce.
- Type of output load: capacitive loads generate two to three times more ground bounce than typical system traces. Increasing the capacitive load to approximately 60–70 pF, increases ground bounce. Beyond 70 pF, ground bounce drops off due to the filtering effect of the load itself. Moving the load away from the output also reduces the ground bounce.

- Location of the output pin: outputs closer to the ground pin exhibit less ground bounce than those further away due to effectively lower L1 and L3.
- Voltage: lowering V_{CC} reduces ground bounce.

Ground bounce produces several symptoms:

- Altered device states.
- Propagation delay degradation.
- Undershoot on active outputs. The worst-case undershoot will be approximately equal to the worst-case quiet output noise.

NOISE SUPPRESSION TECHNIQUES

EMI control techniques involve both hardware implementations and methods and procedures. They may also be divided into intra-system and inter-system EMI control. Our major concern in this Application Note is intra-system EMI control, however, an overview of each may be appropriate at this time.

Figure 17 illustrates the basic elements of concern in an intra-system EMI problem. The test specimen may be a single box, an equipment, subsystem, or system (an ensemble of boxes with interconnecting cables). From a strictly near-sighted or selfish point-of-view, the only EMI concern would appear to be degradation of performance due to self-jamming such as suggested at the top of the figure. While this might be the primary emphasis, the potential problems associated with either (1) susceptibility to outside conducted and/or radiated emissions or (2) tendency to pollute the outside world from its own undesired emissions, come under the primary classification of intra-system EMI. Corresponding EMI-control techniques, however, address themselves to both self-jamming and emission/susceptibility in accordance with applicable EMI specifications. The techniques that will be discussed include filtering, shielding, wiring, and grounding.

Inter-system EMI distinguishes itself by interference between two or more discrete and separate systems or platforms which are frequently under independent user control. Culprit emissions and/or susceptibility situations are divided into two classes: (1) antenna entry/exit and (2) back-door entry/exit. More than 95% of inter-system EMI problems involve the antenna entry/exit route of EMI. We can group inter-system EMI-control techniques by four fundamental categories: frequency management, time management, location management, and direction management.

FIGURE 17. Intra-System EMI Manifestations

TL/DD/10562-25

The first step in locating a solution is to identify the problem as either an inter-system or intra-system EMI situation. Generally, if the specimen has an antenna and the problem develops from what exits or enters the antenna from another specimen or ambient, then the problem is identified as an inter-system EMI one. Otherwise, it is an intra-system EMI situation which we will discuss now.

Intra-System EMI-Control Techniques

Shielding

Shielding is used to reduce the amount of electromagnetic radiation reaching a sensitive victim circuit. Shields are made of metal and work on the principle that electromagnetic fields are reflected and/or attenuated by a metal surface. Different types of shielding are needed for different types of fields. Thus, the type of metal used in the shield and the shield's construction must be considered carefully if the shield is to function properly. The ideal shield has no holes or voids, and, in order to accommodate cooling vents, buttons, lamps, and access panels, special meshes and "EMI-hardened" components are needed.

Once a printed-circuit board design has been optimized for minimal EMI, residual interference can be further reduced if the board is placed in a shielded enclosure. A box's shielding effectiveness in decibels depends on three main factors: its skin, the control of radiation leakage through the box's apertures or open areas (like cooling holes), and the use of filters or shields at entry or exit spots of cables.

A box skin is typically fabricated from sheet metal or metalized plastic. Normally sheet metal skin that is 1 mm thick is more than adequate; it has a shielding effectiveness of more than 100 dB throughout the high-frequency spectrum from 1 MHz to 20 GHz. Conductive coatings on plastic boxes are another matter. Table I shows that at 10 MHz the shielding effectiveness can be as low as 27 dB if a carbon composite is used, or it can run as high as 106 dB for zinc sprayed on plastic by an electric arc process. Plastic filled materials or composites having either conductive powder, flakes, or filament are also used in box shielding; they have an effectiveness similar to that of metalized plastics.

TABLE I

Shielding Material	Surface Resistance,* Ohms/Square	Shielding Effectiveness, dB		
		At 10 MHz	At 100 MHz	At 1 GHz
Silver Acrylic Paint	0.004	67	93	97
Silver Epoxy Paint	0.1	59	81	87
Silver Deposition	0.05	57	82	89
Nickel Composite	3.0	35	47	57
Carbon Composite	10.0	27	35	41
Arc-Sprayed Zinc	0.002	106	92	98
Wire Screen (0.64 mm Grid)	N.A.	86	66	48

*Effectiveness of shielding materials with 25- μ m thickness and for frequencies for which the largest dimension of the shielding plate is less than a quarter of a wavelength.

In many cases shielding effectiveness of at least 40 dB is required of plastic housings for microcontroller-based equipment to reduce printed-circuit board radiation to a level that meets FCC regulations in the United States or those of the VDE in Europe. Such skin shielding is easy to achieve. The problem is aperture leakage. The larger the aperture, the greater its radiation leakage because the shield's natural attenuation has been reduced. On the other hand, multiple small holes matching the same area as the single large aperture can attain the same amount of cooling with little or no loss of attenuation properties.

Filtering

Filters are used to eliminate conducted interference on cables and wires, and can be installed at either the source or the victim. *Figure 18* shows an AC power-line filter. The values of the components are not critical; as a guide, the capacitors can be between 0.01 and 0.001 μF , and the inductors are nominally 6.3 μH . Capacitor C1 is designed to shunt any high-frequency differential-mode currents before they can enter the equipment to be protected. Capacitors C2 and C3 are included to shunt any common-mode currents to ground. The inductors, L1 and L2, are called common-mode chokes, and are placed in the circuit to impede any common-mode currents.

FIGURE 18. Filtering

TL/DD/10562-26

Wiring

Now that the equipment in each box can be successfully designed to combat EMI emission and susceptibility separately, the boxes may be connected together to form a system. Here the input and output cables and, to a lesser extent, the power cable form an "antenna farm" that greatly threatens the overall electromagnetic compatibility of the system. Most field remedies for EMI problems focus on the coupling paths created by the wiring that interconnects systems. By this time most changes to the individual equipment circuits are out of the question.

Let us address five coupling paths that are encountered in typical systems comprised of two or more pieces of equipment connected by cables. These should adequately cover most EMI susceptibility problems. They are:

- A *common ground impedance coupling*—a conducting path in which a common impedance is shared between an undesired emission source and the receptor.
- A *common-mode, radiated field-to-cable coupling*, in which electromagnetic fields penetrate a loop formed by two pieces of equipment, a cable connecting them, and a ground plane.
- A *differential-mode, radiated field-to-cable coupling*, in which the electromagnetic fields penetrate a loop formed by two pieces of equipment and an interconnecting transmission line or cable.
- A *crosstalk coupling*, in which signals in one transmission line or cable are capacitively or inductively coupled into another transmission line.

- A *conductive path* through power lines feeding the equipment.

The first coupling path is formed when two pieces of equipment are connected to the same ground conductor at different points, an arrangement that normally produces a voltage difference between the two points. If possible, connecting both pieces of equipment to a single-point ground eliminates this voltage. Another remedy is to increase the impedance along a loop that includes the path between the ground connections of the two boxes. Examples include the isolation of printed-circuit boards from their cabinet or case, the use of a shielded isolation transformer in the signal path, or the insertion of an inductor between one or both boxes and the ground conductor. The use of balanced circuits, differential line drivers and receivers, and absorbing ferrite beads and rods on the interconnecting cable can further reduce currents produced by this undesirable coupling path.

Common Ground Impedance Coupling

TL/DD/10562-27

A balanced circuit is configured so its two output signal leads are electrically symmetrical with respect to ground, as the signal increases on one output the signal on the other decreases. Differential line drivers produce a signal that is electrically symmetrical with respect to ground from a single-ended circuit in which only one lead is changing with respect to ground. Ferrite beads, threaded over electrical conductors, substantially attenuate electromagnetic interference by turning radio-frequency energy into heat, which is dissipated in them.

In the second coupling path, a radiated electromagnetic field is converted into a common-mode voltage in the ground plane loop containing the interconnect cable and both boxes. This voltage may be reduced if the loop area is trimmed.

Common-Mode, Radiated Field-to-Cable Coupling

TL/DD/10562-28

The third coupling path produces a differential-mode voltage that appears across the input terminals of the EMI receptor. One way of controlling this is to cancel or block the pickup of differential-mode radiation. In a balanced transmission line, this is done by use of twisted-wire pairs and a shielded cable.

As for crosstalk, the fourth coupling path—the reduction of capacitive coupling can be achieved by the implementation of at least one of these steps:

- Reducing the spacing between wire pairs in either or both of the transmission lines.
- Increasing the separation between the two transmission lines.
- Reducing the frequency of operation of the source, if possible.
- Adding a cable shield over either or both transmission lines.
- Twisting the source's or receptor's wire pairs.
- Twisting both wire pairs in opposite directions.

The fifth coupling path conductively produces both common-mode and differential-mode noise pollution on the power mains. Among several remedies that can suppress the EMI here are the filters and isolation transformers.

There are only about 50 common practical remedies that can be used in most EMI situations. Of these, about 10 suffice in 80 percent of the situations. Most engineers are aware of at least some of these remedies—for example, twisting wires to reduce radiation pickup.

In order to attack the EMI problem, one can make use of the information contained in Table II. First, decide what coupling path has the worst EMI interference problem. From the 11 most common coupling paths listed at the top of the table, find the problem coupling path. Using the numbers found in that table entry, locate the recommended remedy or remedies from the 12 common EMI fixes identified at the bottom of the table. This procedure should be repeated until all significant coupling paths have been properly controlled and the design goal has been met.

Inter-System EMI Control Techniques

There are many EMI controls that may be carried out to enhance the chances of inter-system EMC. They can be grouped into four categories which we will discuss briefly. The following discussion is not intended to be complete but merely provide an overview of some EMI control techniques available to the intersystem designer and user.

Frequency management suggests both transmitter emission control and improvement of receptors against spurious responses. The object is to design and operationally maintain transmitters so that they occupy the least frequency spectrum possible in order to help control electromagnetic pollution. For example, this implies that long pulse rise and fall times should be used. Quite often one of the most convenient, economic and rapid solutions to an EMI problem in the field, is to change frequency of either the victim receiver or the culprit source.

In those applications where information is passed between systems, a possible time management technique could be utilized where the amount of information transferred is kept to a minimum. This should reduce the amount of time that the receptor is susceptible to any EMI. In communication protocols, for example, essential data could be transmitted in short bursts or control information could be encoded into fewer bits.

Location management refers to EMI control by the selection of location of the potential victim receptor with respect to all other emitters in the environment. In this regard, separation distance between transmitters and receivers is one of the most significant forms of control since interfering source emissions are reduced greatly with the distance between them. The relative position of potentially interfering transmitters to the victim receiver are also significant. If the emitting source and victim receiver are shielded by obstacles, the degree of interference would be substantially reduced.

Direction management refers to the technique of EMI control by gainfully using the direction and attitude of arrival of electromagnetic signals with respect to the potential victim's receiving antenna.

Electromagnetic Interference Fixes

1. Insert Filter In Signal Source
2. Insert Filter in Signal Receptor
3. Insert Filter in Power Source
4. Insert Filter in Power Receptor
5. Twist Wire Pair
6. Shield Cable
7. Use Balanced Circuits
8. Install Differential Line Drivers and Receivers
9. Float Printed Circuit Board(s)
10. Separate Wire Pair
11. Use Ferrite Beads
12. Use a Multilayer Instead of a Single-Layer Printed Circuit Boards

DESIGN GUIDELINES

The growth of concern over electromagnetic compatibility (EMC) in electronic systems continues to rise in the years since the FCC proclaimed that there shall be no more pollution of the electromagnetic spectrum. Still, designers have not yet fully come to grips with a major source and victim of electromagnetic interference—the printed circuit board. The most critical stage for addressing EMI is during the circuit board design. Numerous tales of woe can be recounted about the eleventh hour attempt at solving an EMI problem by retrofit because EMC was given no attention during design. This retrofit ultimately costs much more than design stage EMC, holds up production, and generally makes managers unhappy. With these facts in mind, let's address electromagnetic compatibility considerations in printed circuit board design.

Logic Selection

Logic selection can ultimately dictate how much attention must be given to EMC in the total circuit design. The first guideline should be: use the slowest speed logic that will do the job. Logic speed refers to transition times of output signals and gate responses to input signals. Many emissions and susceptibility problems can be minimized if a slow speed logic is used. For example, a square wave clock or signal pulse with a 3 ns rise time generates radio frequency (100 MHz and higher) energy that is gated about on the PC board. It also means that the logic can respond to comparable radio frequency energy if it gets onto the boards.

The type of logic to be used is normally an early design decision, so that control of edge speeds and, hence, emissions and susceptibility is practical early. Of course, other factors such as required system performance, speed, and timing considerations must enter into this decision. If possible, design the circuit with a slow speed logic. The use of slow speed logic, however, does not guarantee that EMC will exist when the circuit is built; so proper EMC techniques should still be implemented consistently during the remainder of the circuit design.

Component Layout

Component layout is the second stage in PC board design. Schematics tell little or nothing about how systems will perform once the board is etched, stuffed, and powered. A circuit schematic is useful to the design engineer, but an experienced EMC engineer refers to the PC board when troubleshooting. By controlling the board layout in the design stage, the designer realizes two benefits: (1) a decrease in EMI problems when the circuit or system is sent for EMI or quality assurance testing; and (2) the number of EMI coupling paths is reduced, saving troubleshooting time and effort later on.

Some layout guidelines for arranging components according to logic speed, frequency, and function are shown in *Figure 19*. These guidelines are very general. A particular circuit is likely to require a combination and/or tradeoffs of the above arrangements. Isolation of the I/O from digital circuitry is important where emissions or susceptibility may be a problem. For the case of emissions, a frequently encountered coupling path involves a digital energy coupling through I/O circuitry and signal traces onto I/O cables and wires, where the latter subsequently radiate. When susceptibility is a problem, it is common for the EMI energy to couple from I/O circuits onto sensitive digital lines, even though the I/O lines may be "opto-coupled" or otherwise supposedly isolated. In both situations, the solution often lies in the proper

electrical and physical isolation of analog and low speed digital lines from high speed circuits. When high speed signals are designed to leave the board, the reduction of EMI is usually performed via shielding of I/O cables and is not considered here.

Therefore, a major guideline in laying out boards is to isolate the I/O circuitry from the high speed logic. This method applied even if the logic is being clocked at "only" a few MHz. Often, the fundamental frequency is of marginal interest, with the harmonics generated from switching edges of the clock being the biggest emission culprits. Internal system input/output PCB circuitry should be mounted as close to the edge connector as possible and capacitive filtering of these lines may be necessary to reduce EMI on the lines.

High speed logic components should be grouped together. Digital interface circuitry and I/O circuitry should be physically isolated from each other and routed on separate connectors, if possible as shown in *Figure 19d*.

- No High Frequency Signals to the Backplane

FIGURE 19. Board Layout

Power Supply Bussing

Power supply bussing is the next major concern in the design phase. Isolated digital and analog power supplies must be used when mixing analog and digital circuitry on a board. The design preferably should provide for separate power supply distribution for both the analog and digital circuitry. Single point common grounding of analog and digital power supplies should be performed at one point and one point only—usually at the motherboard power supply input for multi-card designs, or at the power supply input edge connector on a single card system. The fundamental feature of good power supply bussing, however, is low impedance and good decoupling over a large range of frequencies. A low impedance distribution system requires two design features: (1) proper power supply and return trace layout and (2) proper use of decoupling capacitors.

At high frequencies, PCB traces and the power supply buses (+V_{CC} and 0V) are viewed as transmission lines with associated characteristic impedance, Z₀, as modeled in Figure 20. The goal of the designer is to maximize the capacitance between the lines and minimize the self-inductance, thus creating a low Z₀. Table III shows the characteristic impedance of various two-trace configurations as a function of trace width, W, and trace separation, h.

TL/DD/10562-29

where L₀ and C₀ are, respectively, the distributed inductance and capacitance per unit length of the line

FIGURE 20

Any one of the three configurations may be viewed as a possible method of routing power supply (or signal) traces. The most important feature of Table III is the noticeable difference in impedance between the parallel strips and strip over ground plane compared with the side-by-side configurations.

As an example of the amount of voltage that can be generated across the impedance of a power bus, consider TTL logic which pulls a current of approximately 16 mA from a supply that has a 25Ω bus impedance (this assumes no decoupling present). The transient voltage is approximately $dV = 0.016 \times 25\Omega = 400 \text{ mV}$, which is equal to the noise immunity level of the TTL logic. A 25Ω (or higher) impedance is not uncommon in many designs where the supply and return traces are routed on the same side of the board in a side-by-side fashion. In fact, it is not uncommon to find situations where the power supply and return traces are routed quite a distance from each other, thereby increasing the overall impedance of the distribution system. This is obviously a poor layout.

Power and ground planes offer the least overall impedance. The use of these planes leads the designer closer to a multi-layer board. At the very least, it is recommended that all open areas on the PC board be "landfilled" with a 0V reference plane so that ground impedance is minimized.

Multi-layer boards offer a considerable reduction in power supply impedance, as well as other benefits. As shown in Table III, the impedance of a multi-layer power/ground plane bus grows very small (on the order of an ohm or less), assuming a W/h ratio greater than 100. Multi-layer board designs also pay dividends in terms of greatly reduced EMI, and they provide close control of line impedances where impedance matching is important. In addition, shielding benefits can be realized. For high-density, high-speed logic applications, the use of a multi-layer board is almost mandatory. The problem with multi-layer boards is the increased cost of design and fabrication and increased difficulty in board repair.

Decoupling

High-speed CMOS has special decoupling and printed circuit board layout requirements. Adhering to these requirements will ensure the maximum advantages are gained with CMOS devices in system performance and EMC performance.

Local high frequency decoupling is required to supply power to the chip when it is transitioning from a LOW to a HIGH value. This power is necessary to charge the load capacitance or drive a line impedance.

For most power distribution networks, the typical impedance can be between 50 and 100Ω. This impedance appears in series with the load impedance and will cause a droop in the

V_{CC} at the part. This limits the available voltage swing at the local node, unless some form of decoupling is used. This drooping of rails will cause the rise and fall times to become elongated. Consider the example presented in *Figure 21* used to help calculate the amount of decoupling necessary. This circuit utilizes an octal buffer driving a 100Ω bus from a point somewhere in the middle.

FIGURE 21

Being in the middle of the bus, the driver will see two 100Ω loads in parallel, or an effective impedance of 50Ω. To switch the line from rail to rail, a drive of 94 mA is needed ($4.8\text{V}/50\Omega$) and more than 750 mA will be required if all eight lines switch at once. This instantaneous current requirement will generate a voltage drop across the impedance of the power lines, causing the actual V_{CC} at the chip to droop. This droop limits the voltage swing available to the driver. The net effect of the voltage droop will be to lengthen device rise and fall times and slow system operation. A local decoupling capacitor is required to act as a low impedance supply for the driver chip during high current demands. It will maintain the voltage within acceptable limits and keep rise and fall times to a minimum. The necessary values for decoupling capacitors can be calculated with the formula given in *Figure 22*.

In this example, if the V_{CC} droop is to be kept below 0.1V and the edge rate equals 4 ns, we can calculate the value of the decoupling capacitor by use of the charge on a capacitor equation: $Q = CV$. The capacitor must supply the high demand current during the transition period and is represented by $I = C (dV/dt)$. Rearranging this somewhat yields $C = I (dt/dV)$.

$$Q = CV \text{ charge on capacitor}$$

$$I = C \text{ dV/dt}$$

$$C = I \text{ dt/dV} = 750 \text{ mA} \times 4 \text{ ns} / 0.1\text{V} = 0.030 \mu\text{F}$$

Select $C_B = 0.047 \mu\text{F}$ or greater

FIGURE 22

Now, $I = 750 \text{ mA}$ assuming all 8 outputs switch simultaneously for worst case conditions, $dt =$ switching period or 4 ns, and dV is the specified V_{CC} droop of 0.1V. This yields

a calculated value of $0.030 \mu\text{F}$ for the decoupling capacitor. So, a selection of $0.047 \mu\text{F}$ or greater should be sufficient. It is good practice to distribute decoupling capacitors evenly throughout the logic on the board, placing one capacitor for every package as close to the power and ground pins as possible. The parasitic inductance in the capacitor leads can be greatly reduced or eliminated by the use of surface mount chip capacitors soldered directly onto the board at the appropriate locations. Decoupling capacitors need to be of the high K ceramic type with low equivalent series resistance (ESR), consisting primarily of series inductance and series resistance. Capacitors using 5ZU dielectric have suitable properties and make a good choice for decoupling capacitors; they offer minimum cost and effective performance.

Proper Signal Trace Layout

Although crosstalk cannot be totally eliminated, there are some design techniques that can reduce system problems resulting from crosstalk. In any design, the distance that lines run adjacent to each other should be kept as short as possible. The best situation is when the lines are perpendicular to each other. Crosstalk problems can also be reduced by moving lines further apart or by inserting ground lines or planes between them.

For those situations where lines must run parallel as in address and data buses, the effects of crosstalk can be minimized by line termination. Terminating a line in its characteristic impedance reduces the amplitude of an initial crosstalk pulse by 50%. Terminating the line will also reduce the amount of ringing.

There are several termination schemes which may be used. They are series, parallel, AC parallel and Thevenin terminations. AC parallel and series terminations are the most useful for low power applications since they do not consume any DC power. Parallel and Thevenin terminations experience high DC power consumption.

Series terminations are most useful in high-speed applications where most of the loads are at the far end of the line. Loads that are between the driver and the end of the line will receive a two-step waveform. The first wave will be the incident wave. The amplitude is dependent upon the output impedance of the driver, the value of the series resistor and the impedance of the line according to the formula:

$$V_W = V_{CC} * Z_{oe} / (Z_{oe} + R_S + Z_S)$$

Series Termination

$$V_W = V_{CC} \times Z_{oe} / (Z_{oe} + R_S + Z_S)$$

where R_S is the series resistor
 Z_S is the output impedance of the driver
 Z_{oe} is the equivalent line impedance

The amplitude will be one-half the voltage swing if R_S (the series resistor) plus the output impedance (Z_S) of the driver is equal to the line impedance (Z_{oe}). The second step of the waveform is the reflection from the end of the line and will have an amplitude equal to that of the first step. All devices on the line will receive a valid level only after the wave has

propagated down the line and returned to the driver. Therefore, all inputs will see the full voltage swing within two times the delay of the line.

Parallel terminations are not generally recommended for CMOS circuits due to their power consumption, which can exceed the power consumption of the logic itself. The power consumption of parallel terminations is a function of the resistor value and the duty cycle of the signal. In addition, parallel termination tends to bias the output levels of the driver towards either V_{CC} or ground depending on which bus the resistor is connected to. While this feature is not desirable for driving CMOS inputs because the trip levels are typically $V_{CC}/2$, it can be useful for driving TTL inputs where level shifting is desirable in order to interface with CMOS devices.

TL/DD/10562-34

AC parallel terminations work well for applications where the increase in bus delays caused by series terminations are undesirable. The effects of AC parallel terminations are similar to the effects of standard parallel terminations. The major difference is that the capacitor blocks any DC current path and helps to reduce power consumption.

Thevenin terminations are not generally recommended due to their power consumption.

TL/DD/10562-35

TL/DD/10562-36

Like parallel terminations, a DC path to ground is created by the terminating resistors. The power consumption of a Thevenin termination, though, will generally be independent of the signal duty cycle. Thevenin terminations are more applicable for driving CMOS inputs because they do not bias the output levels as paralleled terminations do. It should be noted that output lines with Thevenin terminations should not be left floating since this will cause the undriven input levels to float between V_{CC} and ground, increasing power consumption.

Ground Bounce

Observing either one of the following rules is sufficient to avoid running into any of the problems associated with ground bounce:

- First, use caution when driving asynchronous TTL-level inputs from CMOS octal outputs. Ground bounce glitches may cause spurious inputs that will alter the state of non-locked logic.
 - Second, use caution when running control lines (set, reset, load, clock, chip select) which are glitch-sensitive through the same devices that drive data or address lines.
- When it is not possible to avoid the above conditions, there are simple precautions available which can minimize ground bounce noise. These are:
- Choose package outputs that are as close to the ground pin as possible to drive asynchronous TTL-level inputs.
 - Use the lowest V_{CC} possible or separate the power supplies.
 - Use board design practices which reduce any additive noise sources, such as crosstalk, reflections, etc.

Components

The interference effect by rectifier diodes, typically found in power supply sections of PC boards, can be minimized by one or more of the following measures:

- Placing a bypass capacitor in parallel with each rectifier diode.
- Placing a resistor in series with each rectifier diode.
- Placing an R-F bypass capacitor to ground from one or both sides of each rectifier diode.
- Operating the rectifier diodes well below their rated current capability.

TL/DD/10562-37

Connectors

TL/DD/10562-38

Cables and Connectors

Several options are available to reduce EMI from a typical ribbon cable used to interconnect pieces of equipment. These include:

- Reduce spacing between conductors (h in the figure) by reducing the size of wires used and reducing the insulation thickness.
- Join alternate signal returns together at the connectors at each end of the cable.
- Twist parallel wire pairs in ribbon cables.
- Shield ribbon cable with metal foil cover (superior to braid).
- Replace discrete ribbon cable with stripline flexprint cable.

In the case of joining alternate signal returns, wire N is carrying the signal current, i_n , whereas its mates, N-1 and N+1 wires are each carrying one half of the return currents, i_{n-1} and i_{n+1} , respectively. Thus, radiation from pair N and N-1 is out of phase with radiation from pair N and N+1 and will tend to cancel. In practice, however, the net radiation is reduced by 20-30 dB with 30 dB being a good default value.

Alternating Signal Returns Minimizes Radiation

TL/DD/10562-39

The opposite of this is to conserve signal returns by only using one, or two, wires to service N data lines in a ribbon cable. For data lines farther from the return line, the differential mode radiation becomes so great that this cable tends to maximize EMI radiation. Another disadvantage of this approach is poor impedance control in the resulting transmission line. This could result in distortion of pulses and cause reflections, especially for high-speed logic, and common return impedance noise in this single ground wire.

Single Signal Return Maximizes Radiation

TL/DD/10562-40

Ideally, connectors should have negligible resistance for obvious reasons other than EMI control. They should provide foolproof alignment to minimize the possibility of contact damage over time and use which would increase the resistance and be prone to vibration and shock. Adequate force to provide good mating between contacts which will insure low resistance and limit likelihood of damage. Connectors should mate with little friction to minimize the effects of continual disconnections and connections increasing the contact resistance with use as the contacts wear out. A contamination free design should be used to avoid corrosion and oxidation increasing resistance and susceptibility to shock and vibration causing intermittent contact.

Special Considerations with Development Tools

The following set of guidelines have been compiled from the experiences of the Development Systems Group and the Microcontroller Applications Group in Santa Clara. They should be considered *additional* techniques and guidelines to be followed concurrently with the standard ones already presented. Some are general and some may be specific to development systems use.

Ground bounce prevention and minimization techniques presented in this Application Note should be strictly adhered to when using '373 type transparent latches on the HPC's external address/data bus. Multiple simultaneously switching outputs could produce ground bounce significant enough to cause false latching. Observe good EMI planning by locating the latches as close to the HPC as possible. The use of multi-layer printed circuit boards with good ground planes and following appropriate layout techniques is

also essential, especially if emulation will be done at frequencies above 10 MHz. With the foregoing discussions about "antenna farms", radiated noise, and ideal connector characteristics, it becomes obvious that wire-wrap boards and the use of IC sockets is absolutely out of the question. The concern here is not so much EMI affecting the outside world but EMI strangling the operation of the module itself.

The inputs to the buffers in a '244 type octal buffer package are placed adjacent or side-by-side outputs of other buffers in the package. This configuration would tend to maximize the crosstalk or noise coupling from the inputs to the outputs. On the other hand, the buffer inputs in a '544 type package are on one side of the package and the outputs are on the other. The use of these package types in high speed designs can facilitate board layout to help reduce the effects of crosstalk.

Use extra heavy ground wires between emulator and target board. Rely on the ground returns in the emulator cable for reduction of differential-mode noise radiated from the cable but heavy-duty help is required for reducing power line impedance in the integrated development system.

Unused HPC inputs, most importantly NMI and RDY/HLD, must be tied to V_{CC} directly or through a pull-up resistor. This not only tends to reduce power consumption, but will avoid noise problems triggering an unwanted action.

In order to reduce the effects of noise generated by high speed signal changes, a sort of Frequency Management technique might be applied. If possible, develop application hardware and software at a slower crystal operating frequency. If ringing, crosstalk, or other combinations of radiated and conducted noise problems exist, the result may be to move the problem from one point in the affected signal waveform to a different point. Thus, apparent "noise glitches" that caused a latch to erroneously trigger when the input data was still changing, may now come at a time when they are non-destructive such as at a point when the input data is now stable.

Some applications require driving the HPC clock input, CKI, with an external signal. The emulator tools are all clocked using a crystal network with the HPC so that the generation of the system timing is contained on the tool itself. Consequently, there is no connection between the emulator cable connector on the tool and the CKI pin at the HPC. However, when the emulator cable is now inserted into the target board, the target board's clock signal travelling along the cable couples noise onto adjacent signal lines causing symptoms pointing to an apparent failure of the emulator tool. The recommendation is to disable the clock drive to the CKI pin at the HPC pad on the target board whenever the emulator tool is connected. The emulator tools supply the system clock so there is no need for the clock on the target and signal crosstalk on the emulator cable can be greatly reduced with minimal implementation. If one insists that the emulator tool and the target be synchronous, then bring the clock signal from the target to the emulator tool external to the emulator cable via twisted wire pair or coax cable. Remove the clock drive connection to CKI at the target to prevent the signal from entering the cable. Finally, remove crystal components on emulator tool to prevent problems with the signal.

Connecting boards and modules together to make a totally unique system in which EMC was practiced is necessary to ensure little problem with the environment. But, connecting

an emulator tool makes it an entirely new and unique system, both in physical and electrical properties. Treat the emulator tool as part of the system during the design phase and development phase.

NOISE MEASUREMENT

The basic purpose of FCC Part 15J is to minimize the jamming of commercial broadcasting systems by computer devices. Toward this end, the FCC has established test limits, for both conducted and radiated emissions, which must be met. These two tests together span the frequency range from 450 kHz to 1000 MHz. To accomplish FCC Part 15J testing requires the following equipment and associated support items:

- EMC Receivers or Spectrum Analyzers to cover the frequency range from 450 kHz to 1000 MHz.
- Dipole antennas (2) to cover the frequency range from 30 MHz to 1000 MHz.
- Masts or supports which will allow antenna elevation to be increased to at least 4 meters and also allow the polarization to be changed.
- Line impedance stabilization networks (LISN) built in accordance with CISPR requirements. These are 50 Ω , 50 μ H devices and are inserted between power mains and test item to permit making repeatable conducted EMI measurements.
- Power line filters.
- An appropriate test site.

Environment

The most controversial item on the test requirement list is the appropriate test site. The FCC required emission limits are comparable with the ambient RF level. These low limits and the noisy ambient would indicate that the tests should be made in a shielded enclosure. Unfortunately, all shielded enclosures introduce significant errors into the radiated measurements because of room reflections, room resonances, and antenna loading. To reduce the magnitude of these problems, the FCC has specified that measurements should be made at an open-field test site. Open-field test sites frequently have high ambient levels especially in the FM broadcast band. They may also have ground reflection variations as a function of soil moisture.

The FCC will permit the use of anechoic shielded enclosures which have reduced reflections, provided an error analysis is made to show correlation of interior RF levels with those of an open-field test site. The cost of an anechoic enclosure is its major drawback. For measurements other than for certification, the test site does not have to be in accordance with government regulations. There are also alternatives where an agency or private company will perform the tests for you at their facility for a nominal fee.

Many manufacturers are using shielded enclosures that they have constructed on site or purchased from one of the shielded enclosures manufacturers. The measurement requirement is that the RF ambient levels should be 6 dB or more below the specifications limits. This may require 20 dB worth of aluminum foil or 160 dB worth of electrical seals. Only a site survey can provide that answer. In any case, some margin of safety should be made, 6–10 dB, plus periodic check for reflection problems.

Instrumentation

After the appropriate test site has been obtained, whether a room or a quiet open field, then the testing can begin. If the

equipment to be tested is not floor standing, the test sample is placed on a non-conducting stand 80 cm high and at least 40 cm from the wall of the enclosure. Antennas are then set up so that radiated emission levels can be measured. The test sample should be loaded with full electrical and mechanical loads and operated in a manner that closely approximates normal operation. During operation of the equipment under test, the EMI measuring equipment is used to determine the amplitude of the radiated emission.

At NSC, we have a spectrum analyzer that can be attached to a Personal Computer that runs software to control experiments and report results. It automatically marks the computer display with FCC limits for quick comparison with the amplitude of the emissions signal. This setup is outside the shielded enclosure and can be used to determine if the equipment under test is failing any FCC requirements.

If the test sample fails, we can move inside the room and use near-field probes to help pinpoint the source of emissions. The spectrum analyzer samples the signal generated by the source at many different frequencies. The scale across the bottom of the screen is frequency and the scale along the side is signal amplitude in dBuV/m. Thus, we can quickly determine where the peak amplitude of the generated noise is located, read what level that is, and at what frequency it is being generated.

A little analysis and thought should then allow you to determine what signal could be the culprit. For example, if the noise problem is at 16 MHz and the system clock is 16 MHz, then the basic clock signal is causing the problem. If the noise problem is at even multiples of 16 MHz it could be caused by rise and fall times on the 16 MHz clock or overshoot and undershoot on that clock. In the case of the HPC, since it generates a clock output that is the system clock divided by 2 (CK2 = CK1/2), the noise frequency generated at the multiple of the 16 MHz signal could also be due to CK2 or any device that is clocked by that signal. Unfortunately for the investigator, everything else inside the part is clocked by CK2, which includes bus transitions and input sampling.

Cost

Basically, the risks of no EMI control will include the following:

- Vehicle/System Performance Degradation
- Degradation to outside world equipment
- Personal Hazards
- Ordinance Hazards
- Acceptance Delays

The sum which can mean anything from a minor system or equipment performance compromise to the total cancellation of a project.

The cost of EMI control will vary and include the following:

- Government procurement requirements
- Company proposal preparation
- EMI Control Plan
- Test Plan
- EMI Tests and Reports

A rough guideline that can be used might be:

- 1%–3% of \$100 Million projects
- 3%–7% of \$1 Million to \$10 Million projects
- 7%–12% of small items

SUMMARY

The design and construction of an electromagnetically compatible printed circuit board does not necessarily require a big change in current practices. On the contrary, the implementation of EMC principles during the design process can fit in with the ongoing design. When EMC is designed into the board, the requirements to shield circuitry, cables, and enclosures, as well as other costly eleventh hour surprises, will be drastically reduced or even eliminated. Without EMC in the design stage, production can be held up and the cost of the project increases.

1.0 INTRODUCTION

Fiber Distributed Data Interface (FDDI) is a high bandwidth (100 Mbits per second) local area network (LAN) which uses a dual redundant ring architecture. The network consists of a number of point to point links connected to form a ring. The physical and electrical characteristics of the ring protocol are covered by the Physical Media Dependent (PMD), Physical (PHY) and Media Access Control (MAC) Standards as defined by the American National Standards Institute (ANSI) X3T9.5 committee, and can be implemented using the DP83200 FDDI chipset from National Semiconductor. The on-line verification of these point to point links, and the formation of a ring is covered by the FDDI Station Management (SMT) Standard.

This application note covers the use of the HPC46064 High Performance Microcontroller from National Semiconductor to provide the local processing power required within a Fiber Distributed Data Interface (FDDI) node for Station Management (SMT). The note covers the interface between the HPC and the FDDI chipset from National Semiconductor and a possible system architecture.

2.0 FDDI INTELLIGENT STATION ARCHITECTURE

In FDDI, the Station Management (SMT) service is split into three main sections, SMT Frame Services, Ring Management (RMT) and Connection Management (CMT). Within the National Semiconductor implementation of FDDI, any controller handling RMT and CMT services need only access the Control Bus directly, although a communications channel to the host is also required. An architecture using the HPC from National Semiconductor is shown in *Figure 1*. This can be implemented directly using the interface shown in *Figure 2*. Using this architecture, the SMT frame services are provided by the host.

The architecture shown is one of several that could be implemented with the HPC and the National FDDI chipset. This architecture connects the HPC multiplexed address/data bus to the control bus of the FDDI devices, allowing the HPC to access these devices directly with single instructions. The 16 Kbyte ROM of the HPC46064 is used to minimize chip count, though this architecture allows external ROM or RAM to be used if additional functions are implemented.

The HPC has sufficient performance to handle all of SMT, including frame based management, but this would require that the HPC have access to the frame buffer memory. This requires an arbitration scheme to resolve conflicts between the host and the HPC in accessing the buffer RAM. The arbitration scheme could be simply implemented using the HOLD and HLDA (Hold Acknowledge) pins of the HPC.

An advantage of putting all of SMT on the board is that the SMT function need not be resident in the host memory. The removal of TSRs or daemons from host memory leaves more room for applications.

An alternative architecture would run the HPC in single chip mode, reducing the chip count and allowing the Universal Peripheral Interface (UPI) port to be used as the host interface. This would require software drivers to simulate the FDDI control bus signals using the I/O ports of the HPC.

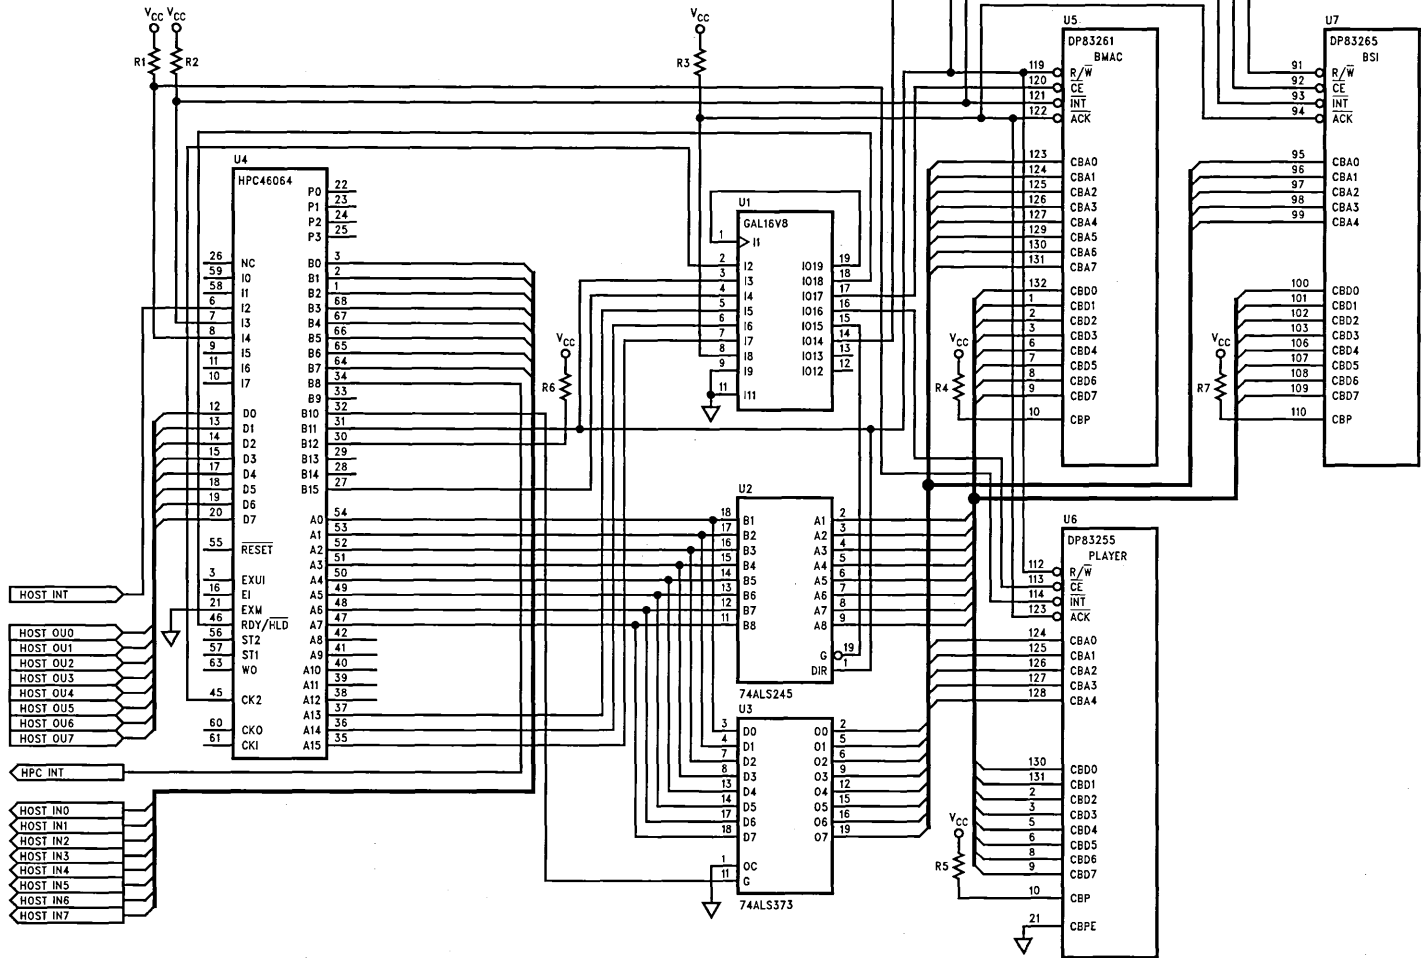

FIGURE 2. HPC to FDDI Chipset Interface

3.0 DP83200 FDDI CHIPSET

The DP83200 FDDI chipset from National Semiconductor implements the PHY and MAC Standards as defined by the American National Standards Institute (ANSI) X3T9.5 committee. The chipset includes the following devices.

DP83231 Clock Recovery Device (CRD™ DEVICE)

The Clock Recovery Device extracts a 125 MHz clock from the incoming data of the upstream station. Its features include on-chip loopback control, on-chip PLL, ability to lock to a Master Line State in less than 100 μ s, and a single +5V supply.

DP83241 Clock Distribution Device (CDD™ DEVICE)

From a 12.5 MHz reference, the CDD generates the 125 MHz, 25 MHz and 12.5 MHz clocks required by the PLAYER™ and BMAC™ devices.

DP83251/DP83255 Physical Layer Controller (PLAYER™ DEVICE)

The PLAYER device converts the BMAC 12.5 Mbyte/s stream into a 125 Mbaud 4B/5B encoded bit stream as specified in the FDDI PHY Standard. It synchronizes the received bit stream to the local 12.5 MHz clock and decodes the 4B/5B data into internal code. The DP83255 PLAYER device also contains a configuration switch for use in dual attachment stations and concentrators.

DP83261 Basic Media Access Controller (BMAC™ DEVICE)

The BMAC implements the functions defined by ANSI X3T9.5 FDDI Media Access Control Standard. The BMAC consists of the transmit and receive state machines, an address magnitude compare unit, a CRC checker, a CRC generator, protocol timers and diagnostic counters.

DP83265 BMAC System Interface (BSI™ DEVICE)

The BSI device provides a multiframe, multiple channel interface between the BMAC device and a host system. The BSI device interfaces directly to the system bus or through low-cost DRAMs. The efficient data structures employed provide high throughput with minimal host intervention.

For more information on these and other devices in the chipset please consult the appropriate data sheets and application notes.

4.0 HPC46064 High Performance Microcontroller (HPC DEVICE)

The HPC46064 is a member of the HPC family of High Performance Microcontrollers. Each member of the family has the same core CPU with a unique memory and I/O configuration to suit specific applications. The HPC46064 has 16 Kbytes of on-chip ROM and is fabricated in National's microCMOS technology. This process combined with the advanced architecture provides fast, flexible I/O, efficient data manipulation, and high speed computation.

The HPC46064 features include 16 bit internal architecture, 16- or 8-bit external data bus, 16 bit address and up to 52 general purpose I/O lines. The HPC46064 also includes a full duplex UART, four 16-bit timers, 16 Kbytes of ROM and 512 bytes of RAM.

The HPC46064 is used in this design because its 16 Kbytes of on-chip ROM remove the need for an external EPROM.

For prototyping or small production runs the pin compatible HPC467064 may be used, which has 16 Kbytes of on-chip EPROM.

Devices in the HPC family can directly address 64 Kbytes of external memory. This address range can be expanded to over 500 Kbytes without additional devices by using I/O pins to implement a simple bank switching technique.

This additional addressing range may be needed if the HPC implements the whole SMT function. The HPC development tools support this bank switching technique, allowing this low-cost microcontroller to handle the whole SMT function while minimizing the software development effort.

The performance of the system will not be affected by using this bank switching approach because many of the SMT functions are never performed simultaneously. The HPC could, for example, run the Physical Connection Management (PCM) from one memory bank, then switch to the bank containing the frame-based management functions at its leisure.

5.0 CONTROL BUS INTERFACE

The FDDI chipset from National Semiconductor provides the PHY and MAC services as detailed in the FDDI Standard. The chipset does not provide the Station Management (SMT) services, but does provide access to all the necessary data through a large array of 8-bit registers located on-board the PLAYER, BMAC, and BSI devices. The interface to these registers is via the Control Bus defined in the data sheet for the BMAC Device (Media Access Controller). The interface consists of an 8-bit address bus, 8-bit data bus and several control lines. The control lines consist of a read/write signal, a chip enable signal and an acknowledge signal. There is also an interrupt signal and a parity bit, which for this application, has been disabled. The interrupt signal and the acknowledge signal are open drain signals and can be wire-ORed.

A transfer cycle on the bus is started when the processor drives the Chip Enable (\overline{CE}) signal low. Within 20 ns, the data (write cycle only), address and read/write signals must all be valid. The device being accessed will respond by driving the Acknowledge (\overline{ACK}) signal low when data is valid (read cycle) or when the data has been clocked in (write cycle). The processor can now end the transfer by driving \overline{CE} high and the device will complete the cycle by driving \overline{ACK} TRI-STATE®.

The HPC provides a multiplexed 16 bit bus for interfacing to external memory. As only 8 bits are required for the Control Bus, the interface can be achieved with minimal components (see Figure 2). The multiplexed address is latched by the flow-through latch, U3. The data bus is buffered by the bi-directional buffer, U2, which is enabled whenever either read or write signals is asserted by the HPC. The direction is controlled by the Write (WR) signal. Two chip enables are provided (PCE and BCE) by decoding the read, write and upper address bits. The chip enables are delayed until the next Clock (CK2) falling edge so that during a write cycle, the data is available within 20 ns of the chip enable. The Ready (RDY) signal forces the HPC to insert wait states until an \overline{ACK} is received from the Control Bus. (See Figures 3 and 4 for interface waveforms.)

No polling of the Control Bus is required as the interrupt signals for each device are brought into the HPC separately. A simple host interface is provided consisting of two interrupt signals and two eight bit ports, one for read and one for write.

Device U1 is a GAL16V8 (a programmable logic device) and performs all of the logic functions required to generate the control signals used by this system. The programming of this device using the ABEL language is straightforward, as shown by Figure 5.

LCD Direct Drive Using HPC

National Semiconductor
Application Note 786
Santanu Roy

AN-786

INTRODUCTION

Liquid Crystal Displays (LCD) are used in a wide variety of applications. They are extremely popular because of their low power consumption. Manufacturers of Automobiles to Measuring Equipment have taken advantage of these low power displays. Driving LCDs has always been done with dedicated driver chips which not only increase the system cost, but also increase the chip count and board space. This note is developed to demonstrate a low cost solution using the HPC to directly drive LCDs without any driver interface in applications involving LCD display control. A customized 2-way multiplexed LCD (I3420) is being used to illustrate the above capability of HPC microcontrollers in the form of a simple decimal counter.

DRIVING AN LCD

An LCD consists of a backplane and any number of segments which will be used to form the image being displayed. Applying a voltage (nominally 4V–5V) between any segment and the backplane causes the segment to darken. The only catch is that the polarity of the applied voltage has to be periodically reversed, or else a chemical reaction takes place in the LCD which causes deterioration and eventual failure of the liquid crystal. (DC components higher than 100 mV can cause electrochemical reactions in LCDs). To prevent this from happening, the backplane and all the segments are driven with an AC signal, which is derived from a rectangular waveform. To turn a segment *OFF*, it is driven by the same waveform as the backplane. Thus it is always at backplane potential. If a segment is to be *ON*, it is driven with a waveform that is the inverse of the backplane waveform. Thus it has periodically changing polarity between it and the backplane.

MULTIPLEXED LCDs

Today a wide variety of LCDs ranging from static to multiplex rates of 1:64 are available on the market. The *MULTIPLEX* rate of an LCD is determined by the number of backplanes. The higher the multiplex rate the more individual segments can be controlled using only one line e.g., a static LCD has only one backplane and hence only one segment can be controlled using one line. A two way multiplexed LCD has two backplanes and two segments can be controlled with one line. In general if the multiplex ratio of the LCD is N and the number of available outputs is M, the number of segments that can be driven is:

$$S = (M - N) * N$$

i.e., N lines out of M outputs will be used to drive N backplanes, the rest (M – N) outputs are available for segment control. Each line can control N segments, so (M – N) lines can drive (M – N)*N segments. So the maximum number of segments in a 2-way MUX LCD that can be driven with an HPC (if all outputs—16 PortA, 16 PortB, and 4 PortP are used) is:

$$S = (36 - 2) * 2 = 68$$

The number of backplanes in the LCD also determines the number of levels to be generated for their control signals,

e.g., three different voltage levels V, 1/2V, and 0 are to be generated for a 1:2 LCD device (V = operating voltage of the LCD). A *Refresh Cycle* of LCDs (also known as "*Scan Frequency*") is the time period during which all backplanes and segments have to be updated. Typically this is between 39 Hz–208 Hz. During each half of the refresh cycle (*Frame Time*), the polarities of the voltages driving the backplanes and the segments are reversed because of the reason stated above. The current consumption of typical LCDs is in the range of 3 μ A–4 μ A (at V = 4.5, refresh rate 60 Hz) per square centimeter of activated area. Thus the backplane and segment terminals can be treated as Hi-Z loads. At high refresh rates the current consumption of LCDs increases dramatically, a reason why many LCD manufacturers recommend not to exceed a refresh rate of 60 Hz.

LCD CONTROL AND HPC

Figure 1 shows the schematic of the system. With the HPC, each I/O pin can be set individually to TRI-STATE®, "HI" or "LO". Here, in this application, B4 and B5 on the HPC's PortB are selected for backplane control of a 1:2 multiplexed customized LCD—I3420. The three different voltage levels viz. V, V/2, and 0 required for backplane control are achieved through an external voltage divider circuit. The procedure is to set B4 and B5 to "LO" for 0, Hi-Z (configuring them as inputs) for 0.5V, and "HI" for V at the backplane electrodes. For segment control: 8 PortA lines (A0–A7), 4 PortP lines (P0–P3) and 3 PortB lines (B0–B2) are used. All are used as outputs to drive individual segments of the LCD. The HPC in this application is used in single-chip mode to maximize the I/O pin count for LCD control.

TIMING CONSIDERATIONS

Figure 2 shows the backplane and segment waveforms of a typical 1:2 multiplexed LCD. One Refresh Cycle T_{scan} is subdivided into four equally spaced time slots t_a , t_b , t_c and t_d during which the backplane and segment terminals have to be updated in order to switch a specific segment "ON" or "OFF". The voltage waveform during BP– is the mirror image of the waveform during BP+ which satisfies polarity reversal every T_{frame} . Considering a refresh frequency of 50 Hz i.e., $T_{scan} = 20$ ms: t_a , t_b , t_c and t_d are each equal to 5 ms. The timer T2 is used to mark off one time phase ($1/4$ of T_{scan}) of the driving voltage waveform. The timer and autoreload value to get 5 ms time-out is 4999 (decimal) at an operating frequency of 16.0 MHz.

SEGMENT CONTROL

In *Figure 2a*, BP1 and BP2 are the typical backplane waveform of a 2-way multiplexed LCD. During BP+ time, backplane outputs are *ON* for driving voltage level V and *OFF* for the level $1/2$ V. Again for BP– frame time, backplane outputs are *ON* for "0" and *OFF* for " $1/2$ V". Voltage at a particular LCD segment is the resultant of the backplane output and voltage at the line driving that segment. *Figure 2(b)* shows the waveform at an LCD segment. *Figure 2(c)* and *2(d)* are the resultant waveforms with respect to BP1 and BP2 obtained by subtracting the segment waveform in *Figure 2(b)* from the backplane waveforms BP1 and BP2 respectively.

Figure 3 shows the four different waveforms which must be generated at the segments to meet all possible combinations ON and OFF sequence viz. OFF-OFF, ON-ON, ON-OFF, and OFF-ON. A segment is ON if the resultant voltage across it periodically oscillates between +V and -V and is OFF if the swing is between +V/2 and -V/2. The result of the combination is showed in form of white and black circles, representing OFF and ON segments respectively e.g., a waveform pattern "1" will always turn a segment OFF with respect to both the backplanes. However, the waveform "2" will keep it ON with respect to BP1 and BP2. Figurea 4a and Figure 4b show the resultant voltage waveforms at an LCD segment for the above possible combinations and the status of the segment during display operation. Figures 5 and 6 shows the internal segment and backplane connections for a typical 2-way LCD. Figure 7 gives the details of the LCD used in this application.

LCD DRIVE SUBROUTINE

The software for the LCD drive is provided at the end of this application note. The drive subroutine DISPL converts a 16-bit binary value to a 20-bit BCD value for easier display data fetch. This subroutine itself is comprised of a main routine for backplane refresh and seven subroutines (SEGTA, SEGTB, SEGTC, SEGTD, SEGOUT, TMPND, and DISPD). The subroutines SEGTA through SEGTD are used to fetch LCD segment data from a lookup table in ROM for time phases ta, tb, tc, and td respectively. In the table, the subroutine SEGOUT writes these data for each time phase to the respective ports of the HPC connected to the LCD

device. For a refresh cycle of 50 Hz (20 ms), each time phase (1/4 of T_{scan}) is equal to 5.0 ms. This time base is generated by the HPC timer T2 with the associated autoreload register R2. The polling routine TMPND checks for timer underflow flag at the end of each time phase. If the flag is set, it is reset and the program returns to the calling routine. This way a 5 ms time delay is created before the segment and backplane data for the next time phase is updated. The DISPD subroutine switches the LCD OFF by driving the segment and backplane ports to logic "LO". In this application, the display is initialized with "399.9" (which uses all LCD segments) for a BCD down counter. Each count is displayed for a fixed period of time (here a present time of 100 ms is chosen) which is user programmable. The special segments e.g., "m", "A", "V" ... etc. which are not used are all connected together to a common port pin (B2) of the HPC and kept turned OFF throughout the display. It is mandatory to drive any unused segment lines to the OFF state rather than leaving them open or grounded which might result in ghost images.

Note: Selecting the resistors for the voltage divider circuits on B4 and B5 will depend on the type of LCD used.

TYPICAL APPLICATIONS

- Automotive test and control systems
- Weighing scales
- Control Panel
- Microwave
- Clocks and watches etc.

(One segment)

FIGURE 7

Improved UART Cloning Techniques on New Generation HPCs

National Semiconductor
Application Note 798
Ravi Kumar

The new generation HPCs have on-chip UARTs with much better baud rate generation techniques and better status reporting capabilities. This article explains in detail, accurate baud rate generation on HPC46400E and HPC+ UARTs with appropriate examples.

UART implemented on the HPC46400E and HPC+ is an upward compatible enhancement of the UART present on the HPC46083. Unlike the UART on HPC46083, the operating mode may be selected as either Asynchronous or Synchronous. Here we can also select the baud rate through software in conjunction with both prescaler and baud select registers.

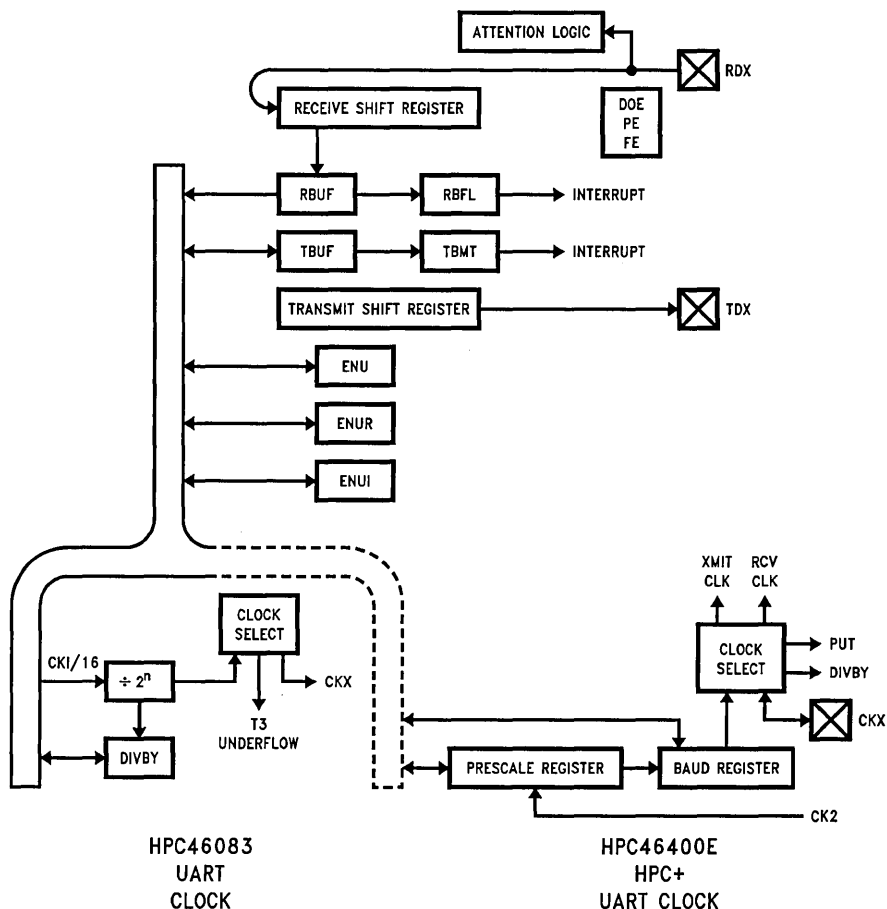

FIGURE 1

TL/DD/11292-1

COMMON FEATURES SUPPORTED BY HPC46083 UART AND THE NEWER VERSION OF UART ON HPC46400E AND HPC+

- Fully programmable serial interface characteristics, including:
 - 8- or 9-bit characters
 - 1 or 2 stop bits
- Two interrupt sources (Receiver buffer full, Transmit buffer empty)
- Independent clock inputs (either on-chip or off-chip) for the transmitter and receiver
- Error reporting capabilities (Data overrun error, framing error)
- Attention or wake up mode for receiver to enhance networking capability

ADDITIONAL UART FEATURES AVAILABLE ON HPC46400E AND HPC+

- Upwardly compatible from earlier HPC UARTs such as HPC16083

- Fully programmable serial interface characteristics, including:
 - Accurate baud rate generation without the penalty of using an expensive crystal up to 625k baud
 - 7-bit characters possible
 - $\frac{7}{8}$, $1\frac{1}{8}$ stop bit lengths
 - Odd, Even, Mark, Space or no parity bit generation and detection
- Selectable Asynchronous or Synchronous mode of operation
- Loopback Diagnostic test capability

Now lets see various methods of BAUD Rate generation. First we shall discuss how DIVBY can be used to generate required baud-rate.

1.0 UART CLOCK SOURCE FROM DIVBY REGISTER

Clock for DIVBY register can be generated using precise value crystals or T3 underflow. Referring to *Figure 2*, we see that baud rate is from internal source for DIVBY register.

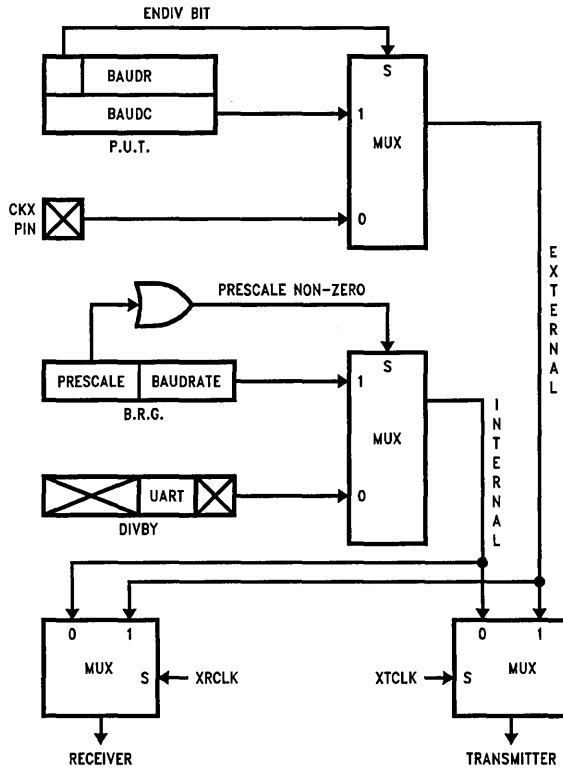

FIGURE 2. Simplified UART Clock Routing

TL/DD/11292-2

The following is a sample assembly language routine illustrating BAUD Rate generation using DIVBY register through precise value crystal.

```

;This program will test the HFCL6400E UART for 9600 baud.
;using 10.0 MHz crystal and DIVBY (baud clock from internal source).
;*****
;The power-up default setup is:
;a) Baud clock from internal source DIVBY
;b) Frame format is 1 start, 8 data, and 1 stop bit.
;The clock should be a 10.0 MHz crystal

.sect uart, rom16

begin:
    sbit 0,Of2.b           ;DIRB reg pin 1 outward direction
    sibit 0,Of4.b         ;BFUNL reg, turns on TDX bit
    rbit 2,0x122.b        ;xtclk
    rbit 3,0x122.b        ;xrclk
    ld 018e.b,#040        ;Load DIVBY from table to generate
                        ;9600 baud (CKI/64)

;The baud clock = baud rate * 16
;So, for 9600 baud, belk = 9600 * 16 = 153600 Hz
;With 10.0 MHz clock → 10.0 MHz/64 = 156250 Hz (within 5%)

xmit:    ld a,#041        ;load char "A"
        st a,0126.b      ;Load TBUF reg to transmit
chk:     ifbit 0,0120.b
        jp xmit          ;continue to xmit
        jp chk

.endsect
.end begin

```

Hence we see the percentage error of Baud Rate produced is:

$$\begin{aligned} \% \text{ error} &= (156250 - 153600)/153600 \\ &= 1.72 \end{aligned}$$

which is within the error limits.

A) Baud Rate Calculation Using DIVBY Register through Precise Value Crystal

Table I gives the bit values to be loaded into UART section of the DIVBY register. This table defines the baud rates for two different crystals at 9.304 MHz and 19.6608 MHz.

We see that more care in selecting the crystal frequency is necessary to generate exact baud rates. Obviously the baud rate generation is restricted by the crystal frequency.

TABLE I

Bit 7	Bit 6	Bit 5	Bit 4	Baud Clock (x16 Clock)	Baud Rate 9.8304 MHz Crystal	Baud Rate 17.6603 MHz Crystal
0	0	0	0	← Not Allowed →		
0	0	0	0	← Defined by Timer T3 Underflow →		
0	0	1	0	CKI/16	38400	65536
0	0	1	1	CKI/32	19200	32768
0	1	0	0	CKI/64	9600	16384
0	1	0	1	CKI/128	4800	8192
0	1	1	0	CKI/256	2400	4096
0	1	1	1	CKI/512	1200	2048
1	0	0	0	CKI/1024	600	1024
1	0	0	1	CKI/2048	300	512
1	0	1	0	CKI/4096	150	256
1	0	1	1	CKI/8192	75	128
1	1	0	0	CKI/16384	38	64
1	1	0	1	CKI/32768	19	32
1	1	1	0	CKI/65536	9.4	16
1	1	1	1	CKI/131072	4.7	8

B) Baud Rate Calculation Using DIVBY Register and Timer T3 Underflow

Suppose we want to generate 9600 baud. In the DIVBY register, load the UART bits with value 0001, which means Baud Clock is defined by T3 underflow (refer to Table I). Once again referring to *Figure 2*, we see BAUD clock is from internal source.

Let's calculate the Pre-Scale value to be loaded into T3 register (0X018C) and R3 register (0X018A)

Baud Clock = Required baud rate \times 16

$$\text{Clock Input} = \frac{\text{Crystal Freq}}{16}$$

$$\text{Pre-Scale Value} = \frac{\text{Clock Input}}{\text{Baud Clock}}$$

In our specific case

required BAUD Rate = 9600

crystal freq = 20 MHz

$$\rightarrow \text{Baud Clock} = 9600 \times 16 = 15360$$

$$\text{Clock Input} = 20/16 = 1.25 \text{ MHz} = 1.25 \times 10^6 \text{ Hz}$$

$$\text{Pre-Scale Value} = \frac{1.25 \times 10^6}{153600} \approx 8$$

Pre-Scale Value = 8

Actual value to be loaded into T3 and R3 register is (Pre-scale value - 1) i.e., 7 in this case.

Percentage error of Baud Rate produced is:

Pre-Scale Value = 8

Baud Rate = Baud Clock/16

Baud Clock = Clock Input/Pre-Scale Value

Clock Input = CKI/16 = 20 MHz/16

= 1.25 MHz

Baud Clock = 1.25 MHz/8 = 156250

Therefore Baud Rate = 156250/16 = 9765.62

Hence % error = (9765.62 - 9600)/9600
= 1.72

Which is within the error limits.

The following is a sample assembly language routine illustrating BAUD Rate generation through DIVBY and T3 underflow.

```

;***** Generation of BAUD clock through timer3 without triggering timer intrpt *****

.sect uart, rom16

chk:          ifbit 0,_enu.b
              jp xmit
              jp chk

.endsect
.end tmr

```

2.0 BAUD RATE CALCULATION USING PUT (PRECISION UART TIMER)

The Precision UART Timer (PUT) is now obsolete and kept only for compatibility with software developed for those earlier components. PUT has two registers i.e., BAUDR with 15-bit divisor field and BAUDC, a 15-bit free-running down counter. These can be programmed to divide the CK2 (CKI/2) clock by a factor of from 3 to 32767, in units of CK2, thus yielding a time base to the UART of higher resolution than that available through the DIVBY register.

Referring to *Figure 2* we see that BAUD clock source for PUT is external.

Suppose the Clock input is 16 MHz and the required baud rate is 9600, then the value to be loaded into BAUDR register will be

$$\text{Required Baud Rate} = \frac{(\text{CK2}/16)}{(\text{BAUDR} + 1)}$$

Where CK2 = CKI/2
Given CKI = 16 MHz
Hence CK2 = 8 MHz

$$(\text{BAUDR} + 1) = \frac{\text{CK2}/16}{\text{Required Baud Rate}}$$

$$(\text{BAUDR} + 1) = \frac{8 \text{ MHz}/16}{(9600)}$$

The following is a sample assembly language routine illustrating BAUD Rate generation through PUT.

```

;This program will test the HPC16400E UART for 9600 baud.
;Using PUT for generating 9600 baud at 20 MHz
.sect code, rom 16
This is for 20 MHz CKI
;
;Using PUT for generating 9600 baud at 20 MHz
.sect code, rom 16
main:

        ld 0x017e.w,#0x0000      ;for 9600 baud @ 20 MHz
        ld 0x017c.w,#0x8033      ;UDIV w/xtclk or xrelk (baud count)
        sbit 2, 0x122.b          ;baud div value to generate 9600 baud
        sbit 3, 0x122.b          ;UDIVR (baud div) register
                                   ;xtclk
                                   ;xrelk

        ld 0f2.b,#0x05           ;DIRB reg pin 1 outward direction.
        ld 0f4.b,#0x05           ;BFUNL reg, turns on TDX bit

;char xmission
ld a,#041                        ;Load char "A"
xmit:
st a,0126.b                      ;Load TBUF reg to transmit

jp xmit                          ;Continue to xmit

.endsect
.end main

```

$$\therefore \text{BAUDR} \approx 52 - 1 \quad 51 \text{ in decimal}$$

and here value to be loaded into BAUDR register will be 33 hex.

Now to select PUT timer as external clock source MSB of BAUDR register must be 1.

$$\begin{array}{r} 1000 \ 0000 \ 0011 \ 0011 \text{ — Binary} \\ 8 \quad 0 \quad 3 \quad 3 \quad \text{— Hex} \end{array}$$

Note: BAUDC must also be loaded with same value (Reload Value).

Percentage error of Baud Rate produced is:

$$\text{BAUDR} = 51$$

$$\text{Therefore Baud Rate} = \frac{8 \text{ MHz}/16}{(51 + 1)}$$

$$= 9615.38$$

$$\text{Required Baud Rate} = 9600$$

$$\text{Hence \% Error} = (9615.38 - 9600)/9600$$

$$= 0.16$$

Which is well within the error limits.

3.0 BAUD RATE CALCULATIONS USING BRG (BAUD RATE GENERATOR).

The most flexible and accurate on-chip clocking is provided by the BAUD Rate generator and (BRG). The BAUD Rate generator is controlled by the register pair PSR and BAUD, shown below. The Prescale factor is selected by the upper 5 bits of the PSR register (the PRESCALE field), in units of the CK2 clock from 1 to 16 in 1/2 step increments. The lower 3

bits of the PSR register, in conjunction with the 8 bits of the baud register, form the 11-bit BAUDRATE field, which defines a baud rate divisor ranging from 1 to 2048, in units of the prescaled clock selected by the PRESCALE field. In Asynchronous Mode, the resulting baud rate is 1/16 of the clocking rate selected through the BRG circuit. The maximum baud rate generated using BRG is 625 kbaud.

TL/DD/11292-3

Formula:

$$\text{Required Baud Rate} = \frac{\text{CKI}}{32 * N * P}$$

where CK = Input Clock

N = Baud Rate Divisor

P = Prescaler Division Factor

Note: This calculation is for Asynchronous mode of UART operation.

Suppose we need 9600 Baud with given Clock i.e., CKI = 20 MHz

then

$$\text{Required Baud Rate} = 9600$$

$$\text{CKI} = 20 \text{ MHz}$$

From formula stated earlier for required baud rate, we have

$$9600 = \frac{20 \text{ MHz}}{32 * N * P}$$

$$\rightarrow N * P = \frac{20 * 10^6}{32 * 9600}$$

$$N * P = 65.1$$

$$\text{or } N = 65.1/P$$

P, which is a prescaler factor, should be selected from Table II in such a way that "N" should be close to an integer. Therefore substituting values of P in the table and calculating N we have the following table.

TABLE II

P Prescaler	N N = (65.104/P)
1	65.104
1.5	43.402
2	32.552
2.5	26.041
3	21.701
3.5	18.601
4	16.276
4.5	14.467
5	13.020
5.5	11.837
6	10.850
6.5	10.016
7	9.300
7.5	8.680
8	8.138
8.5	7.659
9	7.233
9.5	6.853
10	6.510
10.5	6.200
11	5.918
11.5	5.661
12	5.425
12.5	5.203
13	5.008
13.5	4.822
14	4.650
14.5	4.489
15	4.340
15.5	4.200
16	4.069

← Value Closest
to an Integer

Now choose N in such a way that it's closest to an integer. Obviously N = 5.008 is the closest to being an integer therefore, the value of P when N = 5.008 is 13

$$\rightarrow P = 13 \text{ and } N = 5$$

Now from the table "UART Prescaler Factors" select the binary "Prescale field" using the value of N derived above.

Percentage error of the Baud Rate produced is:

from the above table P = 13 and N = 5.008

$$\therefore \text{Baud Rate} = \frac{20 \text{ MHz}}{32 \times N \times P}$$

$$\frac{20 \times 10^6}{32 \times 5.008 \times 12} = 9600.02$$

$$\% \text{ error} = (9600.02 - 9600)/9600$$

$$= 0.0002\%$$

Which is obviously negligible.

UART Prescaler Factors

Prescale Field (Binary)	Prescaler Factor
00000	(Compatibility Mode)
00001	1
00010	1.5
00011	2
00100	2.5
00101	3
00110	3.5
00111	4
01000	4.5
01001	5
01010	5.5
01011	6
01100	6.5
01101	7
01110	7.5
01111	8
10000	8.5
10001	9
10010	9.5
10011	10
10100	10.5
10101	11
10110	11.5
10111	12
11000	12.5
11010	13.5
11010	13.5
11011	14
11100	14.5
11101	15
11110	15.5
11111	16

in Binary format

$$P = 11001 \quad (N - 1) = 100$$

Therefore Prescaler field is $P = 11001$ and baud rate divisor or baud rate field $N = 100$

Referring to BRG register format in page 7 we can combine 5 bits of P and 11 bits of baud rate field to load Prescaler bits (PSR) and Baud Rate generate bits (BRG) respectively.

$$PSR = 11001$$

$$\text{Baud Rate field } (N - 1) = 00000000100$$

Combined value in binary format is

$$1100 \ 1000 \ 0000 \ 0100$$

which in hex is

$$\text{C} \quad \text{8} \quad \text{0} \quad \text{4}$$

therefore load BRG register with C804.

The following is a sample assemble language routine illustrating BAUD Rate generation through BRG.

```

;Baud rate generation using BRG register
;BAUD RATE = CKI/(32 * N * P) where P = 5 bit prescalar value and N = 11 bit
;baud rate filed. For 9600 baud at 20 MHz → NP = 52.083 and so P = 13 and N = 4
;
;At 16 MHz crystal (CKI) for PSR use #0c8 and for BAUD use #07
;At 20 MHz crystal (CKI) for PSR use #0c8 and for BAUD use #04
;*****
.sect code, roml6
main:
                                ;First exit compatibility mode

                                ;ENUI register, 2 stop bits
                                ;DIRB register pin 1 outward direction
                                ;BFUNL register, turns on TDX bit
                                ;Loop to continuously xmit chars at specified baud rate.
xmit:   ld a,#041                ;load char "A"
                                ;Load TBUF reg to transmit
                                ;Continue to xmit.
                                st a,0126.b
                                jp xmit
.endsect
.end main

```

Performance Comparison of PUT and BRG Regarding Higher Baud Rate Generation.

Let's take a case where the required Baud rate is 625k baud at 20 MHz.

PUT:

$$\text{BAUDR} + 1 = \frac{\text{CK2/16}}{\text{Required Baud Rate}}$$

$$\text{Therefore BAUR} + = \frac{10 \times 10^6 / 16}{625 \times 10^3}$$

$$\text{BAUDR} + 1 = 0.1$$

$$\text{BAUDR} = -(0.9)$$

Therefore we see that, PUT can not be used to generate 6.25k baud limit on PUT is 208.3 baud.

BRG:

$$\text{Baud Rate Required} = \frac{\text{CKI}}{32 * N * P}$$

$$625k = \frac{20 \times 10^6}{32 * N * P}$$

$$N \times P = 1$$

$$N = 1 \quad P = 1$$

i.e. Prescale field = 00001 N - 1 = 000

i.e., 000 1000 0000 0000 = 0 × 0800

Therefore load BRG register with 0x 0800 to generate 625k baud @ 20 MHz

Conclusion:

Thus we see that the clocking techniques on new generation HPCs are more accurate and very flexible. Generation of higher rates can be done with relative ease. We can also observe that, using newer UART clocking techniques the percentage error i.e., difference between the required baud rate and the actual baud rate produced goes down significantly.

MICROWIRE/PLUS
Peripherals**

Section 6 Contents

MICROWIRE and MICROWIRE/PLUS: 3-Wire Serial Interface	6-3
COP472-3 Liquid Crystal Display Controller	6-7

MICROWIRE™ and MICROWIRE/PLUS™: 3-Wire Serial Interface

National's MICROWIRE and MICROWIRE/PLUS provide for high-speed, serial communications in a simple 3-wire implementation.

Originally designed to interface COP400 microcontrollers to peripheral devices, the MICROWIRE protocol has been extended to both the COP800 and HPCTM families with the enhanced version, MICROWIRE/PLUS.

Because the shift clock in MICROWIRE/PLUS can be internal or external, the interface can be designated as either bus master or slave, giving it the flexibility necessary for distributed and multiprocessing applications.

With its simple 3-wire interface, MICROWIRE/PLUS can connect a variety of nodes in a serial-communication network.

This simple 3-wire design also helps increase system reliability while reducing system size and development time.

MICROWIRE/PLUS consists of an 8-bit serial shift register (SIO), serial data input (SI), serial data output (SO), and a serial shift clock (SK).

Because the COP800 and HPC families have memory-mapped architectures, the contents of the SIO register can be accessed through standard memory-addressing instructions.

The control register (CNTRL) is used to configure and control the mode and operation of the interface through user-selectable bits that program the internal shift rate. This greatly increases the flexibility of the interface.

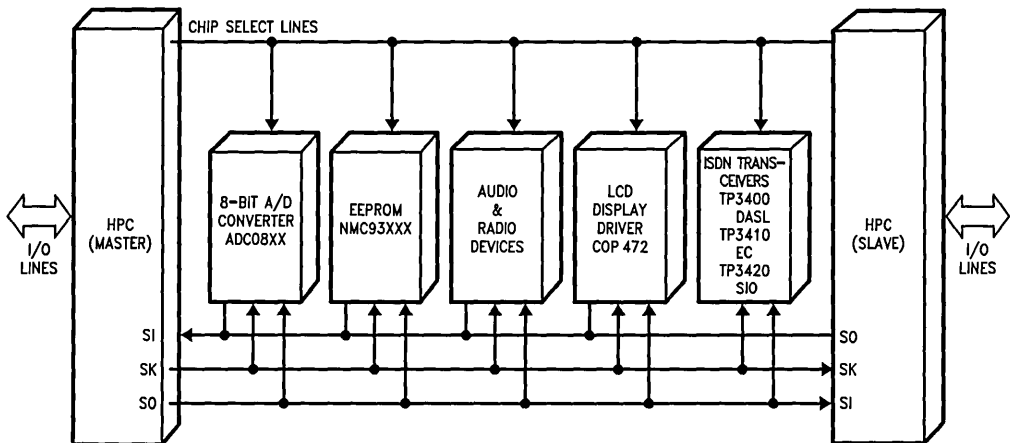

MICROWIRE/PLUS can also provide additional I/O capability for COP800 and HPC microcontrollers by connecting, for example, external 8-bit parallel-to-serial shift registers to 8-bit serial-to-parallel shift registers.

And it can interface a wide variety of peripherals:

- Memory (CMOS RAM and EEPROM)
- A/D converters
- Timers/counters
- Digital phase locked-loops
- Telecom peripherals
- Vacuum fluorescent display drivers
- LED display drivers
- LCD display drivers

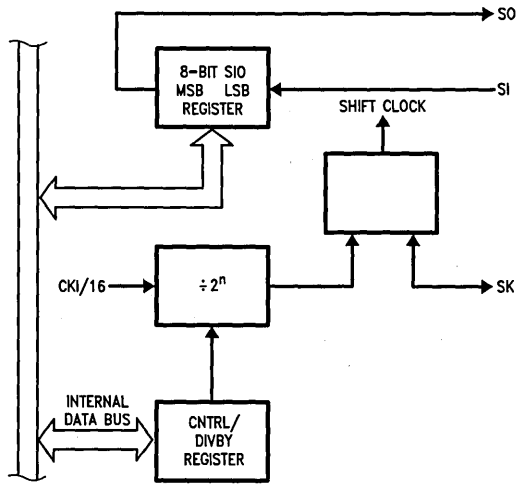

Both MICROWIRE and MICROWIRE/PLUS give all the members of National's microcontroller families the flexibility and design-ease to implement a solution quickly, simply, and cost-effectively.

COP472-3 Liquid Crystal Display Controller

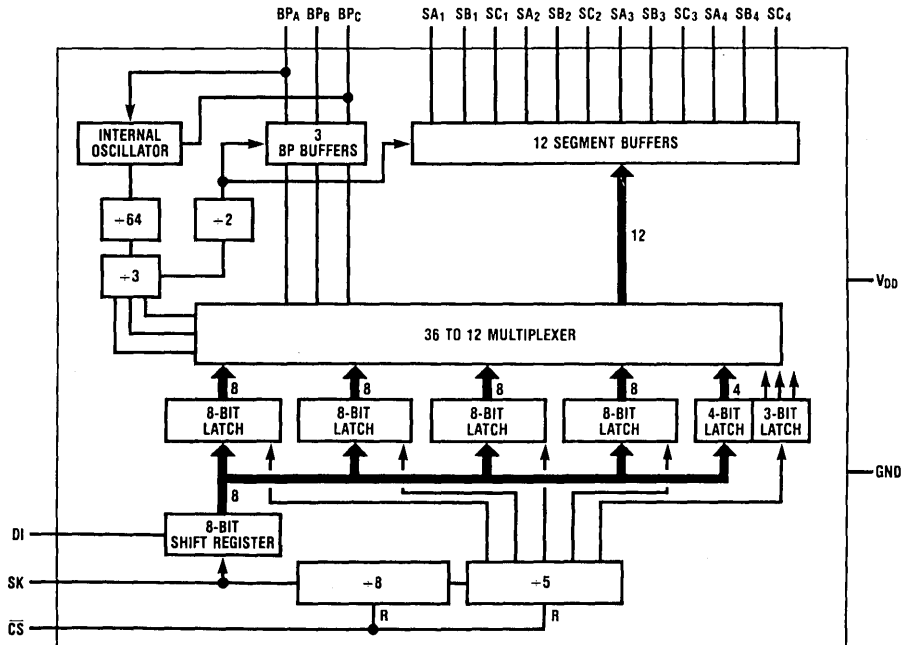

General Description

The COP472-3 Liquid Crystal Display (LCD) Controller is a peripheral member of the COPSTM family, fabricated using CMOS technology. The COP472-3 drives a multiplexed liquid crystal display directly. Data is loaded serially and is held in internal latches. The COP472-3 contains an on-chip oscillator and generates all the multi-level waveforms for backplanes and segment outputs on a triplex display. One COP472-3 can drive 36 segments multiplexed as 3 x 12 (4½ digit display). Two COP472-3 devices can be used together to drive 72 segments (3 x 24) which could be an 8½ digit display.

Features

- Direct interface to TRIPLEX LCD
- Low power dissipation (100 μ W typ.)
- Low cost
- Compatible with all COP400 processors
- Needs no refresh from processor
- On-chip oscillator and latches
- Expandable to longer displays
- Software compatible with COP470 V.F. Display Driver chip
- Operates from display voltage
- MICROWIRE™ compatible serial I/O
- 20-pin Dual-In-Line package

Epson LD-370

Functional Description

The COP472-3 drives 36 bits of display information organized as twelve segments and three backplanes. The COP472-3 requires 40 information bits: 36 data and 4 control. The function of each control bit is described below. Display information format is a function of the LCD interconnections. A typical segment/backplane configuration is illustrated in *Figure 5*, with this configuration the COP472-3 will drive 4 digits of 9 segments.

To adapt the COP472-3 to any LCD display configuration, the segment/backplane multiplex scheme is illustrated in Table I.

Two or more COP472-3 chips can be cascaded to drive additional segments. There is no limit to the number of COP472-3's that can be used as long as the output loading capacitance does not exceed specification.

TABLE I. COP472-3 Segment/Backplane Multiplex Scheme

Bit Number	Segment, Backplane	Data to Numeric Display	
1	SA1, BPC	SH	
2	SB1, BPB	SG	
3	SC1, BPA	SF	
4	SC1, BPB	SE	Digit 1
5	SB1, BPC	SD

SEGMENT DATA BITS

Data is loaded in serially, in sets of eight bits. Each set of segment data is in the following format:

SA	SB	SC	SD	SE	SF	SG	SH
----	----	----	----	----	----	----	----

Data is shifted into an eight bit shift register. The first bit of the data is for segment H, digit 1. The eighth bit is segment A, digit 1. A set of eight bits is shifted in and then loaded into the digit one latches. The second set of 8 bits is loaded into digit two latches. The third set into digit three latches, and the fourth set is loaded into digit four latches.

CONTROL BITS

The fifth set of 8 data bits contains special segment data and control data in the following format:

SYNC	Q7	Q6	X	SP4	SP3	SP2	SP1
------	----	----	---	-----	-----	-----	-----

The first four bits shifted in contain the special character segment data. The fifth bit is not used. The sixth and seventh bits program the COP472-3 as a stand alone LCD driver or as a master or slave for cascading COP472-3's. BPC of the master is connected to BPA of each slave. The following table summarizes the function of bits six and seven:

Q7	Q6	Function	BPC Output	BPA Output
1	1	Slave	Backplane Output	Oscillator Input
0	1	Stand Alone	Backplane Output	Backplane Output
1	0	Not Used	Internal Osc. Output	Oscillator Input
0	0	Master	Internal Osc. Output	Backplane Output

The eighth bit is used to synchronize two COP472-3's to drive an 8½-digit display.

LOADING SEQUENCE TO DRIVE A 4½-DIGIT DISPLAY

Steps:

1. Turn \overline{CE} low.
2. Clock in 8 bits of data for digit 1.
3. Clock in 8 bits of data for digit 2.
4. Clock in 8 bits of data for digit 3.
5. Clock in 8 bits of data for digit 4.
6. Clock in 8 bits of data for special segment and control function of BPC and BPA.

0	0	1	1	SP4	SP3	SP2	SP1
---	---	---	---	-----	-----	-----	-----

7. Turn \overline{CS} high.

Note: \overline{CS} may be turned high after any step. For example to load only 2 digits of data, do steps 1, 2, 3, and 7.

\overline{CS} must make a high to low transition before loading data in order to reset internal counters.

LOADING SEQUENCE TO DRIVE AN 8½-DIGIT DISPLAY

Two or more COP472-3's may be connected together to drive additional segments. An eight digit multiplexed display is shown in Figure 7. The following is the loading sequence to drive an eight digit display using two COP472-3's. The right chip is the master and the left the slave.

Steps:

1. Turn \overline{CS} low on both COP472-3's.
2. Shift in 32 bits of data for the slave's four digits.
3. Shift in 4 bits of special segment data: a zero and three ones.

1	1	1	0	SP4	SP3	SP2	SP1
---	---	---	---	-----	-----	-----	-----

This synchronizes both the chips and BPA is oscillator input. Both chips are now stopped.

4. Turn \overline{CS} high to both chips.
5. Turn \overline{CS} low to master COP472-3.
6. Shift in 32 bits of data for the master's 4 digits.
7. Shift in four bits of special segment data, a one and three zeros.

0	0	0	1	SP4	SP3	SP2	SP1
---	---	---	---	-----	-----	-----	-----

This sets the master COP472-3 to BPA as a normal backplane output and BPC as oscillator output. Now both the chips start and run off the same oscillator.

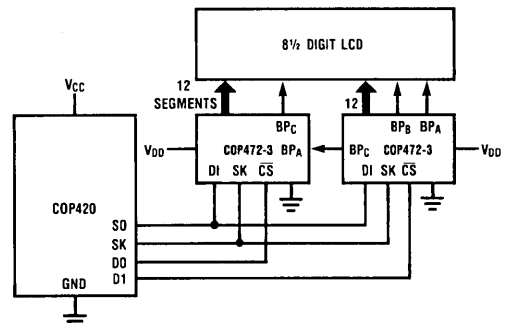

8. Turn \overline{CS} high.

The chips are now synchronized and driving 8 digits of display. To load new data simply load each chip separately in the normal manner, keeping the correct status bits to each COP472-3 (0110 or 0001).

Development Support

Our job doesn't end when you buy a National microcontroller, it only begins.

The next step is to help you put that microcontroller to work—delivering real-world performance in a real-world application.

That's why we offer you such a comprehensive, powerful, easy-to-use package of development tools.

Microcontroller Development Support COP400 Family

The COP^{STM} Microcontroller Development system is a complete, inexpensive system, designed to support both hardware and software development of the COP400 family of microcontrollers.

Using a standard IBM® PC® platform as a host, this system provides the tools to write, assemble, debug and emulate software for user target design.

The development system itself consists of two circuit boards that interface with each other and to the host computer using a software package. The first board is called the Brain Board. It provides the major functional features of the system, linking the various elements of the host system. The other board is called the Personality Board and it is common for all members of the COP400 family of microcontrollers.

Microcontroller Development Support COP800 Family

MetaLink Corporation's iceMASTER™ COP8 Model 400 In-Circuit Emulator provides complete real-time full speed emulation of all COP8 family devices. It consists of a base unit and interchangeable probe cards, which support various configurations and packages. The source symbolic debugger with a window based user interface is a powerful tool to accomplish software and hardware debug and integration tasks.

COP800 code development is supported by a macro cross-assembler running DOS on the IBM compatible PC.

COP800 development is also supported with a low cost Designer's Kit. The Designer's Kit includes a simulator with a window based menu driven user interface and the COP8 cross-assembler. It is a tool designed for product evaluation and code development and debug. It comes equipped with complete debug capability and full assembler. The host for the designer kit is an IBM PC/XT/AT or compatible running DOS.

Microcontroller Development Support HPC™ Family

HPC-MDS is a complete packaged system for all members of the HPC family except for HPC46100. The host system is IBM PC/AT® (PC-DOS, MS-DOS) and Sun® SPARCstation (SunOS™). It provides true real time in-system emulation with support tools such as ANSI compatible C-Compiler, assembler, Linker and Source/Symbolic debugger. The debugger interface is based on MS-Windows 3.0 for IBM PC/AT and a line debugger for Sun SPARCstation users.

HPC-MDS gives the user the flexibility to symbolically debug his code and download it to the target hardware. The user can set breakpoints and traces, can execute time measurements and examine and modify internal registers and I/O.

A low cost HPC designer's kit is also available. The kit has complete in-system emulation capability and is packaged with an evaluation version of C compiler and full package of Assembler/Linker.

The HPC46100 DSP-Microcontroller, is supported by a development kit for ROM emulation, logic and timing analysis, code debug with inverse assembly and PC based debug monitor. The kit consists of a Logic Analyzer Interface Board, a Target Board, Assembler/Linker/Librarian software, an inverse assembler to run on Hewlett-Packard 1650 and 16500A/B logic analyzers and PC based debug monitor, "The Serial Hook".

Third Party development support is also available for various sources for the HPC family.

Hewlett Packard offers HP64775 emulator/analyzer for 30 MHz HPC 16083/16064 and 20 MHz 16400E emulation. The stand alone HP system provides a very fast serial link to the host system and offers complete emulation and timing and logic analysis capability. The software tools for HP emulator are provided by National Semiconductor®.

Signum System offers a USP-HPC in-circuit emulator for the HPC46100 with 40 MHz 1 wait state real time emulation. This system is supported with 256 kbyte overlay emulation memory, 32k frames deep trace buffer memory, complex breakpoints, high level language source/symbolic debugger, fast serial download and a window based menu driven user interface.

The language tools hosted on the IBM PC/AT and compatibles and Sun SPARCstation are available from National Semiconductor to support third party emulation systems.

Emulation Technology offers a passive preprocessor and inverse assembler package for HP1650 and 16500A series of Logic analyzers. The preprocessor provides a low cost and convenient way of doing timing and state analysis of the HPC based design.

Emulation Technology also offers debug tool accessories for 68-pin PLCC and 80-pin (QFP) Quad Flat Packages. This includes PLCC to QFP adapter, QFP test clip and a QFP surface mount replacement base.

Programming support for the HPC emulator devices is available from Data I/O on their Unisite models.

For more details on the third party support tools for NSC's microcontroller products, please contact the third party office in your area or the National Semiconductor sales office.

Dial-A-Helper On-Line Applications Support

Dial-A-Helper lets you communicate directly with the Microcontroller Applications Engineers at National.

Using standard computer communications software, you can dial into the automated Dial-A-Helper Information System 24 hours a day.

You can leave messages on the electronic bulletin board for the Applications Engineers, then retrieve their responses.

You can select and then download specific applications data.

Dial-A-Helper

Voice: (408) 721-5582 (8 a.m.-5 p.m. PST)

Modem: (408) 739-1162 (24 Hrs./day)

Setup: Baud rate 300 bps or 1200 bps 8 bits, no parity, 1 stop

Dedicated Applications Engineers

We've assembled a dedicated team of highly trained, highly experienced engineering professionals to help you implement your solution quickly, effectively, efficiently and to ensure that it's the best solution for your specific application.

At National, we believe that the best technology is also the most usable technology. That's why our microcontrollers provide such practical solutions to such real design problems. And that's why our microcontroller development support includes such comprehensive tools and such powerful engineering resources.

No one makes more microcontrollers than National and no one does more to help you put those microcontrollers to work.

COP400 (COPS™ DS) Microcontroller Development Support

TL/DD/8630-14

Development Tools

The NSC Microcontroller On Line Emulator Development System is designed to support the development of NSC COPS Microcontroller products. This system provides effective support for the development of both software and hardware in Microcontroller-based applications.

A system consists of three components: a Brain Board, a Personality Board, and software for a host computer. The host may be an IBM®-PC, or one of a number of inexpensive PC compatibles. The cross-assemblers and debugger provided by National Semiconductor will run under control of the host computer MS-DOS operating system.

The Brain Board provides the development system with the capability of communicating with the user's Host CPU. Resident firmware on the Brain Board allows the user to download assembled load modules over the RS-232 link from the host computer, display and alter code initiate Breakpoints, Traces, and timing on addresses and external events, examine and modi-

fy the internal resources of the microcontroller being emulated. The Brain Board also provides all the hardware and firmware to program standard EPROMs up to 27256's (32k x 8).

The Personality Board supports the emulation of the COP 400 family of microcontrollers.

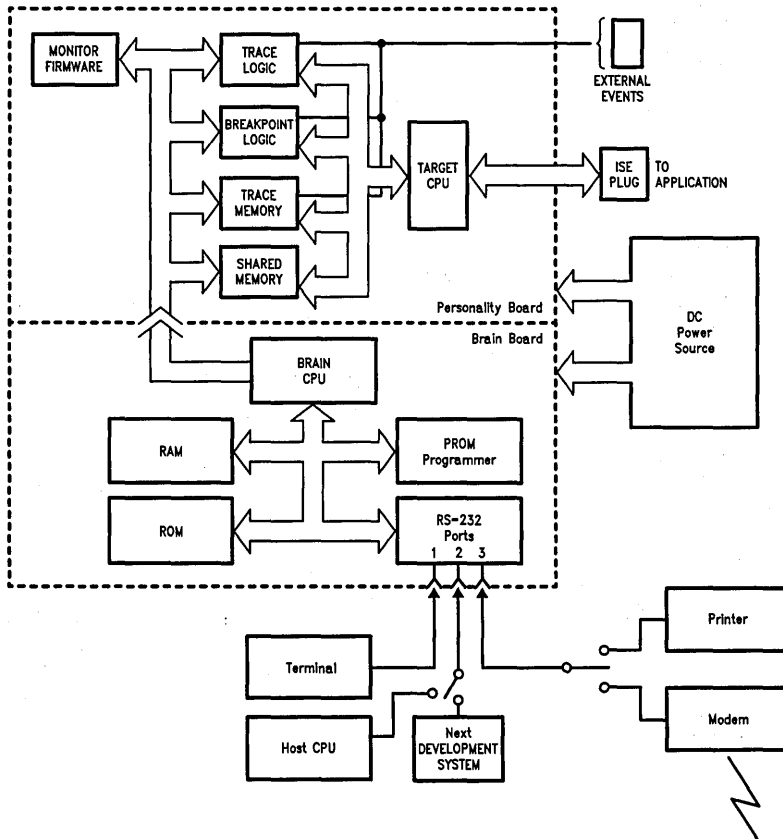

The host CPU contributes cost effective bulk storage and high speed processing. Disk editing and assembly operations are controlled by the host CPU. The results are down loaded to the Brain Board over the RS-232 link.

The Microcontroller On-Line Emulator Development System concept provides the user with a powerful development system based around a familiar host. The Brain Board/Personality Board/Host combination provides FULL emulation capability. This modular design provides maximum flexibility and maximum utility for the development of Microcontroller based systems.

TL/DD/8830-3

System Block Diagram

TL/DD/8830-2

Brain Board

TL/DD/6830-19

General Description

The Brain Board is the pivotal component of the development system concept. In conjunction with a terminal and Personality Board it provides the user with a freestanding workstation for Microcontroller emulation. It ties the system together by communicating with the Personality Board, printers, modems, optional host computer, and other Brain Boards. Multiple Brain Boards, tied to a common host, can function as emulators for individual projects where each Brain Board is a separate workstation. They can also function as individual Microcontroller emulators within a multicontroller system.

The Brain Board utilizes a NSC800™ Microprocessor with 64k RAM and firmware ROM. It has an EPROM programmer for on-line changes. There are three RS-232 ports and a bus to connect the Brain to the Personality Board for actual emulation of code in the user's application system.

The RS-232 ports are used via the communication routines in firmware to interface with a host computer, terminal, modem, printer, or other development systems, for greater flexibility during system development.

The development system firmware is controlled by an EXEC. There are three major sets of EXEC commands. The first set of commands are calls to other main programs. These are:

COMM	Invoke Communications Program
DIAG	Invoke Diagnostics Program
MONITOR	Invoke Personality Emulation Monitor
PROG	Invoke PROM Programming Program

The second set of EXEC commands are:

CALC	Adds/Subtracts decimal and hex numbers
COMPARE	Compares one buffer with another
ERASE	Used to erase all or part of a buffer
HELP	Prints a summary of EXEC commands
MOVE	Moves data from one buffer to another
STATUS	Display status of buffers, display and alter RS-232 parameters

The third set of commands are used exclusively for multiple system configurations and they are:

CONNECT	Connect the user with the requested system
DISCONNECT	Disconnects the system
IDENT	Identifies the system

The Brain Board supports NSC's COP4 development system Personality board.

Features

- Single 5V operation
- Ability to interface to host computers
- Full communication control of other systems with host computer and a modem
- Three RS-232 ports
- Auto baud selection (110, 300, 600, 1200, 2400, 4800, 9600, 19200 baud)
- Self diagnostics

Features (Continued)

- Program EPROMS
 - MM2716, NMC27C16
 - MM2732, NMC27C32
 - NMC2764
 - NMC27256

PHYSICAL SIZE
10" x 12"

POWER REQUIREMENTS

+5V DC @ 3.5A
+12.5/ +21V or +25V @ 50 mA
(Optional—required only for PROM programming)

COP400 Family Personality Board

COPS Personality Board

TL/DD/8830-6

General Description

The COPS Family Personality Board supports the emulation of COP400 family of Microcontrollers. The Personality Board allows the user to emulate the appropriate Microcontroller in the user's end system for fast development of application code and hardware. The Personality Board consists of: a Monitor, the hardware to control the operation of the Microcontroller in the emulation system, and an emulation cable to connect the emulator to the application system. The cable has the same pin configuration as the final masked part.

The Personality Board Monitor is contained in firmware ROM, contains an assembler and disassembler and is directly executable by the NSC800 on the Brain Board. The Monitor commands will allow the user to execute the application code, examine and modify internal registers and I/O, examine and alter object code in hex or mnemonic format, execute Time measurements, and set Trace and Breakpoints.

The Personality Board also contains 2k bytes of shared memory (RAM) for application code and the necessary hardware for Trace and Breakpoint operation.

Features

- Supports entire COPS CMOS and NMOS family
- Single 5V operation
- Firmware monitor
- Firmware diagnostics
- Firmware Line-by-Line Assembler and Unassembler
- 2k bytes of shared memory
- 256 deep trace memory
- Eight external event inputs
- Trace on multiple addresses, address ranges, or external events
- Breakpoint on multiple addresses, address ranges or external events
- List and alter shared memory
- Print and modify internal registers
- Singlestep
- Next—singlestep around subroutine calls
- Trigger output for logic analyzer
- Real time emulation

Features (Continued)**Common Monitor Commands**

Alter	Alter consecutive bytes in shared memory
AUtoprint	Specify information to be printed on Breakpoint
Breakpoint	Set trigger point(s) for Breakpoint
Clear	Clear Breakpoint, Time and Trace functions
Deposit	Deposit byte value into range of shared memory
Dlagnostic	On-board test routine for system checkout
Find	Find data or string in shared memory
Go	Start program execution or enable function
Help	On-screen Help menu
List	List data in shared memory
Modify	Modify on-chip RAM or Registers during Breakpt
Next	Singlestep through subroutine
Put	One-line assembler
Reset	Reset chip
RGo	Reset chip and execute Go automatically
SEarch	Search Trace memory for data or address
Singlestep	Execute one instruction, then Breakpoint
STatus	Show chip and development system Status
Time	Time program execution or external events
TRace	Specify triggers for capturing Trace data
Type	Type Trace data or on-chip data during Breakpt
Unassemble	Disassembler for Trace or shared memory
Chip	Specify COP device to emulate
Option	Specify COP chip options being emulated
Set	Set special emulation options

PHYSICAL SIZE

12" x 12"

 National Semiconductor

COP800 Development System

iceMASTER™ COP8/400

TL/DD/11386-1

Product Overview

The iceMASTER COP8/400 in-circuit emulator manufactured by MetaLink Corporation and marketed by National Semiconductor provides complete real-time emulation support for all members of the COP8 family. This stand-alone system is designed to provide maximum flexibility to the user through the interchangeable probe cards to support the various configurations and packages of the COP8 family. The interchangeable probe card connects to a common base unit which is linked with an IBM® PC® host through the RS-232 serial communications channel. Full assembly-level symbolic debugging is supported.

MetaLink COP8 iceMASTER Feature List

- Flexible, easy-to-use windowed interface, with window size, position, contents and color being completely configurable.
- Fast serial download with 115.2 kBaud using a standard PC COMM port.
- Context-sensitive hypertext on-line help system.
- Commands can be accessed via pull-down menus and/or redefinable hot keys.
- Dynamically annotated code feature displays contents of all accessed (read and write) memory locations and registers, as well as flow-of-control direction change markers next to each instruction executed when single-stepping.
- 4k-frame trace buffer captures data in real-time. Trace information consists of address and data bus values and user-selectable probe clips (external event lines). Trace buffer data can be viewed as raw hex or disassembled instructions. The probe clip bit values can be displayed in binary, hex or digital waveform formats.
- Performance analyzer with a resolution better than 6 μ s. Up to 15 independent memory areas based on code address, line number or label ranges can be defined. Analysis results can be viewed in bar graph format or as actual frequency count.
- 32k of break and trace triggers. Triggers can be enabled, disabled, set or cleared. They can be simple triggers based on code or address ranges or complex triggers based on code address, direct address, opcode value, opcode class or immediate operand. Complex breakpoints can be ANDed and ORed together.
- Memory operations for program memory include single-line assembler, disassembler, view, change, and write to file.
- Memory operations for data memory include fill, move, change, compare, dump to file and examine, modify for registers and program variables.
- Complete status of debugger including breakpoints, trace triggers, etc. can be saved to file for later resumption of debugging process.

COP800 DESIGNER'S TOOL KIT

TL/DD/11386-2

General Description

The COP800 Designer's Tool Kit is available today to help you evaluate National's COP800 microcontroller family. The Kit contains programmer's manuals, device data sheets, application notes, and pocket reference guides for immediate in-circuit evaluation. The Designer Kit includes an assembler and simulator, which allow you to write, test and debug COP800 code before your target system is finalized.

The simulator can handle script files that simulate hardware inputs and interrupts to the device being simulated. Any simulator command and comments may be included in a script file. The simulator also supports an additional command called WAIT, used to simulate machine cycles to delay before continuing with the script file.

A capture file feature enables you to record current cycle count and changes to an output port which are caused by the program under test. When used in combination with script files, this feature provides powerful software testing and debug capability.

Features

- Software simulator
- Assembler
- Programmer's manuals
- Device data sheets
- Application notes
- Assembler manual
- Tool kit user's guide
- Pocket reference guides
- COP8 SIM user's guide

Features (Continued)**Simulator Commands**

@RAM [ramadd]	Causes a break in execution to occur when a write to the specified RAM location is attempted.	LISTON	Turns on screen listing during stepping.
ASM [add]	Assembles directly to ROM at specified address or starting at last address used by command.	LISTOFF	Turns off screen listing.
BR [add]	Set breakpoint at the indicated ROM address.	LOAD filename	Loads Intel hex format file into simulator.
CAPTURE fname	Saves all hardware outputs in the file specified.	PRINTON	Sends all debug output to printer.
CAPTUREOFF	Stops capture and closes capture file.	PRINTOFF	Stops sending debug output to printer.
CY n	Sets cycle counter.	RAM add [n]	Sets RAM location at indicated address to value specified.
DASM [add]	Disassembles memory to screen starting at specified address or last location disassembled.	REG	Shows register status in debug window.
EVAL n [op] [n]	Evaluates input in decimal, hex, and binary. Can do simple calculations where op may be +, -, /, or *.	RESET	Simulates a hardware reset.
GO [add] [add]	Sets breakpoint at second address. Go from first address.	RESTORE fname	Restores simulator state from a file created with the SAVE command.
GOTIL add	Go from the current PC until the PC = add.	ROM add [n]	Sets ROM location at indicated address to value specified.
		SAVE filename	Saves the simulator state in the specified file.
		SCRIPT fname	Executes a script file.
		STEP [n]	Single step execution of n instructions.
		STEPTIL add	Single step until the PC = add.
		QUIT, EXIT	Return to DOS.

HPC™ Microcontroller Development System

TL/DD/11211-1

General Description

The HPC Microcontroller Development System provides an optimized environment for real time emulation and software debugging for High Performance Controller (HPC) based designs. The system features National's powerful C and Assembly Source/Symbolic debugger. Development software consisting of an ANSI compatible C compiler/Assembler/Linker is hosted on an IBM® PC-AT® class computer as well as Sun® SPARCstations, with automatic download capability provided by the Source debugger through serial link to user target system. Microsoft™ Window 3.0 is used as the user interface for IBM hosts. A line debugger is supported for Sun SPARCstation under Sunview. HPC-MDS gives you complete control over hardware/software development, integration and debug.

The Source/Symbolic debugger provides a pull down menu, multiple windows and on-line help to make the system easy to learn and use. The Source/Symbolic debugger supports real-time transparent emulation to 20 MHz, one wait state for the entire HPC microcontroller product family. The Source/Symbolic debugger

is also equipped with interactive tutorials which would allow faster learning of the HPC-MDS environment.

The Real time trace capability is fully supported by the Source/Symbolic debugger. The debugger will allow complete trace and breakpoint triggering on C or Assembly Source statements, labels, symbols or line numbers. The system offers 8 hardware breakpoints with capability to break on multiple addresses, address ranges or external events.

Features

- 20 MHz 1 wait state real time emulation
- 2k x 48-bit Trace Memory
- 8 hardware breakpoints with break on 8 multiple addresses, address ranges or external events
- 64k x 8-bit emulation memory in 4k bytes mapping
- Real time trace
- External input events captured in trace
- Single line assembly/disassembly
- Modular designed POD cable for optimum AC emulation and ease of upgrading
- Fully supports development of system using HPC in Extended Memory mode
- Complete Source/Symbolic debug
- Graphical user interface (MS-WINDOWS)

Physical Dimensions

Weight:	22 lbs	Height	15½"	Depth	17½"
Width	7⅞"				
Cable Length:		Emulator to POD		29¾"	
		POD to Target		3⅜"	

HPC-MDS Monitor Commands

Alter	Alter consecutive bytes in shared memory
AUtoprint	Specify information to be printed on Breakpoint
Breakpoint	Set trigger point(s) for Breakpoint
Clear	Clear Breakpoint, Time and Trace functions
Deposit	Deposit byte value into range of shared memory
Dlagnostic	On-board test routine for system checkout
Find	Find data or string in shared memory
Go	Start program execution or enable function
Help	On-screen Help menu
List	List data in shared memory
Modify	Modify on-chip RAM or Registers during Breakpt
Next	Singlestep through subroutine
Put	One-line assembler
Reset	Reset chip
RGo	Reset chip and execute Go automatically
SEarch	Search Trace memory for data or address
Singlestep	Execute one instruction, then Breakpoint
STatus	Show chip and development system Status
Tlme	Time program execution or external events
TRace	Specify triggers for capturing Trace date
Type	Type Trace data or on-chip data during Breakpt
Unassemble	Disassembler for Trace or shared memory
AlterWord	Alter consecutive words in shared memory
BAnk	Specify bank trigger information
CHip	Select chip and specify system memory map
DepositWord	Deposit word value in range of shared memory
End	Exit Monitor and return to Exec
ERror	Enable/disable HPC access error checking
EXclusion	Specify address ranges to exclude from Trace
FindWord	Find word values in shared memory
ListWord	List shared memory or memory range as words
MAp	Specify address range of memory on-board development system
XMove	Move data from one address range to another

HP 64700 Series Emulators/Analyzers for National Semiconductor HPC16003, 16083, 16004, 16064, 16400E

TL/DD/11211-3

Real-Time, Transparent Emulation and Analysis

Description

HP 64700 Series Emulators/Analyzers provide real-time, transparent emulation and analysis for National Semiconductor's HPC family of 16-bit microcontrollers.

Model 64775 emulator/analyzer is a self-contained emulation and analysis vehicle tuned for development of HPC16003, 16083, 16004, 16064, and 16400E based systems. HP 64775 emulator/analyzer focuses on powerful, nonintrusive analysis to trace complex program flow and characterize overall system performance. Choice of user interface plus high-speed program download maximize system integration efficiency. Reliable target system connection is made through a slim, flexible 1.5-foot cable ending in a PLCC probe, with an adapter for PGA.

Software development tools from National Semiconductor include a C compiler, assembler, and linker hosted on both the PC and the HP 9000 Series 300 workstation. A PC-hosted debugger is also available, which runs under Microsoft Window 3.0.

Powerful real-time, nonintrusive logic analysis functions use HP's "logic analyzer on-a-chip" technology.

A 48-channel state analyzer traces address, data, and status conditions.

In expanded memory applications, addresses can be treated as a 4-bit bank code plus a 16-bit offset in user-selectable bank-switch models. Eight hardware and 32 software breakpoints give the user enhanced control over the analysis of complex instruction expressions, ranges, and sequences without altering program code. An optional 16-channel external analyzer allows for a choice of synchronous or asynchronous signal analysis.

Emulation Features

- Real-time, zero-wait-state operation to 20 MHz with 32k bytes of emulation memory for internal ROM support (not available for HPC16400E)
- 128k bytes of real-time emulation memory for external memory support to 30 MHz (20 MHz for HPC16400E)
- Mapping terms of RAM, ROM, or guarded memory accesses
- Target/emulation memory mappable in 256 byte blocks
- 8 real-time hardware breakpoints

Emulation Features (Continued)

- 32 software breakpoints
- Hybrid foreground/background monitor with shared NMI entry; both modifiable with user-supplied routines
- Full support for user-selectable bank-switching models—20-bit addressing range
- Emulation support for 8- or 16-bit memory and 16-bit on-chip memory
- 1.5 ft, slim, flexible cable ending in a PLCC emulation probe, with PGA adapter
- Full coordinated measurement bus for synchronizing or cross triggering up to 32 HP 647xx emulators
- 48 channels of state analysis with optional 16-channel external state/timing analysis
- Choice of user-interface software: firmware-based ASCII interface for true host-independent operation; MS-DOS multiwindow interface on IBM PC, HP Vectra PC, and compatibles enhances ease of use with popular low-cost platforms; or HP 9000 Series 300 computer offers the advantages of a powerful multiuser, multi-tasking platform
- For more Information call 1-800-447-3282

HPC Designer's Kits

HPC Designer's Kits

TL/DD/11211-2

General Description

The HPC Designer's Kit is a 16-bit microcontroller Development System for program development and real-time emulation. An on-board HPC microcontroller executes monitor firmware and also acts as the target processor.

When used as the target processor, all of the features of the HPC are available for use in the application. All operating modes of the HPC are supported, with up to 8k bytes of addressable memory available for application programs.

This kit contains all of the components, manuals, and software to design an HPC system. Just add an IBM or compatible PC, +5V DC 1.0A power supply and RS232 cables.

The development package has a complete Assembler/Linker/Librarian with no code limitations and an evaluation C-Compiler.

Features

- Supports HPC microcontroller family
- Single 5V operation
- Firmware monitor directly executed by the HPC
- Firmware diagnostics directly executed by the HPC
- Firmware Line-by-Line Assembler and Unassembler
- 8k bytes of user program memory
- Breakpoint on multiple addresses
- List and alter memory
- Print and modify internal registers
- Singlestep
- Real time emulation
- Evaluation module that allows up to 1000 lines of code to be developed for evaluation purposes

Emulation Features**HPC Development Board Monitor**

Alter	Alter consecutive bytes in shared memory
AUtoprint	Specify information to be printed on Breakpoint
BAud	Set or display the host or terminal Baud rate
BYpass	Connect terminal port to host port
Breakpoint	Set trigger point(s) for Breakpoint
Clear	Clear Breakpoint function
Deposit	Deposit byte value into range of shared memory
Dlagonstic	On-board test routine for system checkout
Go	Start program execution
Help	On-screen Help menu
List	List data in shared memory
ListUnassemble	List shared memory in mnemonic form
LOad	Load hex object file from terminal or host port
Modify	Modify on-chip RAM or Registers during Breakpt
ModifyByte	Modify on-chip RAM or registers as bytes
ModifyWord	Modify on-chip RAM or registers as words
Put	One-line assembler
Restart	Restart HPC chip
Singlestep	Execute one instruction, then Breakpoint
Type	Type on-chip data during Breakpoint
Unassemble	Disassembler for shared memory

HPC Plus (HPC46100) Development Kit

TL/DD/11211-4

General Description

The HPC Plus Development kit is a low cost development tool package for HPC46100. The kit contains HPC software and hardware which enables the user to assemble, link and download the user programs and debug the code running on the application target with the help of the debug software hosted on IBM PC/AT compatible machines running DOS operating system.

The Development kit is a combination of PROM Emulator, Logic Analyzer Interface, with a PROM based Monitor and a Host software (Serial Hook) which communicates to the Development kit through the serial COM port on the PC. It also has an evaluation board (Design and Test Board) for the users who don't have their target board designed yet, but want to verify the program.

The Serial Hook and the Monitor Firmware together give the ability to debug the application run by the target HPC at full speed. The Logic Analyzer Interface helps the user to connect HP1650/16500 analyzer easily and trace the code execution. The kit also contains configuration and inverse assembly software for the HP analyzer with which one can analyze the code in the disassembled form.

The kit comes with all the necessary hardware components and user needs the IBM PC/AT running DOS 3.0 or above and a +5V DC 1.0A power supply.

The software package provided along with the kit contains the HPC Assembler/Linker/Librarian, Serial Hook Host interface software and the HP Logic Analyzer configuration/inverse assembly floppy.

Features

- Supports HPC46100 microcontroller
- Single supply +5V operation
- Compact Monitor Firmware executed by Target HPC
- Target Access through EPROM Socket
- 64k bytes of emulation memory
- Monitor reserved address space mappable
- Program control through Break Point, Single Step
- Memory and Register examine and Alter commands
- Real Time emulation
- Honor Interrupts while break pointed
- Unrestricted Assembler package

Accessories from Emulation Technology

HP PREPROCESSOR FOR HPC FAMILY

The preprocessor provided by Emulation Technology simplifies inter-connection between the HP-1650A/B, 16510A/B series of logic analyzers and the HPC family of microcontrollers when used in the ROMless mode. It will provide all clocking and status lines to capture and decode the operation of the HPC Microcontroller.

The preprocessor is available in 68-pin PLCC and 80-pin PQFP inserts. The inverse assembler software included in the package, configure logic analyzer and translate data into HPC specific mnemonics. The user can compare the resulting display to the original assembly language code to help debug the software.

HPC-Microcontroller Development System

HOST SYSTEM REQUIREMENTS

IBM PC/AT Hosts

Without Source/Symbolic Debugger

IBM PC/AT or 100% compatible with 512k bytes of available user memory PC-DOS or MS-DOS 3.0 or above

5.25" floppy drive capable of reading double sided high density format diskette. One RS-232 synchronous serial port for Communication.

With Source/Symbolic Debugger with Graphical User Interface

2 Mbytes of available user memory

MS-Windows 3.0

A Serial or Bus mouse

Sun Workstation Hosts

Sun SPARCstation 1 or 2

SunOS™ version 4.0.3 or later

HPC™ Software Support Package

TL/DD/9727-1

■ **Choice of host systems**

- IBM® AT PC-DOS, MS-DOS
- SunOS™ SPARC Station

■ **CCHPC C Compiler**

- ANSI Standard C
- Additional storage class modifiers supported
- Additional statement types included
- Supports embedded assembly code
- Supports multiple source files

■ **ASM HPC Assembler**

- Macro and conditional assembly
- Instruction size optimization
- Symbol table and cross reference output
- Object files are linkable and relocatable

■ **LIBHPC Librarian**

- Supports user developed library modules

■ **LNHPC Linker**

- Links multiple relocatable object modules
- Selects required modules from library files

■ **DBHPC Source debugger**

- C Source, Assembly Symbolic debugger
- Microsoft Window 3.0 user interface for IBM PC/AT hosts
- Line debugger under Sunview for SunOS SPARC Station hosts

General Description

Software Development tools available from National consist of ANSI Compatible C Compiler with hardware specific extension to produce HPC optimized Code. HPC Assembler package has been designed to produce instruction size optimized relocatable object code for speed critical applications. HPC cross linker is used to link object modules produced by assembler or selected from the library file.

The most critical phase of development is when the designer has to integrate and debug hardware and software. National provides a C source and Assembly symbolic debugger. The user interface is MS-windows for PC/ATs and a line debugger under Sunview for Sun SparcStations. This graphical interface is user friendly and provides graphical menu driven debug environment. Source/Symbolic debugger fully supports all features of HPC-MDS and HP64775 emulator/analyzer for real time hardware emulation, breakpoints and trace. Multiple windows can be user defined and will display source file listing, symbols and debugger status. Top figure shows the interaction of software

packages and In-System Emulator. NSC and HP have worked together to ensure that all modes of HPC are properly emulated and development software works properly with HP Emulator/Analyzer.

All HPC development software is hosted on IBM PC/AT, operating in MS-DOS or PC-DOS environment and under UNIX environment supporting SUN operating system using SPARC Station as the host.

The assembler produces relocatable object modules from the HPC macro assembly language instructions. The object modules are then linked and located to absolute memory locations. The absolute object module may be downloaded to the HPC-MDS development system or HP64775 Emulator for debugging.

The C compiler generates assembly source. The C compiler may optionally pass symbolic information through the assembler and linker to the absolute object module. The source debugger then uses this information for C and Assembly language debugging on the host in conjunction with MDS or HP64775.

HPC C Compiler—CCHPC Introduction

The HPC C Compiler (CCHPC) is a full and complete implementation of ANSI Standard C for freestanding environment. Certain additions are included to take advantage of special features of the HPC (for the specific needs of microcontrollers). The enhancements include the support of two non-standard statement types (loop and switch), non-standard storage class modifiers and the ability to include assembly code inline. The compiler supports enumerated types of structures by value, functions returning structures, function prototyping and argument checking.

Symbol Names, both internal and external, are 32 characters. Numerics are 16-bit for **short** or **int**, 32-bit for **long**, and 8-bit for **char**, all as either **signed** or **unsigned**; floating point is offered as **float** or **double**, both using IEEE format.

All data types, storage classes and modifiers are supported. Additional storage class modifiers are provided:

BASEPAGE place **static** variable in faster and more efficient on-chip basepage memory.

NOLOCAL declare function without local variables, thus no stack frame.

INTERRUPTn declare function to execute in response to specific interrupt(s).

ACTIVE declare function to be accessed via faster and more efficient function call mechanism.

All statement types are supported, and two additions are provided:

loop (count) simpler, more efficient **for** looping command.

switchf (value) faster form of **switch** command without constraint checking.

CCHPC SPECIFICATIONS

Note: Enhancements are boldface.

Name length	32 letters, 2 cases
Numbers	
Integer, Signed and Unsigned	16–32 bits
Short and Long	16 bits and 32 bits
Floating, Single and Double	32 bits and 32 bits

Preprocessor

```
#include
#define #define() #undef
#if #ifndef #ifndef #if defined #else #elif #endif
```

Declarations

```
auto register const volatile BASEPAGE
static static global static function NOLOCAL INTERRUPTn ACTIVE
extern extern global extern function
char short int long signed unsigned float double void
struct union bit field enum
pointer to array of function returning
type cast typedef initialization
```

Statements

```
; { ... } expression; assignment; structure assignments;
while () ...; do ... while (); for(;;) ...; loop () ...;
if () ... else ...; switch () ...; case: ...; default: ...; switchf () ...;
return; break; continue; goto ...; ...;
```

Operators

```
primary: function() array[] struct_union . struct_pointer ->
unary: * & + - ! ~ ++ -- sizeof (typecast)
arithmetic: * / % + - << >>
relational: < > <= >= == !=
boolean: & ^ | && ||
assignment: = += -= *= /= %= >>= <<= &= ^= |=
misc.: ? ,
```

Functions

```
arguments: Numbers, Pointers, Structures
return values: Numbers, Pointers, Structures
forward reference (argument checking)
```

Library Definition **Limited-Freestanding environment**

Embedded Assembly Code

HPC C Compiler—CCHPC Introduction (Continued)

All operators are supported, and anachronisms have been eliminated (as per the standard). Structure assignment, structure arguments, and structure functions are also supported. Forward reference functions and argument type checking is supported.

Assembly code may be embedded within C programs between special delimiters.

COMPILER COMMAND FEATURES

The CCHPC runs under different host operating systems. Depending on the host system and the CCHPC command line options, ordering of the elements and their syntax may vary. In all cases, the command line consists of the command name, options or switches, and the filename to be compiled.

The compiler output, in the form of ASMHPC assembler source statements, is put in a file with the extension ".asm".

The following is a description of the CCHPC options or switches:

Include C code in assembler code output—Assembler output file contains the C source code lines as comments.

Invoke C preprocessor before compilation—Allows the C preprocessor invocation to be skipped.

Invoke an alternative C preprocessor before compilation—Allows an alternative preprocessor to be used.

Setting the stack size—This switch takes a numeric argument in the form of a C constant. If the module being compiled contains the function main, the compiler uses the number as the size of the program's execution stack, in words. The option is ignored if the module does not contain main.

Creating 8-bit wide code—This switch creates code that can be executed from 8-bit wide memory by avoiding the use of instructions that fetch 16-bit operands (such as JIDW). This option DOES NOT allow the use of 16-bit values or data in 8-bit memory.

Placing string literals in ROM—The ANSI draft language standard calls for string literals, and individual copies for each usage of the literal to be stored in RAM. This switch allows CCHPC to override this requirement for efficiency, saving startup time, RAM and ROM space. Turn off compiler warning messages.

Indicating directories for include files—This switch takes a string argument which is passed to the C preprocessor. The C preprocessor uses it as a directory to search for include files.

Defining symbol names—This switch passes the string argument to the C preprocessor. It instructs the preprocessor to perform the same function as the #define, allowing the symbol definitions to be moved to the invocation line.

Undefining symbol names—Similarly, this switch passes a string argument to the C preprocessor. It removes any previous definitions.

Permit old-fashioned constructs—Certain anachronisms from Kernighan and Ritchie C that are not permitted in ANSI C will be accepted by the compiler if this option is specified. This option is a convenience for users porting a C program to CCHPC from a Kernighan and Ritchie compiler.

Set chip revision level—This switch is used to generate code to work around bugs in specified chip revisions.

Generate symbolic debug information—This option causes the compiler to create symbolic debug information which is passed to the output assembly file.

BASIC DEFINITIONS

Names may be arbitrarily long, but only the first 32 characters are significant. Case distinctions are respected.

Constants may be of type decimal, octal, hex, character and string.

Escape sequences for new line, horizontal and vertical tab, backspace, carriage return, form feed, alert, backslash, single quote, double quote, octal and hexadecimal numbers are supported.

Comments imbedded in the source code begin with "/*" and end with "*/". Comments can not be nested.

CCHPC supports the following Data types:

Name	Size in Bits
char	8
short	16
int	16
enum	8 or 16
long	32
signed char	8
signed short	16
signed int	16
signed long	32
unsigned char	8
unsigned short	16
unsigned int	16
unsigned long	32
float	32
double	32
long double	32
struct	sum of component sizes
union	maximum of component sizes

The type "char" is treated as signed. Unsigned operations are treated the same as signed operation, except for multiplication, division, remainder, right shifts and comparisons. For signed integers, the compiler uses an arithmetic right shift. For unsigned integers, a logical shift is used when shifting right.

HPC C Compiler—CCHPC Introduction (Continued)

Keywords `const` and `volatile` can be applied to any data. `const` indicates that the symbol refers to a location which is read-only. If the symbol is in static or global storage, it will be assigned to ROM memory. `volatile` indicates that optimization must not change or reduce the accesses to the symbol.

Since the HPC supports 8-bit operations, CCHPC does not automatically promote "char" types to "int" when evaluating expressions. For a binary operation, the compiler promotes a "char" to an "int" only if the other operand is a 16-bit (or more) value or if the result of the operation is required to be a 16-bit (or more) value. The use of 8-bit operations yields efficient code without compromising the correctness of the result.

CCHPC uses the standard C preprocessor and any standard preprocessor functions, including "#define", "#include" and macros with arguments are supported.

A program is set of intermixed variable and function definitions. Variables must always be defined before use, functions may be defined in any order.

Variable initialization is performed according to the draft ANSI standard rules.

Standard C operators, and their hierarchy are as described in the ANSI standard draft.

CCHPC allows the programmer to imbed assembler code directly in the C source. All data between "/"\$ and "\$/" is copied directly to the assembler output file generated by CCHPC.

CCHPC IMPLEMENTATION DEPENDENT CONSIDERATIONS

Memory

CCHPC is designed to execute in a 16-bit environment. Special care must be taken when using CCHPC in an 8-bit HPC system.

Storage Classes

CCHPC supports the following storage classes:

- auto
- static
- register
- typedef
- extern

Due to HPC architectural features, the "register" storage class is limited. A variable can be assigned a "register" only if it is of type pointer and only if a register is available. The first "register" pointer variable encountered is assigned to the HPC B register, the second to the HPC X register and any subsequent ones are treated as "auto" (unless `NOLOCAL` is in effect, in which case it will be treated as "static").

The default storage class for global declarations is "static". The default storage class for declarations within functions is "auto".

Storage Class Modifiers

To make maximum efficient use of HPC architectural features CCHPC supports the notion of "storage class modifiers". A storage class modifier may appear with or in place of a storage class. Following is the set of storage class modifiers:

Keyword	Applicable to
BASEPAGE	variable
ACTIVE	function
NOLOCAL	function
INTERRUPT _n (where n = 1 to 7)	function

Storage class modifiers may be supplied with each variable or function declaration. The effect of each storage class modifier is described in the following:

BASEPAGE—The variable will be allocated in the BASE section. Accessing a basepage variable is more efficient than accessing any other type of variable but the amount of basepage storage is limited.

ACTIVE—The address of the function is placed in the 16 word JSRP table. Calls to the function will require 1 byte of code. The most frequently called functions should be considered for designation as ACTIVE functions for maximum code efficiency.

NOLOCAL—The functions local variables are not allocated on the run-time stack. Instead, they are allocated in static storage. Access to local variables in a NOLOCAL function will be more efficient since access can be direct rather than indexed from the frame pointer. If a function has no arguments or local variables, then entry and exit from the function will be much more efficient since there will be no need to adjust the frame pointer on entry and exit of the function.

INTERRUPT_n—These modifiers can be used to set interrupt vectors (one through seven) to point to a particular function. Any function which has an INTERRUPT storage class modifier has special entry and exit code generated. This code will push all HPC registers (A, B, K, X, PSW and word at RAM address 0) onto the stack before executing normal function entry code. Exit code restores all registers before returning from the interrupt.

C Stack Formation

The Stack Pointer (SP) is initialized to the start address assigned by the linker. The Stack Pointer always points to the next free location at the top of the stack.

Within a function, the compiler maintains a Frame Pointer which is used to access function arguments and local automatic variables. The Frame Pointer location is reserved by the compiler at location Oxbe.

HPC C Compiler—CCHPC Introduction (Continued)

To call a function, the compiler pushes arguments onto the stack in reverse order, performs a jump subroutine to the function. Since all stack pushes are 16-bits, any 8-bit arguments are automatically promoted to 16-bits. On function entry, the compiler creates new stack and frame pointers for the function. On exit, the stack and frame pointers are restored to the values they had on entry to the function.

Using In-Line Assembler Code

CCHPC allows in-line assembler code to be entered in the body of a C function. The assembler code can access any of the currently active variables or can get the address of a variable.

Efficiency Considerations

HPC code size and execution time can be optimized by making maximum use of BASEPAGE variables. When BASEPAGE is full, static variables are next most efficient. The least efficient variables are automatic since they require an indirect indexed access. Minimizing the use of longs and floats will improve efficiency. The HPC architecture strongly supports unsigned arithmetic, so the programmer should use unsigned variables except for cases that absolutely require signed arithmetic. The compiler does not attempt to identify common subexpressions for computation only once, so this must be done by the programmer.

Statements and Implementation

The following C statements are supported by CCHPC:

```
expression;
if
if ... else
while ...
do ... while
for ...
break
goto
continue
return
return ...
case ...
default
switch ...
switchf ...
loop ...
```

The switch statement will generate an efficient jump table for a set of cases if the cases are sufficiently close, or it will generate individual tests for each case. The switchf statement is the same as the switch statement except that when a jump table is generated for the switchf statement the compiler does not generate the code necessary to check the bounds of the value to be switched on. This creates a more efficient form of the switch statement but the programmer must insure that the value being switched on is in range.

The loop statement is an extension to the ANSI standard. Loop allows the programmer to create a code efficient loop by using the HPC DECSZ instruction. The loop statement may be nested. A break statement inside the loop will cause an immediate exit from the loop.

Run-Time Notes

During evaluation of complex expressions, the compiler uses the stack to store intermediate results.

All HPC C programs start with a call to the function "main" with no arguments. Before calling "main", run-time start-up code initializes RAM. The initial values of static or global variables with initialization are stored in ROM and copied to the appropriate variables in RAM. Static or global variables without initialization are cleared to zero. The function "main" must be defined. When "main" returns to the run-time start-up routine it executes the HALT macro provided which puts the chip in an infinite loop.

Since the run-time stack is of fixed size and there is no check for stack overflow, it is up to the programmer to insure that the stack area is large enough to prevent stack overflow.

Memory location zero is reserved by the compiler.

The HPC C Compiler User's Manual provides additional information on the features and functions of CCHPC.

HPC Assembler—ASMHPC

INTRODUCTION

The HPC assembler (ASMHPC) is a cross-assembler for the NSC HPC family of microcontrollers. ASMHPC translates symbolic input files into object modules and generates an output listing of the source statements, machine code, memory locations, error messages, and other information useful in debugging and verifying programs.

ASMHPC has the following useful features—

- Macro capability that allows common code sequences to be coded once.
- Conditional code assembly is supported.
- Translates symbolic assembly code modules into object code. Object modules are linkable and relocatable.
- Symbolic names may be defined for any HPC register, memory location or I/O port. Symbols may be defined as byte or word size.
- Symbol table and cross-reference output is provided.
- Full set of Assembler directives are provided for ease of generating vector tables for interrupts, short subroutine calls, jump indirects and other data generation within the object program.
- Data and code sections are user definable. Sections may be relocatable or absolute. Sections

HPC Assembler—ASMHPC (Continued)

may be assigned to 8-bit memory to support the HPC 8-bit mode. Data sections may be assigned to basepage RAM on the HPC to maximize efficient access to variables.

- Accepts assembly source code generated by the HPC C Compiler, CCHPC.
- Full set of Assembler controls for greater flexibility in debugging modules and programs created by ASMHPC.

ASSEMBLY LANGUAGE ELEMENTS**Assembly Language Statement**

Assembly language statements are comprised of four fields of information.

Label field—This is an optional field. It may contain a symbol used to identify a statement referenced by other statements. A symbol used in this manner is called a label.

Operation field—This field contains an identifier which indicates what type of statement is on the line. The identifier may be an instruction mnemonic or an assembler directive. The operation field is required on all assembler statement lines, except those lines which consist of only a label and/or comment.

Operand field—The operand field contains entries that identify data to be acted upon by the operation defined in the operation field. Operand examples are source or target addresses for data movement, immediate data for register initialization, etc.

Comment field—Comments are optional descriptive notes that are included in the program and listings for programmer reference and program documentation. Comments have no effect on the assembled object module file.

Character Set

Each assembly language statement is written using the following characters:

Letters—A through Z (a through z)

Numbers—0 through 9

Special Characters—!\$%'()* +, - . / : ; < = & # ? _ b^a

Note: Upper and lower case are distinct; b^a indicates a blank.

Location Counter

There is a separate location counter for each program section, and the counter is relative to the start of that section. The assembler uses the location counter in determining where the current statement goes in the current program section. If the program section is relocatable, the linker does the final job of assigning an absolute address to the instruction.

Symbols and Labels

Symbols and labels are used to provide a convenient name for values and statements. Symbols and labels have the same rules for construction, only their use distinguishes a symbol from a label.

Rules for symbol or label construction are:

1. The first character must be either a letter, a question mark (?), an underscore (_), a dollar sign (\$) or a period (.).
2. All other characters may be any alphanumeric character, dollar sign (\$), question mark (?) or underscore (_).
3. The maximum number of characters in a symbol or label may be selected by the user with the SIZE-SYMBOL control. The default is 64.
4. Symbols starting with dollar sign (\$) are local symbols and are defined only within a local region.
5. Labels and symbols are case sensitive.

Operand Expression Evaluation

The expression evaluator in the assembler evaluates an expression in the operand field of a source program. The expressions are composed of combinations of terms and operators. An expression may consist of a single term or may consist of two or more terms combined using operators. Terms are—numbers in decimal, hexadecimal, octal or binary, string constants, labels and symbols or the location counter symbol. Each term has four attributes: its' value, relocation type, memory type and size. The relocation type is either absolute or relocatable. The memory type indicates whether the term represents a BASE, RAM8, ROM8, RAM16, ROM16 or null (in the case of an absolute term). The size of a term is null, byte or word.

The operators allowed in ASMHPC are: arithmetic, logical, relational, upper and lower byte extraction and untype operators. Arithmetic operators are +, -, *, /, MOD, SHL, ROL and ROR. The logical operators are NOT, AND, OR and XOR. The relational operators are EQ, NE, GT, LT, GE and LE. Upper and lower extraction operators are HIGH and LOW. The untype operator is &.

Parentheses are permitted in expressions. Parentheses in expressions override the normal order of evaluation, with the expression(s) within parentheses being evaluated before the outer expressions.

Numbers are represented in ASMHPC in 16-bit 2's complement notation. Signed numbers in this representation have a range of -32768 (x'8000) to +32767 (x'7FFF). Unsigned numbers are in the range of 0 to 65535. String constants are internally represented in the 8-bit ASCII code. All expression evaluation is done treating terms as unsigned numbers, for example, -1 is treated as having the value x'FFFF. The magnitude of the expression must be compatible with the memory storage available for the expression. For example, if the expression is to be stored in an 8-bit memory location, then the value of the evaluated expression must not exceed x'FF.

HPC Assembler—ASMHPC (Continued)**ASSEMBLY PROCESS**

The ASMHPC assembler performs its functions by reading the assembly language statements sequentially from the beginning of a module or a program to the end, generating the object code and a program as it proceeds.

The ASMHPC assembler is a multi-pass assembler which allows it to resolve forward referenced symbols and labels efficiently. The number of passes can be selected using the PASS control. This allows the user to select the level of optimization of forward referenced instructions.

MACROS

Macros help make an assembly language program easier to create, read and maintain. A macro definition is an assembly statement or statements that are referred to by a macro name. The macro may have parameters that are operated upon by the assembly statements. ASMHPC will substitute the macro definition for the macro name with the appropriate parameters during the assembly process. Repetitive or similar code can be defined as macros and the programmer can use the macros to build a library of basic routines. Variables unique to particular applications can be defined in and passed to a particular macro when called by main programs.

Defining a Macro

Macros must be defined before they are used in a program. Macro definitions do not generate code. Code is generated only when the macros are called by the assembly program. Macro definitions have a Macro name by which the macro will be referred in the program, declaration of any parameters to be used in the macro, assembler statements that are contained in the macro body and directives that define the boundaries of the macro.

Following is the macro definition structure:

```
.MACRO mname [,parameters]
```

```
•
•
•
```

```
macro body
```

```
•
•
•
```

```
.ENDM
```

where:

- .MACRO is the assembler directive which initiates the macro definition.
- mname is the name of the macro. Multiple macros can have the same name. The last macro defined is the macro definition used. Macro definitions are retained in the macro definition table; if the current

macro is deleted by the .MDEL directive, the previous definition becomes active. If mname is the same as a valid instruction mnemonic, the macro name is used in place of the normal instruction.

- Parameters are the optional list of parameters used in the macro. Parameters are delimited from mname and additional parameters with commas.
- The macro body is a sequence of assembly language statements and may consist of simple text, text with parameters, and/or macro-time operators.
- .ENDM identifies the end of the macro and must be used to terminate the macro definition.

Calling a Macro

Once a macro has been defined, it may be called by a program to generate code. A macro is called by placing the macro name in the operation field of the assembly language statement, followed by the actual value of the parameters to be used (if any). The form of a macro call is:

```
mname [parameters]
```

where:

- mname is the previously assigned name in the macro definition and
- parameters are the optional list of input parameters. When a macro is defined without parameters, the parameter list is omitted from the call.

The macro call as well as the expanded macro assembly code will appear on the assembler listing if the appropriate controls are enabled.

Using Parameters

The power of a macro can be increased with the use of optional parameters. The parameters allow variable values to be declared when the macro is called.

When parameters are included in a macro call, the following rules apply to the parameter list:

1. One comma and zero or more blanks delimit parameters.
2. A semicolon terminates the parameter list and starts the comment field.
3. Single quotes (') may be included as part of a parameter except as the first character of a parameter.
4. A parameter may be enclosed in single quotes ('), in which case the quotes are removed and the string is used as the parameter. This function allows blanks, commas, or semicolon to be included in the parameter. To include a quote in a quoted parameter, include two quotes (").
5. Missing or null parameters are treated as strings of length zero.

The macro operator @ references the parameter list in macro call. Using the operator @ in an expression, the number of parameters can be used to control conditional macro expansion. The @ operator may also be

HPC Assembler—ASMHPC (Continued)

used with a constant or symbol to reference the individual parameters in the macro parameter list. These capabilities eliminate the need for naming each parameter in the macro definition, which is useful when there are long parameter lists. Using the @ parameter count operator it is possible to create macros which have a variable number of parameters.

The macro operator for concatenation is ^. In a macro expansion the ^ operator is removed and the strings on each side of the operator concatenated after parameter substitution. This operator provides the ability of creating variable labels through the use of macros.

Local Symbols

When a label is defined within a macro, a duplicate definition results with the second and each subsequent call of the macro. This problem can be avoided by using the .MLOC directive to declare labels local to the macro definition.

Conditional Expansion

The conditional assembly directives allow the user to generate different lines of code from the same macro simply by varying the parameter values used in the macro calls.

Nested Macro Calls

Nested macro calls are supported. A macro definition may call another macro. The number of allowable levels of nesting depends on the sizes of the parameter lists, but at least ten is typical.

A logical extension of the nested macro call is the recursive macro call, that is a macro that calls itself. This is allowed, but the programmer must insure that the call does not create an infinite loop.

Nested Macro Definitions

A macro definition may be nested within another macro. Such a macro is not defined until the outer macro is expanded and the nested macro is executed. This allows the creation of special purpose macros based on the outer macro parameters. Using the .MDEL directive and the nested macro capability a macro can be defined only within the range of the macro that uses it.

Macro Comments

All lines within a macro definition are stored with the macro, however, any text following “;” is removed before being stored. This text will appear on the listing of the macro definition but will not appear on the macro expansion.

ASSEMBLY LISTING

The listing generated by ASMHPC contains program assembly language statements, line numbers, page numbers, error messages and a list of the symbols used in the program. The listing of assembly language statements which generate machine code includes the hexadecimal address of memory locations used

for the statement and the contents of these locations. To the left of the instruction, an “R” indicates a relocatable argument in this instruction, “X” indicates an external argument, “C” indicates a complex argument and “+” indicates macro expansion.

The assembler listing optionally includes an alphabetical listing of all symbols used in the program together with their values, absolute or relocatable type, word or byte or null type, section memory type and public or external. Optionally a cross reference of all symbol usage by source line number is given; the defining line number is preceded by a “-”.

The total number of errors and warnings, if any, is printed with the listing. Errors and warnings associated with assembly language statements are flagged with descriptive messages on the appropriate statement lines.

Directives

Directive statements control the assembly process and may generate data in the object program. The directive name may be preceded by one or more labels, and may be followed by a comment. The directive's name occupies the operation field. Some directives require an operand field expression.

Assembler Controls

An assembler control is a command that may be used in the source program on a control line or on the invocation line as an option. A control line is indicated by a # in column 1 of the source line. Comments may be included on a control line by preceding the comment with a semicolon. Invocation line controls are masters and override the same controls in the program source. Examples of assembler control capabilities are: format control of the assembly listing, enable/disable listing of conditional code and conditional directives, listing of comment lines, macro expansion lines, macro object lines only. Cross references and symbol tables can be generated in the listing file, macro local symbols and constants can be put into the symbol table, number of assembler passes specified, assembler controls saved and restored . . .

ASSEMBLER INVOCATION

ASMHPC invocation will vary somewhat depending upon the host operating system being used. All systems have a similar invocation line format. The arguments for ASMHPC invocation are: the name of the assembly program(s) or module(s) to be assembled, list of assembler options and the name of a command file that contains additional invocation line source filenames and/or options. An assembler invocation line option is an assembler control that is specified in a manner consistent with the requirements of the operating system. When specifying a filename, the name may include a directory path. If no arguments are specified on the invocation line, the ASMHPC HELP menu is displayed.

HPC Cross-Linker—LNHPC

INTRODUCTION

The HPC linker (LNHPC) links object files generated by ASMHPC. The result is an absolute load module in various formats, such as NSC ".lm" format, INTEL Hex or COFF formats. LNHPC combines a number of ASMHPC relocatable object modules into a single absolute object module with all the relocatable addresses assigned. All external symbol references between modules are resolved, and library object modules are linked as required.

LNHPC creates two outputs:

1. An absolute object module file that can be downloaded to the MDS development system for emulation and debugging. The output could also be used by the HPC Source Level Debugger for "C" Source or assembly symbolic debugging.
2. A load map that shows the result of the link with an optional cross reference listing.

LNHPC MEMORY ALLOCATION

The Linker places each section in memory based on the attributes of the section and the memory that is available. Available memory is specified by the RANGE command. Each section has the following attributes:

Memory type—BASE, ROM8, ROM16, RAM8, RAM16

Size—determined from the object modules

Absolute—section was specified as absolute in assembler

Fixed—starting address was specified by the SECT command

Ranged—memory range was specified by the SECT command.

Memory is allocated section by section. Sections are allocated in the following order:

1. Each absolute or fixed section is placed in memory at its specified address.
2. Each ranged section is placed in memory within the specified range, regardless of whether this memory has been allocated in the Range Definition. An error will occur if the section can not be located.
3. All remaining sections are allocated as follows: As each section is processed, the ranges for its memory type are examined to find enough free space to allocate the section. Each range is examined in order. The first space large enough to contain the section is used. At this point, the memory allocated is marked used. If not enough memory is available to allocate the section, an error message is displayed. For efficiency, sections which may contain

word aligned data (ROM16, RAM16, BASE which are word aligned) are allocated first. The user will benefit if the word aligned data is placed in these sections and byte data in other sections.

The load map shows the following:

- Range definitions showing the memory ranges specified by the /RANGE option or by the default.
- The Memory Order Map showing the starting and ending addresses of each contiguous range of memory used.
- The Memory Type Map showing how memory is allocated organized by the memory type.
- The Total Memory Map showing the allocation of all ROM and all RAM.
- The Section Table showing each section in the link, along with its starting and ending address. Section attributes are also displayed.

LINKER INVOCATION

LNHPC invocation will vary somewhat depending upon the host operating system being used. All systems have a similar invocation line format. The arguments for LNHPC invocation are—the name of the object file(s), module(s) or libraries to be linked, list of linker options and the name of a command file that contains additional invocation line source filenames and/or options. A linker invocation line option is a linker control that is specified in a manner consistent with the requirements of the operating system. When specifying a filename, the name may include a directory path. If no arguments are specified on the invocation line, the LNHPC HELP menu is displayed.

HPC Librarian—LIBHPC

INTRODUCTION

The HPC librarian (LIBHPC) reads object modules produced by ASMHPC and combines them into one file called a library. The linker can then search the library for any undefined external symbols and link the object module associated with the external symbol. LNHPC will only link in those library object modules required to satisfy external references to maximize efficient use of memory space. LIBHPC is a librarian utility that is provided to allow the user to develop standard modules and place them in libraries. The user may add, delete and list modules in a library file. A library of typical C functions is supplied with the HPC C Compiler (CCHPC). This library is an example of the type of library that could be created for an HPC application program. It is intended to be used as a template for the user to create a custom library specific to the application for maximum code efficiency.

HPC Librarian—LIBHPC (Continued)**LIBRARIAN INVOCATION**

LIBHPC invocation will vary somewhat depending upon the host operating system being used. All systems have a similar invocation line format. The arguments for LIBHPC invocation are—the name of the library file to process, list of librarian options and the name of a command file that contains additional invo-

cation line source filenames and/or options. A librarian invocation line option is a librarian control that is specified in a manner consistent with the requirements of the operating system. When specifying a filename, the name may include a directory path. If no arguments are specified on the invocation line, the LIBHPC HELP menu is displayed.

ISDN Basic Rate Interface Software for the HPC16400E High Performance Data Communications Microcontroller

General Description

The ISDN Basic Rate Interface Software Package implemented on the National Semiconductor HPC™ Microcontroller Family contains the software elements that are necessary to implement CCITT standards Q.921 and Q.931 as approved by ANSI committees for North America.

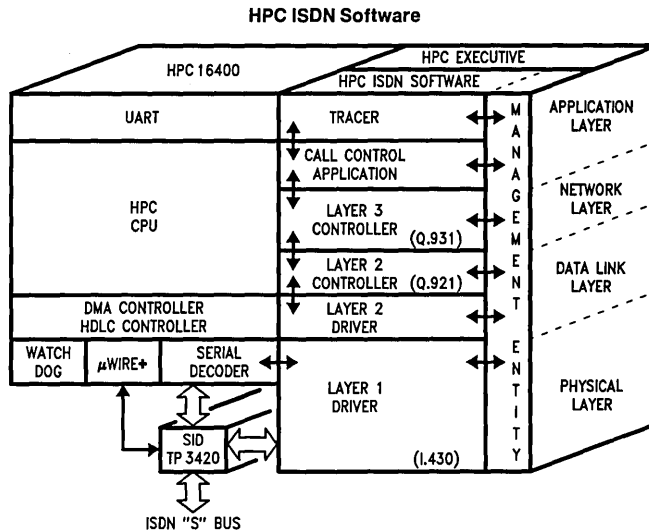

The software package is designed to be easily unbundled and used independently by a software developer. Each layer or function is written as a separate software task. This modular design and well defined task interface make it easy to interface application dependent software to the modules provided. The coding standards for software development have been designed to ensure development of consistent, structured code, which can be easily used and maintained over the life of the code.

This software is supplied as a disk set and is used in conjunction with HPC development tools and software.

Features

- Multi-tasking executive
- Preemptive scheduling
- Modular software design
- Multiple timer facility
- HPC physical layer I/O interface
- Layer 2 link access procedure for the D channel (LAPD)
- Layer 2 link access procedure for the B channel (LAPB)
- Layer 3 protocol control procedure for a terminal endpoint
- Layer management entity support
- Demonstration Call Control Task
- Task_View task exerciser and debugger
- Message trace capability
- Split frame message formatting
- Source code in C language

Block Diagram

TL/DD/10077-1

1.0 Architectural Description

1.1 INTRODUCTION

This description defines the software required to implement the ISDN Basic Rate Interface on the HPC family of micro-controllers, including the HPC16400 which has onboard hardware specifically designed for Data Communication and ISDN applications.

The software consists of the following main parts, shown in overview in *Figure 1.1*:

- HPC Executive, providing an operating environment and services for the ISDN software and for additional application software written by OEM users of the HPC.
- I/O Drivers, interfacing to the DMA/HDLC controllers on the HPC16400 and to the TP3420 "S" Interface Device.
- Data Link Layer Software, implementing the CCITT Q.921 and X.25 link access procedures (LAPD and LAPB).
- Network Layer Software, implementing the Protocol Control Procedures defined in the CCITT Q.931 standard.
- Demonstration Call Control Module, allowing a development engineer at a terminal to make and receive ISDN phone calls which exercise the above software.
- Tracer Module, allowing a development engineer at a terminal to monitor the operation of the above software.
- Management Entity Module

1.2 SOFTWARE ARCHITECTURAL PRINCIPLES

1.2.1 Modular Multitasking Environment

Each layer or function is written as a separate software task. Intertask communications and the interface between tasks

and I/O drivers is by means of mail messages and semaphores, which are managed by the multi-tasking HPC Executive.

This modular design and well defined intertask interface make it easy for users to interface application-dependent software to the modules provided. The services of the HPC Executive (mail, semaphores, timers, memory management) facilitate the writing of software tasks and I/O drivers. These services are available to all tasks and to interrupt-level drivers.

1.2.2 Event-Driven State-Machine Architecture

Telecommunication software typically involves many invocations of the same code (one per call, one per logical connection, etc.) and requires a particular software architecture: tasks must be structured as event-driven state machines. Each task has one or more mailboxes and operates by picking up mail, one message at a time, from the mail queue, and processing the message to completion before returning for the next mail message.

Each "entity" within a task (each call, each logical connection, etc.) has a state block, indicating its current state. After picking up a mail message, the task identifies the entity involved in the message, accesses the state block for that entity, processes the message based on the state of the entity, and finally sets the state block to the new state of the entity.

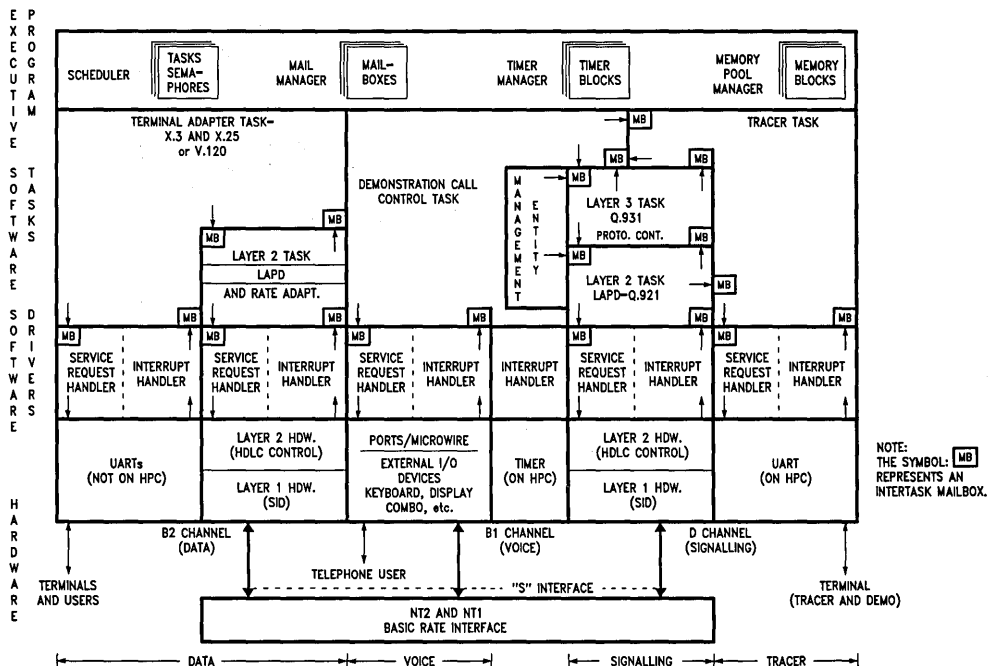

FIGURE 1.1 HPC16400 Software for ISDN

TL/DD/10077-2

1.0 Architectural Description (Continued)

1.2.3 Coding Standards

The coding standards for software development have been designed to ensure development of consistent, structured code, which can be easily used and easily maintained over the life of the code.

1.3 HPC EXECUTIVE

The HPC Executive provides an operating environment for the Layer 2 and Layer 3 tasks, the application tasks, the various support tasks, and the I/O drivers which interface to the hardware. It provides the following services to the tasks and I/O drivers:

- Scheduling of tasks that are ready to run, based on task priority. Preemptive scheduling and time slicing can be optionally enabled.
- Task-task and driver-task communication, by means of mail messages, which can be sent and picked up, and semaphores, which can be signaled and awaited.
- Timers, which are equivalent to mail messages with a specified delay and which allow tasks and drivers to time their activities and time out when an expected event does not occur.
- Memory management, to allocate and deallocate fixed-size buffers as needed by tasks and drivers.

Application tasks and I/O drivers developed by users of the HPC can easily be inserted in the HPC Executive environment and can take full advantage of its services.

1.4 ISDN TELECOMMUNICATIONS STANDARDS

1.4.1 CCITT Standards

The Layer 2 Task implements CCITT 1988 (Blue Book) specification Q.921 (LAPD) and Layer 2 (LA(B) of CCITT specification x.25.

The Layer 3 Task implements the Protocol Control Procedures of CCITT 1988 Specification Q.931.

The Layer 3 Task implements the circuit-switched procedures described in Section 5. The Layer 3 Task implements the Protocol Control procedures and some of the Resource Management. The Call Control Task implements a demonstration version of the Call Control Procedures and the balance of the Resource Management.

In terms of the specification and description language (SDL) diagrams in the Q.931 specification, the Layer 3 Task implements *Figure 38* (26 pages).

The establishment and release of logical links are fully covered in the Layer 2 specifications (Q.921), but the Layer 3 aspects of this are not handled in the version of Q.931 on which the Layer 3 Task is based. Therefore, additional Layer 3 states and SDL diagrams have been created and additional software has been written to handle this requirement.

1.5 ISDN TELECOMMUNICATIONS SOFTWARE

The software packages described below are designed to be easily "unbundled" and used independently by a software developer.

1.5.1 Layer 1 I/O Driver

The Layer 1 I/O Driver controls the HPC MICROWIRE/PLUSTM interface, and the onboard Serial Decoder. This driver is responsible for the hardware initialization, the control of the Serial Decoder, the activation and the deactivation of the Layer 1 I/O device. Use of the HPC Executive mail and semaphore services makes this driver simple to implement and easy to enhance by users that require additional Layer 1 hardware interfaces.

1.5.2 Layer 2 I/O Driver

The Layer 2 I/O Driver controls the HDLC/DMA controllers onboard the HPC16400, and interfaces this hardware to the Layer 2 Task. This driver is responsible for the hardware initialization, the reception of frames toward the HPC, the transmission of frames away from the HPC, and appropriate error handling. Use of the HPC Executive mail and semaphore services makes this driver simple to implement and easy to replace with alternative drivers that a user may wish to develop.

1.5.3 Layer 2 Task

The Layer 2 Task implements the full LAPD protocol defined in Q.921, providing error free in-sequence transmission, reception and multiplexing of the messages received by an HDLC controller connected to the D signaling channel. The event-driven state machine architecture, described above, enables a single software module to support simultaneous activity on multiple logical connections. The Layer 2 Task also supports X.25 LAPB processing for messages received by a second HDLC controller connected to a bearer B channel.

1.5.4 Layer 3 Task

The Layer 3 Task implements the user side of the Protocol Control Procedures of Q.931, which are used to setup, answer, suspend, resume, and disconnect a call. Specifically, it implements all of *Figure 2/Q.931* of Q.931. The event-driven state machine architecture, described above, enables a single software module to support simultaneous activity relating to calls on both bearer B channels.

1.5.5 Demonstration Call Control Task

The latest versions of Q.931 separate the Layer 3 procedures into Protocol Control Procedures and Call Control Procedures. Call Control Procedures are application dependent. These procedures handle bearer channel selection and actual establishment of the voice channel. As Q.931 notes, these procedures can also be considered to be part of the Applications Layer. The Call Control Task implements a minimal subset of the Call Control Procedures, for demonstration purposes. In an actual application, this task will be replaced by an application-specific task, tailored to the capabilities of the actual terminal equipment (number of terminals, handsets, etc.).

1.5.6 Management Entity Task

The Management Entity Task, which is only generically defined in Q.921 and Q.931, handles housekeeping functions

1.0 Architectural Description (Continued)

for all layers. These functions include TEI negotiation with the network management entity, and the handling of unrecoverable errors. This task implements as much of the management entity as is currently defined and in addition whatever is necessary for the operation of the other tasks.

1.5.7 Tracer Task

The Tracer Task serves two purposes; to demonstrate the lower ISDN layers via a menu-driven telephone emulation mode, and to trace system mail message traffic.

1.5.8 Task_View Task Exerciser and Debugger

Task_View is a special-purpose task that can be inserted into the multi-tasking Executive environment in place of the Tracer Task. It reads and interprets a user supplied ASCII scenario file. Under control of this scenario file, Task_View sends mail messages to a specified mailbox (or mailboxes), where they are read by the task under test. Mail messages sent by the task under test in response to this input are then displayed by Task_View. In this way the task may be exercised and debugged.

2.0 Functional Description

2.1 INTRODUCTION

This description defines the functional requirements of the ISDN Basic Rate Interface Software Package implemented on the National Semiconductor HPC Microcontroller Family. Specifically, the HPC16400 Software Package implements or supports the following high-level functions:

- Multi-Tasking Executive
- HPC Physical Layer I/O Interface
- Layer 2 Link Access Procedure for the D Channel (LAPD)
- Layer 2 Link Access Procedure for the B Channel (LAPB)
- Layer 3 Protocol Control Procedure for a Terminal Endpoint

- Management Entity Support
- Call Control Demonstration Task
- Message Trace Capability

The HPC ISDN Software Package has been divided into several functional software elements, as illustrated in the HPC ISDN Functional Block Diagram, *Figure 2.1*. These functional elements correspond to software modules. The purpose of this section is to introduce the various software elements, to define their interactions, and to relate their functionality to the appropriate ISDN standards, where applicable.

The HPC ISDN Software Package will require additional software drivers and application-specific tasks prior to serving as a useful ISDN Terminal Endpoint (TE) entity. The HPC ISDN software has been coded and documented to allow easy integration of additional application code.

The HPC ISDN Software elements illustrated in *Figure 2.1* have been divided into the following categories.

- HPC Executive (2.2)
- I/O Device Drivers (2.3)
- ISDN Layer Protocol Tasks (2.4)
- Application Tasks (2.5)
- System Utilities (2.6)

The HPC Executive contains software elements that are necessary for HPC ISDN Applications. These elements include a Multi-Tasking Scheduler, a Memory Manager, a Timer Manager and a Mail Manager. The HPC Executive software elements are tightly coupled, and streamlined for the National Semiconductor HPC family of controllers.

The I/O Device Drivers interface the HPC hardware elements to the HPC ISDN Software. The Layer 1 Driver implements the ISDN PHYSICAL Layer 1 requirements for the HPC ISDN system. The Layer 2 Driver interfaces the HPC DMA/HDLC controller channels to the Layer 2 Link Access

FIGURE 2.1 HPC ISDN Software Functional Block Diagram

TL/DD/10077-3

2.0 Functional Description (Continued)

Procedures. The Terminal Device Driver interfaces the HPC on-board UART to the ISDN Software. Device initialization sequences, service request tasks and accompanying interrupt service routines are all defined in the I/O Device Driver section of this document.

The Layer Protocol Tasks implement the ISDN DATA LINK Layer 2 and the NETWORK Layer 3 requirements for the HPC ISDN system. These tasks are designed to be hardware configuration and application independent. The Layer 2 Task provides both the "USER SIDE" and the "NETWORK SIDE" implementation of the CCITT Specification Q.921. The Layer 3 Task provides the "USER SIDE" implementation of CCITT Specification Q.931.

The Layer 2 Task has been designed to use many of the same routines to implement the link access procedures on either the signaling D channel or the bearer B channel (LAPD or LAPB). Design decisions have also been made to facilitate the implementation of V.120, the rate adaption protocol that processes LAPD frames on a bearer B channel.

The Management Entity Task and the Call Control Task are Application (Specific) Tasks that are closely coupled to the specific system hardware configuration and the Central Office Network Entity Software. These tasks are provided for demonstration purposes to drive the ISDN layer entities. Application users must either replace or extensively rewrite these tasks to match their particular ISDN Application environment.

The System Utilities include the power-up reset Main Task, the NMI handler, the Timer interrupt handler, and the Watchdog Task.

The Tracer utility provides the capability of on-line tracing of intertask mail messages and task states. Tracer is primarily a passive task; it displays messages that it receives from other tasks. Tracer also provides a user interface for Telephone Simulation.

The remainder of this document is devoted to defining each of the software elements at the functional level. Where applicable, specific ISDN standard documents such as CCITT Q.921, Q.931 and X.25 will be referenced, rather than duplicating the information here.

2.2 HPC EXECUTIVE

The HPC Executive provides a multitasking environment within which the ISDN and applications tasks can run and it provides various system services to those tasks. The services of the Executive are available to both tasks and interrupt service routines.

2.2.1 Tasks, Priorities, and the Ready Queue

A task is a subroutine which can be run (called) by the Executive. Tasks are managed by the Executive as Task Control Blocks (TCB's). A task's TCB contains all the parameters needed by the Executive to handle the task, in particular, the task's priority and its current starting address.

Tasks which are not blocked waiting for a semaphore or for mail are considered to be ready to run and their TCB's are queued on the Ready Queue, in the order of the tasks' priorities. The Task Scheduler runs the task at the head of the Ready Queue, i.e., the highest priority task that is ready to run. In this way the processor is always given to the highest priority task that is ready to run.

Once a task is started, it continues to run until it does a Semaphore Wait, ReadMail, or Return or, until a higher priority task is put on the Ready Queue, at which time the scheduler has the opportunity to once again choose the task at the head of prioritized Ready Queue and run that task.

A task may change the priority of any task, including itself. The priority change takes place immediately, to the extent that the target task's TCB is updated with the new priority and the queue in which the target task's TCB is waiting is resorted to reflect the new priority.

If the target task is in the Ready Queue and its new priority is higher than the priority of the running task, then the target task will run once all protected sections are exited. See Section 2.2.3, below.

2.2.2 Semaphores

A semaphore is a global variable, accessed through the Executive, which can be Signaled (incremented) by one task and Waited on by another task. A semaphore is typically used to manage the sharing between tasks of some resource, e.g., an I/O device, mail messages, etc. At any moment the value of a semaphore may be positive, negative, or zero. A positive value indicates the number of resources available, a negative value indicates the number of tasks waiting for resources and a zero value indicates that there are no resources available and no tasks waiting for them.

When a task Waits on a semaphore, if the semaphore has a nonzero positive value, the task will immediately go on the Ready Queue and the semaphore value will be decremented by one. On the other hand, if the semaphore has a zero or negative value, the task will be queued on the semaphore and the semaphore value will be decremented by one. When a task Signals a semaphore, the semaphore's value is incremented by one and the highest priority task waiting on the semaphore is put on the Ready Queue.

A common use for a semaphore is the management of a non-shareable resource, such as an I/O device. When the device is available, the associated semaphore has the value +1. When a task wishes to obtain exclusive use of the device, it Waits on the semaphore, which is then decremented to 0, with the task going immediately back on the Ready Queue. If another task then attempts to use the device, its Wait call will cause it to be placed on the Semaphore Queue and the value of the semaphore will be decremented to -1. Other tasks may also Wait on the semaphore, each decrementing its value by one. The negative value of the semaphore indicates the number of tasks Waiting for the device. The waiting tasks are ordered in the semaphore queue according to their priority. When the first task is done with the device, it Signals the semaphore, which moves the first waiting task to the Ready Queue and increments the semaphore or, if there are no waiting tasks, returns the semaphore to its original value of +1.

2.2.3 Preemptive Scheduling

Preemptive scheduling enables the executive to respond quickly to high priority events. If a task that is waiting on a Semaphore Queue moves to the Ready Queue and if that task is of higher priority than the currently running task, then, as soon as the currently running task emerges from all critical sections and non-preempt sections, the currently running task will stop running. The task that was moved to the Ready Queue will run. The preempted task will be placed on the Ready Queue in the normal manner.

2.0 Functional Description (Continued)

Executive functions allow preemption to be selectively turned on or off by task or for an entire application.

2.2.4 Time Slicing

Time slicing modifies the task scheduling algorithm as follows: at each "tick" of the timer clock (the clock which also controls the time-out timers), if the currently running task has the same priority as the task at the head of the Ready Queue, then, if the currently running task is not in a non-preempt section, it will stop running and the task at the head of the Ready Queue will run. The task that stops running is placed on the Ready Queue in the normal manner, i.e., after all tasks of equal priority. Time slicing enables the Executive to share the processor equally between tasks of equal priority.

2.2.5 Mailboxes and Mail Messages

The main form of intertask communication is the sending and receiving of mail. Mailboxes exist independently of tasks; any task may send mail to any mailbox and any task may read mail from any mailbox. However, in a typical system, each task has one mailbox from which it reads all its mail and to which other tasks send mail destined for that task.

Mail is prioritized. When a task calls upon the Executive to perform a SendMail, it specifies the priority of the message, which is inserted in the specified mailbox queue sorted by priority.

2.2.6 Timers

The Executive includes a timing facility specifically designed to handle the time-outs typical of telecom protocols and other real-time applications.

Timers are essentially a form of delayed mail. When a task sets a timer, the task provides a mailbox identifier, a mail message, and a time delay value. When the specified time delay is up, i.e. when the timer "expires", the mail message is mailed to the specified mailbox. When a task sets a timer, it receives a timer ID, which can be used to cancel the timer, if necessary, before it expires.

2.2.7 Memory Management

The memory manager is responsible for allocating and deallocating fixed-size memory blocks from fixed-size pools, which are completely defined at compile time. A memory pool may reside in extended memory.

2.2.8 System Module and Interface Module

The Multi-Tasking Executive Software is available either as source code or as object code. The interface module, which must be modified to insert application tasks, is always supplied as source code.

2.3 I/O DEVICE DRIVERS

I/O Device Drivers serve as interface routines between the HPC hardware machinery and the HPC Executive and Application Tasks. "Input" operations (data heading toward Application Tasks) are typically fielded by an Interrupt Service Routine (ISR). The ISR may SEND information to the appropriate task via the system mail facility, or it may signal the appropriate semaphore to schedule an I/O task. "Output" operations (data heading away from Application Tasks) are typically fielded by Service Request (SRQ) Tasks. SRQ Tasks communicate directly with the hardware control registers to initiate output operations. These tasks often work

closely with their accompanying ISR for output initiation and completion. Higher layer tasks send mail messages to the SRQ Tasks, using the system mail facility to queue messages pending output.

The HPC ISDN Software includes three I/O Device Drivers: the Layer 1 Driver, the Layer 2 Driver and the Terminal Driver. The functionality of these drivers is defined below. Details of particular Device Driver ISR and SRQ Task interactions are defined in the Software User's Manual.

2.3.1 Layer 1 I/O Device Driver

The Layer 1 I/O Device Driver provides implementation of the ISDN PHYSICAL Layer 1 for the HPC environment. This Device Driver controls the NSC MICROWIRE/PLUS Interface to the NSC TP3420 "S" Interface Device (SID), and the HPC16400 onboard, Serial Decoder. Control of a COMBO™ Codec, a display, and a keypad has been implemented later by either adding to this driver, or using it as a model for additional drivers.

The primary responsibility of this driver is to initialize and control the SID. The higher layer ISDN tasks mail activation and deactivation messages to the Layer 1 Service Request Task. This task sends the appropriate command to the SID via the MICROWIRE/PLUS Interface. The SID interrupts the HPC whenever it changes state. The Layer 1 Interrupt Service Routine fields responses when the SID changes state and mails the information to the Layer 2 Controller Task and to the Management Entity Task.

The Serial Decoder is initialized to MODE 4, with the ISDN D Channel terminated by DMA/HDLC Channel # 1, and Bearer Channel B2 terminated by DMA/HDLC Channel # 2. The SID can swap B1 and B2 internally to allow voice or data on either channel.

The Layer 1 I/O Device Driver can communicate with any other Task via the System Mail Utilities.

2.3.2 Layer 2 I/O Device Driver

The Layer 2 I/O Device Driver interfaces the two HPC16400 onboard DMA/HDLC channels; one to the 16 kbit per second "D" signaling channel, and one to the 64 kbit per second bearer (B2) channel. The Layer 2 Service Request Task receives Physical Layer (PH) Primitives from the Layer 2 Controller Task via the system mail utility. The Layer 2 Interrupt Service Routine handles block messages received from the DMA Controller and mails them as Physical Layer (PH) Data Primitives to the Layer 2 Controller Task. This generic mail message interface allows an Application User to easily introduce external DMA and HDLC Controllers, and accompanying device drivers, that either replace or complement the existing onboard controllers.

HDLC/DMA Channel # 1 is attached to the ISDN signaling D channel, and will be referred to as the LAPD Channel. HDLC/DMA Channel # 2 is attached to bearer channel B2, and will be referred to as the LAPB Channel. The two channels operate independently of each other as much as possible. Since they share the same interrupt hardware, the Layer 2 Interrupt Service Routine must poll the Message Pending Register and the Error Status Register to determine the source of each interrupt. Both HDLC/DMA channels use the HPC field separation feature for transmission and reception of data. This feature relieves some memory concerns, since it allows small memory buffers to be used for mes-

2.0 Functional Description (Continued)

sages that only have headers. In the transmit direction this feature allows large contiguous buffers to be broken up into smaller send buffers without having to copy them following a header. Issues specific to the HDLC/DMA Channels are defined below.

HDLC/DMA Channel #2, the LAPB Channel, requires frame sizes to be nominally 130 bytes, 2 bytes of header and 128 bytes of information. Provision can be made for messages with up to 1026 bytes, 2 bytes header and 1024 bytes of information.

The presentation of data between the Layer 2 Driver and Layer 2 Controller is identical regardless of which channel the frames are associated with.

2.3.3 Terminal Device Driver and Tracer

The Terminal Device Driver interfaces to the HPC onboard UART. The associated SRQ Driver Task, referred to as Tracer, serves primarily as a high-level demonstration vehicle. Tracer can field mail messages from any other task in the system, as well as keystroke mail messages from its accompanying ISR. Tracer's responsibilities include the following functions:

- Management of the Telephone Simulation User Interface,
- Display Management of the System Trace Mail Messages,
- Proper Display of Task-Related Information

The Telephone Simulation function of Tracer allows the user to enter "telephony-like" keystroke characters, that are passed to Tracer, then on to the ISDN layer tasks for processing. Menu responses are fielded by Tracer to select various levels of the Trace function, as well as to enter and exit the Telephone Simulation mode.

Depending on the level of trace that is selected, Tracer receives mail messages from the system tasks and properly formats them on the CRT display. Tracer offers various levels of trace capability. Trace can be turned off all together, in which case only the application layer Telephone Simulation inputs will be displayed. Trace can display all messages from every layer, or it can be set to "zoom" to display only the messages at a particular layer. Messages will generally have address fields and data fields.

The Terminal Driver's Interrupt Service Routine (ISR) handles keyboard characters from the UART and mails them to the Tracer SRQ Task for further processing. The ISR also handles transmission completion of a character that has been sent to the CRT.

The data structures and hardware interface requirements for the Terminal Device Driver, and capabilities of Tracer, are defined in the Software User's Manual.

2.4 ISDN LAYER PROTOCOL TASKS

The ISDN Layer Protocol Tasks provide implementation of the DATA LINK Layer 2 and the NETWORK Layer 3 in accordance with the protocol definitions of the CCITT Specifications. The two Layer Protocol Tasks (the Layer 2 Controller Task and the Layer 3 Controller Task) are designed to satisfy the ISDN Basic Rate Interface (BRI) Terminal Equipment requirements. They are independent of user applications and hardware environment. The PHYSICAL Layer 1 implementation is defined in the I/O Device Driver section of this document. Implementation of layers above the NETWORK Layer 3 are specific to user applications. Two such

layer tasks are provided, the Demonstration Call Control Task and the Management Entity Task. These tasks are defined in the Application Task section of this document.

The purpose of the Layer 2 Controller Task is to provide the NETWORK Layer 3 with an error free, sequenced data frame service. The Layer 2 Controller Task uses CCITT Specifications Q.921 and X.25 and the primary functional specifications. The Layer 2 Controller Task satisfies the Link Access Procedures for both the D Channel and the B Channel (LAPD and LAPB). Design considerations have also been included for the future implementation of V.120, the new CCITT rate adaption scheme.

The Layer 2 Controller Task's data frame delivery service allows the Layer 3 Controller Task to confidently setup and teardown user voice and data calls on the available facilities. The Layer 3 Controller Task uses CCITT Specification Q.931 as the primary functional specification. Note that the X.25 Layer 3 packet processor task is not included in the initial software package.

The Layer Protocol Tasks require a somewhat non-conventional task architecture in order to simultaneously manage a significant number of multiple logical connections. This event-driven state-machine architecture requires that a state memory block be created and maintained for each logical connection. When a Layer Protocol Task "wakes up" due to the arrival of mail, the message's address is interrogated to determine which logical connection is to receive the mail. The particular logical connection's state block is retrieved and the mail message is processed per the CCITT Specification requirements, depending on the state of the particular logical connection. Typically, processing the mail message results in sending a Primitive message to another task, and updating the logical connection's state block. The Layer Protocol Task then returns to its mail box to pick up any subsequent mail.

The interface between all of the ISDN Layer Tasks is deliberately achieved via the System Mail Utilities. This ensures a distinct, uniform layering mechanism in the event that application programmers wish to replace layers with their own implementations.

2.4.1 Layer 2 Controller Task

The primary job of the ISDN Data Link Layer 2 is to deliver error-free, sequenced data frames to the Network Layer 3. The Layer 2 Controller Task implements the following Layer 2 Link Access Procedures (LAP) for the HPC ISDN Software Package:

- LAPB per the X.25 CCITT Specification.
- LAPD per the Q.921 CCITT Specification.
- V.120 Terminal Adaption capability.

Since the Q.921 LAPD requirements were derived from the X.25 LAPB requirements, most of the same Layer 2 Controller Task routines can be used to implement both LAPB and LAPD. Design considerations have been made to allow future implementation of V.120.

The Layer 2 Controller Task communicates with the Layer 2 DMA/HDLC Controller Device Driver Task and the Management Entity Task, via the System Mail Utilities. These tasks interrogate the mail message headers to determine whether to process the frames using LAPB or LAPD procedures. The

2.0 Functional Description (Continued)

LAPD frames are mailed to the Q.931 Layer 3 Controller Task, while the LAPB frames are mailed to the X.25 Layer 3 Task.

The HPC16400 HDLC hardware handles the Layer 2 HDLC Procedures, which includes bit stuffing, address recognition, and Frame Check Sequence generation and detection. The Layer 2 Controller Task is responsible for the Layer 2 "Data Link Procedure", which includes the following functions:

- Data Transmission
- Protocol Exception Management
- LAPD-Specific Functions.

To accomplish these functions the Layer 2 Controller supports the full set of Layer 2 Peer-to-Peer messages defined in the CCITT Specification Q.921. These messages are listed below and defined further in the Software User's Manual.

UI	Unnumbered Information Frames
UA	Unnumbered Acknowledge
SABM(E)	Set Asynchronous Balanced Mode (Extended)
DISC	Disconnect Command
DM	Disconnect Mode
I	Acknowledged Information Frames
RR	Receiver Ready
RNR	Receiver Not Ready
REJ	Request Recrimination of Frames
FRMR	Unrecoverable Error, Frame Reject

The Layer 2 Controller Task also supports the primitives required to communicate with the other ISDN tasks.

2.4.1.1 Layer 2 Data Transmission

Layer 2 peer-to-peer Data Transmission is supported with two modes: Unacknowledged Data Mode and Multi-Frame Acknowledged Data Mode. The Unacknowledged Data Mode is used primarily for setting up logical connections and for peer-to-peer Management Entity communication. This mode uses the Unnumbered Information (UI) and the Unnumbered Acknowledge (UA) messages. The Multi-Frame Acknowledged Mode is established by the Set Asynchronous Balanced Mode (SABM) command. This mode provides the mechanism for acknowledgement of data frame transport in each direction. The Multi-Frame Acknowledged Mode is terminated with the Disconnect (DISC) command. The response to the DISC message can be either an Unnumbered Acknowledge (UA) message or a Disconnect Mode (DM) message. The actual Layer 2 data frames are transmitted in the Information (I) messages, while in the Multi-Framed Acknowledged Mode.

The Layer 2 Controller is responsible for avoiding message congestion and buffer overflow. A Layer 2 entity can issue the Receive Ready (RR) command to its peer to indicate that it is ready to continue data transmission. Likewise, the Layer 2 Controller can issue the Receiver Not Ready (RNR) command to its peer to indicate that it is not ready for data transmission.

2.4.1.2 Layer 2 Protocol Exception Management

The Layer 2 Controller Task is responsible for handling exceptions to the Data Link Protocol. These exceptions are of

two types: recoverable and unrecoverable. Recoverable exceptions in the receive direction are typically failed frames, which are handled by requesting the retransmission of the failed frame with the Reject (REJ) command. Recoverable exceptions in the transmit direction include the expiry of a Layer 2 Timer. Timer expiry requires the retransmission of the frame that was not acknowledged in time, and all subsequent frames. Timer expiry also prompts a message to the Management Entity. Unrecoverable exceptions result in the Frame Reject (FRMR) response. A message to the Management Entity Task is also sent in this case.

2.4.1.3 Layer 2 LAPD-Specific Functions

The following Layer 2 Controller Task functions are LAPD specific. These functions involve establishing and maintaining multiple logical data link connections. Note that a LAPB connection will be maintained as a special independent logical connection.

A two byte address is required for each logical data link. This address is referred to as the Data Link Connection Identifier (DLCI). The DLCI consists of a Service Access Point Identifier (SAPI) and a Terminal Endpoint Identifier (TEI). The Layer 2 Controller Task is responsible for supporting the TEI Assignment Procedure and the TEI Verification Procedure. These procedures are both initiated by the Management Entity. The Layer 2 Controller Task supports both the Automatic and Non-Automatic TEI Assignment Procedures.

Establishment of the LAPD multi-frame acknowledged data transmission mode requires an extended command (SABME) to prompt the peer entity that the frames are intended for a particular logical data connection identified by the accompanying DLCI. The Layer 2 Controller Task maintains each logical link's state and data frames independently, as explained earlier in this section.

The Layer 3 Controller Task addresses and maintains independent logical connections via an identifier called a Connection Endpoint Suffix (CES). Since the CES is different from the Layer 2 Terminal Endpoint Identifier (TEI), a mapping function is required. The Layer 2 Controller Task maintains a CES-TEI translation procedure to properly address Layer 3 logical entities.

2.4.2 Layer 3 Controller Task

The Layer 3 Controller Task implements the application independent portion of the ISDN NETWORK Layer 3 protocol, per the Q.931 CCITT Specification. The primary responsibility of the Layer 3 Controller Task is to establish a network access connection link between a terminal and its peer in the Central Office.

The Layer 3 Controller Task communicates with both the Layer 2 Controller Task and the Call Control Task by sending primitives via the System Mail Utilities. The Layer 3 Controller Task also communicates with the Management Entity Task. The HPC ISDN Layer 3 Controller Task is responsible for the following NETWORK functions:

- Call Establishment and Clearing
- Call Suspension and Resumption
- Call Status and Notification
- Protocol Exception Management.

2.0 Functional Description (Continued)

The Layer 3 Controller Task supports all the Network Layer Peer-to-Peer messages defined in the CCITT Specification Q.931, i.e.:

- Call Establishment and Clearing Messages:

ALERT	Alerting
CALL PROC	Call Proceeding
CONN	Connect
CONN ACK	Connect Acknowledge
INFO	Information
PROG	Progress
SETUP	Setup
SETUP ACK	Setup Acknowledge
DISC	Disconnect
REL	Release
REL COM	Release Complete

- Call Suspension and Resumption Messages

RESUME	Resume
RESUME ACK	Resume Acknowledge
RESUME REJ	Resume Reject
SUSPEND	Suspend
SUSPEND ACK	Suspend Acknowledge
SUSPEND REJ	Suspend Reject

- Miscellaneous Messages

NOTIFY	Notify
STATUS	Status
STATUS EN	Status Enquiry
USER INFO	User Information

2.4.2.1 Call Establishment And Clearing

The Layer 3 Controller Task's primary responsibility is to establish and clear user network connections on available bearer channel facilities. The Q.931 CCITT Specifications include Call Establishment and Clearing of both circuit-switched and packet-switched calls. Initially, the HPC ISDN Software Package only supports circuit-switched call procedures on Basic Rate Interface (BRI) Bearer Channels. The Layer 3 Controller Task is responsible for Call Reference assignment and maintenance. The Layer 3 Controller Task supports Call Establishment using both the Overlap and Non-Overlap (enbloc) addressing modes.

The procedure for establishing and clearing network connections is defined in CCITT Specification Q.931. It is important to note that the Layer 3 Controller Task maintains an associated state block for each network connection. Primitive mail messages arriving at the Layer 3 Controller Task will be interrogated to determine which network connection is to receive the mail. The mail message is processed depending on the state of the network connection. This processing typically includes the transmission of a Primitive to another Layer Task, and the appropriate update of the network connection state block.

2.4.2.2 Call Suspension And Resumption

Call Suspension (SUSPEND) requires that the Bearer Channel facility and the Call Reference for a call be temporarily relinquished. The network connection is left intact, but in the suspend state. The RESUME command reactivates the call by obtaining a Bearer Channel facility and establishing a new Call Reference. The Suspend function is somewhat analogous to the call HOLD feature.

2.4.2.3 Call Status And Notification

The Network can request the status of a network connection at any time via the USER INFO, NOTIFY and STATUS Commands. The information includes Service Validation and Channel Configuration.

2.4.2.4 Layer 3 Protocol Exception Management

The Layer 3 Controller is responsible for handling exceptions to the Network Control Protocol. The primary Layer 3 Controller Task protocol exception is the expiry of the Layer 3 timer. Such an exception requires the retransmission of the particular command and may prompt a message to the Management Entity Task.

2.4.2.5 Timer Support

The Layer 3 Controller supports the following system timers per CCITT Specification Q.931:

T303	SETUP ACK Timer
T305	DISCONNECT ACK Timer
T308	RELEASE ACK Timer
T313	CONNECT ACK Timer

2.4.2.6 SDL Updates

The Layer 3 Controller Task very closely follows the SDL procedures illustrated in CCITT Specification Q.931, with a few enhancements. These enhancements are listed here and fully defined in the Software User's Manual.

- Three new SDL States have been added to accommodate establishing the Data Link corresponding to a particular CES. The new states are:

- IDLESTATE
- RELEASEWAIT
- ESTABLISHWAIT

- The Q.931 NULLSTATE SDL now accepts a new command, CCBROADCASTRESP. This command is sent from the Call Control Task to allow transition from the NULLSTATE(0) to the CALLPRESENT State(6) during a Network Originated call via the Broadcast mechanism.

2.5 APPLICATION TASKS

The Application Tasks are very dependent on both the terminal equipment configuration and the far-end Network Entity software implementation. The HPC ISDN Software Package includes two sample Application Tasks: the Demonstration Call Control Task and the Management Entity Task. Both of these tasks can be replaced or updated when ported to a particular application. These tasks are included in the HPC ISDN Software Package primarily to verify the operation of the OSI Layer Protocol Tasks and the HPC Device Drivers.

2.5.1 Demonstration Call Control Task

The Demonstration Call Control Task is closely coupled to the specific facilities of an application. The interaction between the Layer 3 Controller Task and Call Control is defined in CCITT Specification Q.931. In the HPC ISDN Application, the Call Control Task communicates with the Layer 3 Controller Task and the Tracer Task. The availability of two circuit switched voice bearer channels is simulated in the Call Control Task. The Call Control Task sends standard Terminal Equipment prompts and messages to the Tracer Task where they are displayed on a UART driven CRT. The Call Control Task has the following responsibilities:

- B Channel Resource Management

2.0 Functional Description (Continued)

- Connection Endpoint Suffix (CES) Allocation
- Conversion between L3 Primitives and Terminal Action.

The Call Control Task and the Layer 3 Controller Task communicate via the NL_DATA_REQ and NL_DATA_IND Primitives. The messages that are supported between these tasks are listed below.

- Commands from Call Control to Layer 3

CC_SETUP_REQ	Setup Request
CC_SETUP_RESP	Setup Response
CC_SETUP_REJ_REQ	Setup Reject
CC_INFO_REQ	Information
CC_DISCONNECT_REQ	Disconnect
CC_RELEASE_REQ	Release
CC_ALERTING_REQ	Alerting
CC_BROADCAST_RESP	Broadcast Response
CC_CALLPROC_REQ	Call Proceeding
CC_PROGRESS_REQ	Progress
CC_NOTIFY_REQ	Notify
CC_RESUME_REQ	Resume
CC_RESUME_REJ	Resume Reject
CC_SUSPEND_REQ	Suspend Request
CC_SUSPEND_REJ	Suspend Reject
- Command from Layer 3 to Call Control

CC_SETUP_IND	Setup
CC_SETUP_CONF	Setup Confirm
CC_SETUP_COMP_IND	Setup Complete
CC_INFO_IND	Information Indication
CC_ALERTING_IND	Alerting
CC_PROGRESS_IND	Progress
CC_DISCONNECT_IND	Disconnect
CC_RELEASE_IND	Release
CC_CALLPROC_IND	Call Proceeding
CC_RELEASE_CONF	Release Confirm
CC_STATUS_IND	Status Indication
CC_ERROR_IND	Error Indication
CC_RESUME_CONF	Resume Confirm

The Call Control Task also communicates with the Tracer Task using single byte keystroke like commands. These commands are packaged mail messages containing two bytes: the first byte is the Sender Task's ID, the second byte is the keystroke command. The following messages are sent between Call Control and Tracer:

- Keystroke Commands from Tracer to Call Control Task

TR_ON_HOOK	ON Hook
TR_OFF_HOOK	Off Hook
TR_DIGIT_1	Digit 1
TR_DIGIT_2	Digit 2
TR_DIGIT_3	Digit 3
TR_DIGIT_4	Digit 4
TR_DIGIT_5	Digit 5
TR_DIGIT_6	Digit 6
TR_DIGIT_7	Digit 7
TR_DIGIT_8	Digit 8
TR_DIGIT_9	Digit 9

TR_DIGIT_0	Digit 0
TR_DIGIT_STAR	Digit *
TR_DIGIT_POUND	Digit #

- Commands from Call Control Task to Tracer

TR_IDLE	Idle, ON HOOK
TR_DIALTONE	Dial Tone
TR_DIALING	Dialing
TR_RINGING	Ringing
TR_BUSY	Busy
TR_CONVERSATION	Conversation
TR_RINGBACK	Ringback
TR_ERROR	Error

2.5.2 Management Entity Task

The Management Entity Task is closely coupled to the accompanying Network Management Entity design and to the terminal hardware configuration. Implementation design decisions have been made that make the Management Entity Task unique to a particular application, while still following the general requirements of the CCITT Specifications. Modifications will be required in the Management Entity Task prior to its successful operation in a particular application environment. The Management Entity Task that is included in the HPC ISDN Software Package presumes a particular hardware configuration and Central Office Software implementation.

The Management Entity Task communicates with the Layer 3 Controller Task, the Layer 2 Controller Task, and the Layer 1 Device Driver Task via the System Mail Utilities.

The Management Entity Task has the following responsibilities:

- Initialization of the Terminal Equipment
- Configuration of the Terminal Equipment
- TEI Assignment and Verification
- Multiple Error Notification
- Unrecoverable Error Notification
- Activation/Deactivation of the Terminal Equipment.

2.6 SYSTEM UTILITIES

The system utilities initializes the HPC system upon power-up, and provide support for various machine specific features of the HPC.

2.6.1 Power-Up Reset Main Task

This task is the entry point upon system power-up. The Main Task is responsible for:

- Initializing the general HPC Hardware.
- Initializing the HPC Executive Data Structures.
- Queuing up the Tasks on the Ready Queue.

The Main Task starts with the highest priority, 255. After running, the Main Task has served its purpose and is removed from the system by waiting on a semaphore which is typically never signaled.

2.6.2 Nonmaskable Interrupt (NMI) Handler

Since terminal power is generally a concern, the HPC can go into an idle, low-power mode when the Terminal Equipment is idle. In this mode the HPC is awakened via an NMI, prompted by a local off hook indication, or by a far-end line

2.0 Functional Description (Continued)

signal detection signal from the SID. Conditions for determining when to go in and out of idle mode are application dependent.

2.6.3 Timer Interrupt Handler

The Timer Interrupt Handler fields interrupts from two of the HPC onboard timers. Timer T0, the Watchdog Timer, overflows every 65536 clock counts. When this occurs the Timer Interrupt Handler mails a message to start the Watchdog Task. Timer T1, the ISDN Software Timer, overflows every 10 ms. The ISDN Software Clock is incremented every tenth Timer T1 overflow, resulting in an ISDN Clock with 100 ms resolution, which is used by the Executive Timer facility.

2.6.4 Watchdog Task

A special task is performed by the HPC's watchdog feature to verify system sanity. The Watchdog Task waits for a mail message that is sent by the Timer Interrupt Handler when Timer T0 overflows. This operation requires that the Watchdog Task be regularly scheduled by the HPC Executive. The Watchdog Task is assigned the highest task priority, 255.

3.0 Ordering Information

3.1 LICENSE AGREEMENT

A license agreement is required for the use and sale of the National Semiconductor ISDN Software. Contact your local National Semiconductor field sales office for more information or contact the factory direct at:

National Semiconductor
ISDN Software Support
M/S 16-174
2900 Semiconductor Drive
Santa Clara, CA 95051
(408) 721-5719

3.2 SOFTWARE ORDER INFORMATION

ISDN software is available in either Object or Source Code format. A Demonstration package is also available. Manuals are included with the Demonstration package and with the Executive and Basic Rate Interface Software packages.

Basic Rate Interface (BRI) software is available for several different central office switches. The generic BRI includes a generalized CCITT Switch Interface.

Each BRI Package contains the following modules:

- Layer 1 Driver (controls S device)
- Layer 2 Driver (controls DMA/HDLC)
- Layer 2 Controller (Q.921)
- Layer 3 Controller (Q.931 Protocol Control)
- Management Entity (Q.921 and Q.931)
- Call Control (Demonstration Application)
- Tracer (Demonstration and Development Tool)

The Multi-Tasking Executive contains two modules:

- Executive Core Module
- Executive Interface Module

The Executive Interface Module is always supplied as source code to allow modification to insert application tasks. A Multi-Tasking Executive is required to run the Basic Rate Interface.

Order Part Number Description

Multi-Tasking Executive

HPC-ISDN-EXEC-O Multi-Tasking Executive Object Code

Basic Rate Interface

HPC-ISDN-BRI-S Basic Rate Interface (Generic) Source Code

HPC-ISDN-BRID-S Basic Rate Interface (DMS-100) Source Code

HPC-ISDN-PCDEMO ISDN Basic Rate Interface Demonstration (includes Multi-Tasking Executive and Basic Rate Interface Software Manuals)

4.0 Other Related Information

4.1 DEVICE INFORMATION

Additional technical information on devices referenced in this datasheet is available from National:

- HPC16400 High Performance microController
- HPC16083 High Performance microController
- TP3076 COMBO IITM
- TP3420 CCITT S/T Interface

4.2 DEVELOPMENT SUPPORT INFORMATION

Development tools are available for the HPC Family of Microcontrollers. These tools support the ISDN development environment. ISDN software must be ordered separately.

4.2.1 ISDN Demonstration Kit

A kit is available that demonstrates the software and hardware discussed in this datasheet. Included in this kit is a TP3500 development board featuring the HPC16400, TP3070 COMBO II, TP3420 "SID" and ISDN Basic Rate Interface software in ROM. A complete set of manuals are included. This demonstration kit may be ordered from National, part number.

ISDN-TP3500-Kit

4.2.2 Development Systems

Several different Microcontroller-On-Line-Emulator Development Systems are available for hardware and software development of the HPC Family of Microcontrollers. Complete information on Development Systems and Accessories may be found in the Microcontroller Development Support Datasheet.

Surface Mount

Cost pressures today are forcing many electronics manufacturers to automate their production lines. Surface mount technology plays a key role in this cost-savings trend because:

1. The mounting of devices on the PC board surface eliminates the expense of drilling holes;
2. The use of pick-and-place machines to assemble the PC boards greatly reduces labor costs;
3. The lighter and more compact assembled products resulting from the smaller dimensions of surface mount packages mean lower material costs.

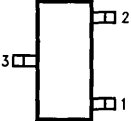

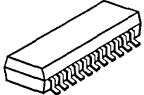

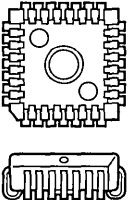

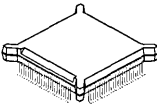

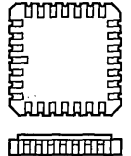

Production processes now permit both surface mount and insertion mount components to be assembled on the same PC board.

SURFACE MOUNT PACKAGING AT NATIONAL

To help our customers take advantage of this new technology, National has developed a line of surface mount packages. Ranging in lead counts from 3 to 360, the package offerings are summarized in Table I.

Lead center spacing keeps shrinking with each new generation of surface mount package. Traditional packages (e.g., DIPs) have a 100 mil lead center spacing. Surface mount packages currently in production (e.g., SOT, SOIC, PCC, LCC, LDCC) have a 50 mil lead center spacing. Surface mount packages in production release (e.g., PQFP) have a 25 mil lead center spacing. Surface mount packages in development (e.g., TAPEPAK®) will have a lead center spacing of only 12–20 mils.

TABLE I. Surface Mount Packages from National

Package Type	Small Outline Transistor (SOT)	Small Outline IC (SOIC)	Plastic Chip Carrier (PCC)	Plastic Quad Flat Pack (PQFP)	Leadless Chip Carrier (LCC) (LDCC)	Leaded Chip Carrier

*In production (or planned) for linear products.

LINEAR PRODUCTS IN SURFACE MOUNT

Linear functions available in surface mount include:

- Op amps
- Comparators
- Regulators
- References
- Data conversion
- Industrial
- Consumer
- Automotive

A complete list of linear part numbers in surface mount is presented in Table III. Refer to the datasheet in the appropriate chapter of this databook for a complete description of the device. In addition, National is continually expanding the list of devices offered in surface mount. If the functions you need do not appear in Table III, contact the sales office or distributor branch nearest you for additional information.

Automated manufacturers can improve their cost savings by using Tape-and-Reel for surface mount devices. Simplified handling results because hundreds-to-thousands of semiconductors are carried on a single Tape-and-Reel pack (see ordering and shipping information—printed later in this section—for a comparison of devices/reel vs. devices/rail for those surface mount package types being used for linear products). With this higher device count per reel (when compared with less than a 100 devices per rail), pick-and-place machines have to be re-loaded less frequently and lower labor costs result.

With Tape-and-Reel, manufacturers save twice—once from using surface mount technology for automated PC board assembly and again from less device handling during shipment and machine set-up.

BOARD CONVERSION

Besides new designs, many manufacturers are converting existing printed circuit board designs to surface mount. The resulting PCB will be smaller, lighter and less expensive to manufacture; but there is one caveat—be careful about the thermal dissipation capability of the surface mount package.

Because the surface mount package is smaller than the traditional dual-in-line package, the surface mount package is not capable of conducting as much heat away as the DIP (i.e., the surface mount package has a higher thermal resistance—see Table II).

The silicon for most National devices can operate up to a 150°C junction temperature (check the datasheet for the rare exception). Like the DIP, the surface mount package can actually withstand an ambient temperature of up to 125°C (although a commercial temperature range device will only be specified for a max ambient temperature of 70°C and an industrial temperature range device will only be specified for a max ambient temperature of 85°C). See AN-336, "Understanding Integrated Circuit Package Power Capabilities", (reprinted in the appendix of each linear databook volume) for more information.

**TABLE II: Surface Mount Package
Thermal Resistance Range***

Package	Thermal Resistance** (θ_{JA} , °C/W)
SO-8	120–175
SO-14	100–140
SO-14 Wide	70–110
SO-16	90–130
SO-16 Wide	70–100
SO-20	60–90
SO-24	55–85
PCC-20	70–100
PCC-28	60–90
PCC-44	40–60

*Actual thermal resistance for a particular device depends on die size. Refer to the datasheet for the actual θ_{JA} value.

**Test conditions: PCB mount (FR4 material), still air (room temperature), copper traces (150 × 20 × 10 mils).

Given a max junction temperature of 150°C and a maximum allowed ambient temperature, the surface mount device will be able to dissipate less power than the DIP device. This factor must be taken into account for new designs.

For board conversion, the DIP and surface mount devices would have to dissipate the same power. This means the surface mount circuit would have a lower maximum allowable ambient temperature than the DIP circuit. For DIP circuits where the maximum ambient temperature required is substantially lower than the maximum ambient temperature allowed, there may be enough margin for safe operation of the surface mount circuit with its lower maximum allowable ambient temperature. But where the maximum ambient temperature required of the DIP current is close to the maximum allowable ambient temperature, the lower maximum ambient temperature allowed for the surface mount circuit may fall below the maximum ambient temperature required. The circuit designer must be aware of this potential pitfall so that an appropriate work-around can be found to keep the surface mount package from being thermally overstressed in the application.

SURFACE MOUNT LITERATURE

National has published extensive literature on the subject of surface mount packaging. Engineers from packaging, quality, reliability, and surface mount applications have pooled their experience to provide you with practical hands-on knowledge about the construction and use of surface mount packages.

The applications note AN-450 "Surface Mounting Methods and their Effect on Product Reliability" is referenced on each SMD datasheet. In addition, "Wave Soldering of Surface Mount Components" is reprinted in this section for your information.

A FINAL WORD

National is a world leader in the design and manufacture of surface mount components.

Because of design innovations such as perforated copper leadframes, our small outline package is as reliable as our DIP—the laws of physics would have meant that a straight “junior copy” of the DIP would have resulted in an “S.O.” package of lower reliability. You benefit from this equivalence of reliability. In addition, our ongoing vigilance at each step of the production process assures that the reliability we designed in stays in so that only devices of the highest quality and reliability are shipped to your factory.

Our surface mount applications lab at our headquarters site in Santa Clara, California continues to research (and publish) methods to make it even easier for you to use surface mount technology. Your problems are our problems.

When you think “Surface Mount”—think “National”!

Ordering and Shipping Information

When you order a surface mount semiconductor, it will be in one of the several available surface mount package types. Specifying the Tape-and-Reel method of shipment means that you will receive your devices in the following quantities per Tape-and-Reel pack: SMD devices can also be supplied in conventional conductive rails.

Package	Package Designator	Max/Rail	Per Reel*
SO-8	M	100	2500
SO-14	M	50	2500
SO-14 Wide	WM	50	1000
SO-16	M	50	2500
SO-16 Wide	WM	50	1000
SO-20	M	40	1000
SO-24	M	30	1000
PCL-20	V	50	1000
PCL-28	V	40	1000
PCL-44	V	25	500
PQFP-196	VF	TBD	—
TP-40	TP	100	TBD
LCC-20	E	50	—
LCC-44	E	25	—

*Incremental ordering quantities. (National Semiconductor reserves the right to provide a smaller quantity of devices per Tape-and-Reel pack to preserve lot or date code integrity. See example below.)

Example: You order 5,000 LM324M ICs shipped in Tape-and-Reel.

- Case 1: All 5,000 devices have the same date code
 - You receive 2 SO-14 (Narrow) Tape-and-Reel packs, each having 2500 LM324M ICs
- Case 2: 3,000 devices have date code A and 2,000 devices have date code B
 - You receive 3 SO-14 (Narrow) Tape-and-Reel packs as follows:
 - Pack #1 has 2,500 LM324M ICs with date code A
 - Pack #2 has 500 LM324M ICs with date code A
 - Pack #3 has 2,000 LM324M ICs with date code B

Wave Soldering of Surface Mount Components

ABSTRACT

In facing the upcoming surge of "surface mount technology", many manufacturers of printed circuit boards have taken steps to convert some portions of their boards to this new process. However, as the availability of surface mount components is still limited, many have taken to mixing the lead-inserted standard dual-in-line packages (DIPs) with the surface mounted devices (SMDs). Furthermore, to take advantage of using both sides of the board, surface-mounted components are generally adhered to the bottom side of the board while the top side is reserved for the conventional lead-inserted packages. If processed through a wave solder machine, the semiconductor components are now subjected to extra thermal stresses (now that the components are totally immersed into the molten solder).

A discussion of the effect of wave soldering on the reliability of plastic semiconductor packages follows. This is intended to highlight the limitations which should be understood in the use of wave soldering of surface mounted components.

ROLE OF WAVE-SOLDERING IN APPLICATION OF SMDs

The generally acceptable methods of soldering SMDs are vapor phase reflow soldering and IR reflow soldering, both requiring application of solder paste on PW boards prior to placement of the components. However, sentiment still exists for retaining the use of the old wave-soldering machine.

Wave Soldering of Surface Mount Components (Continued)

The reasons being:

- 1) Most PC Board Assembly houses already possess wave soldering equipment. Switching to another technology such as vapor phase soldering requires substantial investment in equipment and people.
- 2) Due to the limited number of devices that are surface mount components, it is necessary to mix both lead inserted components and surface mount components on the same board.
- 3) Some components such as relays and switches are made of materials which would not be able to survive the temperature exposure in a vapor phase or IR furnace.

PW BOARD ASSEMBLY PROCEDURES

There are two considerations in which through-hole ICs may be combined with surface mount components on the PW Board:

- a) Whether to mount ICs on one or both sides of the board.
- b) The sequence of soldering using Vapor Phase, IR or Wave Soldering singly or combination of two or more methods.

The various processes that may be employed are:

A) Wave Solder before Vapor/IR reflow solder.

1. Components on the same side of PW Board.
 - Lead insert standard DIPs onto PW Board Wave solder (conventional)
 - Wash and lead trim
 - Dispense solder paste on SMD pads
 - Pick and place SMDs onto PW Board
 - Bake
 - Vapor phase/IR reflow
 - Clean
2. Components on opposite side of PW Board.
 - Lead insert standard DIPs onto PW Board Wave Solder (conventional)
 - Clean and lead trim
 - Invert PW Board
 - Dispense solder paste on SMD pads
 - Dispense drop of adhesive on SMD sites (optional for smaller components)
 - Pick and place SMDs onto board
 - Bake/Cure
 - Invert board to rest on raised fixture
 - Vapor/IR reflow soldering
 - Clean

B) Vapor/IR reflow solder then Wave Solder.

1. Components on the same side of PW Board.
 - Solder paste screened on SMD side of Printed Wire Board
 - Pick and place SMDs
 - Bake
 - Vapor/IR reflow
 - Lead insert on same side as SMDs
 - Wave solder
 - Clean and trim underside of PCB

C) Vapor/IR reflow only.

1. Components on the same side of PW Board.
 - Trim and form standard DIPs in "gull wing" configuration
 - Solder paste screened on PW Board
 - Pick and place SMDs and DIPs
 - Bake
 - Vapor/IR reflow
 - Clean
2. Components on opposite sides of PW Board.
 - Solder paste screened on SMD-side of Printed Wire Board
 - Adhesive dispensed at central location of each component
 - Pick and place SMDs
 - Bake
 - Solder paste screened on all pads on DIP-side or alternatively apply solder rings (performs) on leads
 - Lead insert DIPs
 - Vapor/IR reflow
 - Clean and lead trim

D) Wave Soldering Only

1. Components on opposite sides of PW Board.
 - Adhesive dispense on SMD side of PW Board
 - Pick and place SMDs
 - Cure adhesive
 - Lead insert top side with DIPs
 - Wave solder with SMDs down and into solder bath
 - Clean and lead trim

All of the above assembly procedures can be divided into three categories for I.C. Reliability considerations:

- 1) Components are subjected to both a vapor phase/IR heat cycle then followed by a wave-solder heat cycle or vice versa.
- 2) Components are subjected to only a vapor phase/IR heat cycle.
- 3) Components are subjected to wave-soldering only and SMDs are subjected to heat by immersion into a solder pot.

Of these three categories, the last is the most severe regarding heat treatment to a semiconductor device. However, note that semiconductor molded packages generally possess a coating of solder on their leads as a final finish for solderability and protection of base leadframe material. Most semiconductor manufacturers solder-plate the component leads, while others perform hot solder dip. In the latter case the packages may be subjected to total immersion into a hot solder bath under controlled conditions (manual operation) or be partially immersed while in a 'pallet' where automatic wave or DIP soldering processes are used. It is, therefore, possible to subject SMDs to solder heat under certain conditions and not cause catastrophic failures.

Wave Soldering of Surface Mount Components (Continued)

THERMAL CHARACTERISTICS OF MOLDED INTEGRATED CIRCUITS

Since Plastic DIPs and SMDs are encapsulated with a thermoset epoxy, the thermal characteristics of the material generally correspond to a TMA (Thermo-Mechanical Analysis) graph. The critical parameters are (a) its Linear thermal expansion characteristics and (b) its glass transition temperature after the epoxy has been fully cured. A typical TMA graph is illustrated in *Figure 1*. Note that the epoxy changes to a higher thermal expansion once it is subjected to temperatures exceeding its glass transition temperature. Metals (as used on lead frames, for example) do not have this characteristic and generally will have a consistent Linear thermal expansion over the same temperature range.

In any good reliable plastic package, the choice of lead frame material should be such to match its thermal expansion properties to that of the encapsulating epoxy. In the event that there is a mismatch between the two, stresses can build up at the interface of the epoxy and metal. There now exists a tendency for the epoxy to separate from the metal lead frame in a manner similar to that observed on bi-metallic thermal range.

In most cases when the packages are kept at temperatures below their glass transition, there is a small possibility of separation at the epoxy-metal interface. However, if the package is subjected to temperature above its glass-transition temperature, the epoxy will begin to expand much faster than the metal and the probability of separation is greatly increased.

CONVENTIONAL WAVE-SOLDERING

Most wave-soldering operations occur at temperatures between 240–260°C. Conventional epoxies for encapsulation have glass-transition temperature between 140–170°C. An I.C. directly exposed to these temperatures risks its long term functionality due to epoxy/metal separation.

Fortunately, there are factors that can reduce that element of risk:

- 1) The PW board has a certain amount of heat-sink effect and tends to shield the components from the temperature of the solder (if they were placed on the top side of the board). In actual measurements, DIPs achieve a temperature between 120–150°C in a 5-second pass over the solder. This accounts for the fact that DIPs mounted in the conventional manner are reliable.
- 2) In conventional soldering, only the tip of each lead in a DIP would experience the solder temperature because the epoxy and die are standing above the PW board and out of the solder bath.

EFFECT ON PACKAGE PERFORMANCE BY EPOXY-METAL SEPARATION

In wave soldering, it is necessary to use fluxes to assist the solderability of the components and PW boards. Some facilities may even process the boards and components through some form of acid cleaning prior to the soldering temperature. If separation occurs, the flux residues and acid residues (which may be present owing to inadequate cleaning) will be forced into the package mainly by capillary action as the residues move away from the solder heat source. Once the package is cooled, these contaminants are now trapped within the package and are available to diffuse with moisture from the epoxy over time. It should be noted that electrical tests performed immediately after soldering generally will give no indication of this potential problem. In any case, the end result will be corrosion of the chip metallization over time and premature failure of the device in the field.

VAPOR PHASE/IR REFLOW SOLDERING

In both vapor phase and IR reflow soldering, the risk of separation between epoxy/metal can also be high. Operating temperatures are 215°C (vapor phase) or 240°C (IR) and duration may also be longer (30 sec–60 sec). On the same theoretical basis, there should also be separation. However, in both these methods, solder paste is applied to the pads of the boards; no fluxes are used. Also, the devices are not immersed into the hot solder. This reduces the possibility of solder forcing itself into the epoxy-lead frame interface. Furthermore, in the vapor phase system, the soldering environment is "oxygen-free" and considered "contaminant free". Being so, it could be visualized that as far as reliability with respect to corrosion, both of these methods are advantageous over wave soldering.

BIAS MOISTURE TEST

A bias moisture test was designed to determine the effect on package performance. In this test, the packages are pressured in a stream chamber to accelerate penetration of moisture into the package. An electrical bias is applied on the device. Should there be any contaminants trapped within the package, the moisture will quickly form an electrolyte and cause the electrodes (which are the lead fingers), the gold wire and the aluminum bond-pads of the silicon device to corrode. The aluminum bond-pads, being the weakest link of the system, will generally be the first to fail.

This proprietary accelerated bias/moisture pressure-test is significant in relation to the life test condition at 85°C and

FIGURE 1. Thermal Expansion and Glass Transition Temperature

TL/DD/11325-11

Wave Soldering of Surface Mount Components (Continued)

85% relative humidity. Once cycle of approximately 100 hours has been shown to be equivalent to 2000 hours in the 85/85 condition. Should the packages start to fail within the first cycle in the test, it is anticipated that the boards with these components in the harsh operating environment (85°C/85% RH) will experience corrosion and eventual electrical failures within its first 2000 hours of operation.

Whether this is significant to a circuit board manufacturer will obviously be dependent on the products being manufactured and the workmanship or reliability standards. Generally in systems with a long warranty and containing many components, it is advisable both on a reputation and cost basis to have the most reliable parts available.

TEST RESULTS

The comparison of vapor phase and wave-soldering upon the reliability of molded Small-Outline packages was performed using the bias moisture test (see Table IV). It is clearly seen that vapor phase reflow soldering gave more consistent results. Wave-soldering results were based on manual operation giving variations in soldering parameters such as temperature and duration.

TABLE IV. Vapor Phase vs. Wave Solder

1. Vapor phase (60 sec. exposure @ 215°C)
= 9 failures/1723 samples
= 0.5% (average over 32 sample lots)
2. Wave solder (2 sec total immersion @ 260°C)
= 16 failures/1201 samples
= 1.3% (average over 27 sample lots)
Package: SO-14 lead
Test: Bias moisture test 85% R.H.,
85°C for 2000 hours
Device: LM324M

In Table V we examine the tolerance of the Small-Outlined (SOIC) package to varying immersion time in a hot solder pot. SO-14 lead molded packages were subjected to the bias moisture test after being treated to the various soldering conditions and repeated four (4) times. End point was an electrical test after an equivalent of 4000 hours 85/85 test. Results were compared for packages by itself against packages which were surface-mounted onto a FR-4 printed wire board.

**TABLE V. Summary of Wave Solder Results
(85% R.H./85°C Bias Moisture Test, 2000 hours)
(# Failures/Total Tested)**

	Unmounted	Mounted
Control/Vapor Phase 15 sec @ 215°C	0/114	0/84
Solder Dip 2 sec @ 260°C	2/144 (1.4%)	0/85
Solder Dip 4 sec @ 260°C	—	0/83
Solder Dip 6 sec @ 260°C	13/248 (5.2%)	1/76 (1.3%)
Solder Dip 10 sec @ 260°C	14/127 (11.0%)	3/79 (3.8%)
Package: SO-14 lead		
Device: LM324M		

Since the package is of very small mass and experiences a rather sharp thermal shock followed by stresses created by the mismatch in expansion, the results show the package being susceptible to failures after being immersed in excess of 6 seconds in a solder pot. In the second case where the packages were mounted, the effect of severe temperature excursion was reduced. In the second case where the packages were mounted, the effect of severe temperature excursion was reduced. In any case, because of the repeated treatment, the package had failures when subjected in excess of 6 seconds immersion in hot solder. The safety margin is therefore recommended as maximum 4 seconds immersion. If packages were immersed longer than 4 seconds, there is a probable chance of finding some long term reliability failures even though the immediate electrical test data could be acceptable.

Finally, Table VI examines the bias moisture test performed on surface mount (SOIC) components manufactured by various semiconductor houses. End point was an electrical test after an equivalent of 6000 hours in a 85/85 test. Failures were analyzed and corrosion was checked for in each case to detect flaws in package integrity.

**TABLE VI. U.S. Manufacturers Integrated Circuits
Reliability in Various Solder Environments
(# Failure/Total Tested)**

SUMMARY

Based on the results presented, it is noted that surface-mounted components are as reliable as standard molded DIP packages. Whereas DIPs were never processed by being totally immersed in a hot solder wave during printed circuit board soldering, surface mounted components such as SOICs (Small Outline) are expected to survive a total immersion in the hot solder in order to capitalize on maximum population on boards. Being constructed from a thermoset plastic of relatively low Tg compared to the soldering temperature, the ability of the package to survive is dependent on the time of immersion and also the cleanliness of material. The results indicate that one should limit the immersion time of package in the solder wave to a maximum of 4 seconds in order to truly duplicate the reliability of a DIP. As the package size is reduced, as in a SO-8 lead, the requirement becomes even more critical. This is shown by the various manufacturers' performance. Results indicate there is room for improvement since not all survived the hot solder immersion without compromise to lower reliability.

Small Outline (SO) Package Surface Mounting Methods—Parameters and Their Effect on Product Reliability

The SO (small outline) package has been developed to meet customer demand for ever-increasing miniaturization and component density.

COMPONENT SIZE COMPARISON

TL/DD/11325-12

TL/DD/11325-13

Because of its small size, reliability of the product assembled in SO packages needs to be carefully evaluated.

SO packages at National were internally qualified for production under the condition that they be of comparable reliability performance to a standard dual in line package under all accelerated environmental tests. *Figure A* is a summary of accelerated bias moisture test performance on 30V bipolar and 15V CMOS product assembled in SO and DIP (control) packages.

FIGURE A

TL/DD/11325-14

In order to achieve reliability performance comparable to DIPs—SO packages are designed and built with materials and processes that effectively compensate for their small size.

All SO packages tested on 85%RA, 85°C were assembled on PC conversion boards using vapor-phase reflow soldering. With this approach we are able to measure the effect of surface mounting methods on reliability of the process. As illustrated in *Figure A* no significant difference was detected between the long term reliability performance of surface mounted S.O. packages and the DIP control product for up to 6000 hours of accelerated 85%/85°C testing.

SURFACE-MOUNT PROCESS FLOW

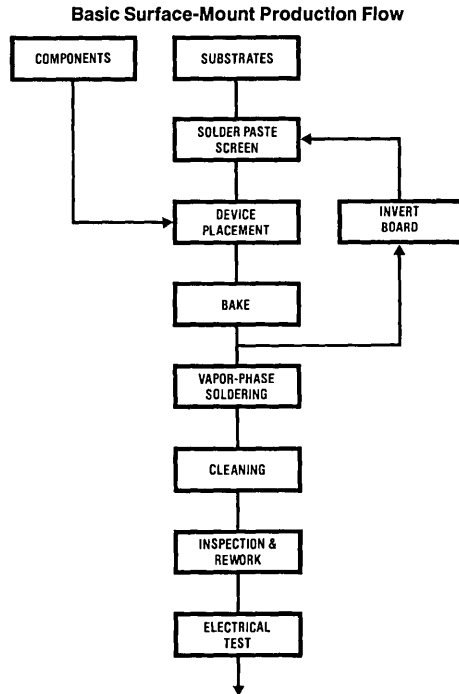

The standard process flowcharts for basic surface-mount operation and mixed-lead insertion/surface-mount operations, are illustrated on the following pages.

Usual variations encountered by users of SO packages are:

- Single-sided boards, surface-mounted components only.
- Single-sided boards, mixed-lead inserted and surface-mounted components.
- Double-sided boards, surface-mounted components only.
- Double-sided boards, mixed-lead inserted and surface-mounted components.

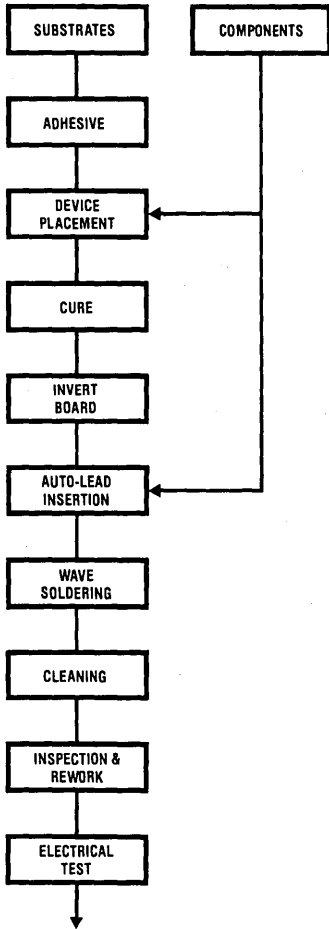

In consideration of these variations, it became necessary for users to utilize techniques involving wave soldering and adhesive applications, along with the commonly-used vapor-phase solder reflow soldering technique.

PRODUCTION FLOW

TL/DD/11325-15

Mixed Surface-Mount and Axial-Leaded Insertion Components Production Flow

TL/DD/11325-16

Thermal stress of the packages during surface-mounting processing is more severe than during standard DIP PC board mounting processes. *Figure B* illustrates package temperature versus wave soldering dwell time for surface mounted packages (components are immersed into the molten solder) and the standard DIP wave soldering process. (Only leads of the package are immersed into the molten solder).

TL/DD/11325-17

FIGURE B

For an ideal package, the thermal expansion rate of the encapsulant should match that of the leadframe material in order for the package to maintain mechanical integrity during the soldering process. Unfortunately, a perfect matchup of thermal expansion rates with most presently used packaging materials is scarce. The problem lies primarily with the epoxy compound.

Normally, thermal expansion rates for epoxy encapsulant and metal lead frame materials are linear and remain fairly close at temperatures approaching 160°C, *Figure C*. At lower temperatures the difference in expansion rate of the two materials is not great enough to cause interface separation. However, when the package reaches the glass-transition temperature (T_g) of epoxy (typically 160–165°C), the thermal expansion rate of the encapsulant increases sharply, and the material undergoes a transition into a plastic state. The epoxy begins to expand at a rate three times or more greater than the metal leadframe, causing a separation at the interface.

TL/DD/11325-18

FIGURE C

When this happens during a conventional wave soldering process using flux and acid cleaners, process residues and even solder can enter the cavity created by the separation and become entrapped when the material cools. These contaminants can eventually diffuse into the interior of the package, especially in the presence of moisture. The result is die contamination, excessive leakage, and even catastrophic failure. Unfortunately, electrical tests performed immediately following soldering may not detect potential flaws.

Most soldering processes involve temperatures ranging up to 260°C, which far exceeds the glass-transition temperature of epoxy. Clearly, circuit boards containing SMD packages require tighter process controls than those used for boards populated solely by DIPs.

Figure D is a summary of accelerated bias moisture test performance on the 30V bipolar process.

Group 1 — Standard DIP package

4 — dwell time 4 seconds

5 — dwell time 6 seconds

6 — dwell time 10 seconds

TL/DD/11325-19

FIGURE D

It is clear based on the data presented that SO packages soldered onto PC boards with the vapor phase reflow process have the best long term bias moisture performance and this is comparable to the performance of standard DIP packages. The key advantage of reflow soldering methods is the clean environment that minimized the potential for contamination of surface mounted packages, and is preferred for the surface-mount process.

When wave soldering is used to surface mount components on the board, the dwell time of the component under molten solder should be no more than 4 seconds, preferably under 2 seconds in order to prevent damage to the component. Non-Halide, or (organic acid) fluxes are highly recommended.

PICK AND PLACE

The choice of automatic (all generally programmable) pick-and-place machines to handle surface mounting has grown considerably, and their selection is based on individual needs and degree of sophistication.

The basic component-placement systems available are classified as:

- (a) In-line placement
 - Fixed placement stations
 - Boards indexed under head and respective components placed
- (b) Sequential placement
 - Either a X-Y moving table system or a θ , X-Y moving pickup system used
 - Individual components picked and placed onto boards
- (c) Simultaneous placement
 - Multiple pickup heads
 - Whole array of components placed onto the PCB at the same time
- (d) Sequential/simultaneous placement
 - X-Y moving table, multiple pickup heads system
 - Components placed on PCB by successive or simultaneous actuation of pickup heads

The SO package is treated almost the same as surface-mount, passive components requiring correct orientation in placement on the board.

Pick and Place Action

TL/DD/11325-20

BAKE

This is recommended, despite claims made by some solder paste suppliers that this step be omitted.

The functions of this step are:

- Holds down the solder globules during subsequent reflow soldering process and prevents expulsion of small solder balls.
- Acts as an adhesive to hold the components in place during handling between placement to reflow soldering.
- Holds components in position when a double-sided surface-mounted board is held upside down going into a vapor-phase reflow soldering operation.
- Removes solvents which might otherwise contaminate other equipment.
- Initiates activator cleaning of surfaces to be soldered.
- Prevents moisture absorption.

The process is moreover very simple. The usual schedule is about 20 minutes in a 65°C–95°C (dependent on solvent system of solder paste) oven with adequate venting. Longer bake time is not recommended due to the following reasons:

- The flux will degrade and affect the characteristics of the paste.
- Solder globules will begin to oxidize and cause solderability problems.
- The paste will creep and after reflow, may leave behind residues between traces which are difficult to remove and vulnerable to electro-migration problems.

REFLOW SOLDERING

There are various methods for reflowing the solder paste, namely:

- Hot air reflow
- Infrared heating (furnaces)
- Convectional oven heating
- Vapor-phase reflow soldering
- Laser soldering

For SO applications, hot air reflow/infrared furnace may be used for low-volume production or prototype work, but vapor-phase soldering reflow is more efficient for consistency and speed. Oven heating is not recommended because of "hot spots" in the oven and uneven melting may result. Laser soldering is more for specialized applications and requires a great amount of investment.

HOT GAS REFLOW/INFRARED HEATING

A hand-held or table-mount air blower (with appropriate orifice mask) can be used.

The boards are preheated to about 100°C and then subjected to an air jet at about 260°C. This is a slow process and results may be inconsistent due to various heat-sink properties of passive components.

Use of an infrared furnace is the next step to automating the concept, except that the heating is promoted by use of IR lamps or panels. The main objection to this method is that certain materials may heat up at different rates under IR radiation and may result in damage to these components (usually sockets and connectors). This could be minimized by using far-infrared (non-focused) system.

VAPOR-PHASE REFLOW SOLDERING

Currently the most popular and consistent method, vapor-phase soldering utilizes a fluoroinert fluid with excellent heat-transfer properties to heat up components until the solder paste reflows. The maximum temperature is limited by the vapor temperature of the fluid.

The commonly used fluids (supplied by 3M Corp) are:

- FC-70, 215°C vapor (most applications) or FX-38
- FC-71, 253°C vapor (low-lead or tin-plate)

HTC, Concord, CA, manufactures equipment that utilizes this technique, with two options:

- Batch systems, where boards are lowered in a basket and subjected to the vapor from a tank of boiling fluid.
- In-line conveyerized systems, where boards are placed onto a continuous belt which transports them into a concealed tank where they are subjected to an environment of hot vapor.

Dwell time in the vapor is generally on the order of 15–30 seconds (depending on the mass of the boards and the loading density of boards on the belt).

In-Line Conveyerized Vapor-Phase Soldering

TL/DD/11325-21

The question of thermal shock is asked frequently because of the relatively sharp increase in component temperature from room temperature to 215°C. SO packages mounted on representative boards have been tested and have shown little effect on the integrity of the packages. Various packages, such as cerdips, metal cans and TO-5 cans with glass seals, have also been tested.

PRINTED CIRCUIT BOARD

The SO package is molded out of clean, thermoset plastic compound and has no particular compatibility problems with most printed circuit board substrates.

The package can be reliably mounted onto substrates such as:

- G10 or FR4 glass/resin
- FR5 glass/resin systems for high-temperature applications
- Polyimide boards, also high-temperature applications
- Ceramic substrates

General requirements for printed circuit boards are:

- Mounting pads should be solder-plated whenever applicable.
- Solder masks are commonly used to prevent solder bridging of fine lines during soldering.

The mask also protects circuits from processing chemical contamination and corrosion.

If coated over pre-tinned traces, residues may accumulate at the mask/trace interface during subsequent reflow, leading to possible reliability failures.

Recommended application of solder resist on bare, clean traces prior to coating exposed areas with solder.

General requirements for solder mask:

- Good pattern resolution.
- Complete coverage of circuit lines and resistance to flaking during soldering.
- Adhesion should be excellent on substrate material to keep off moisture and chemicals.
- Compatible with soldering and cleaning requirements.

SOLDER PASTE SCREEN PRINTING

With the initial choice of printed circuit lithographic design and substrate material, the first step in surface mounting is the application of solder paste.

The typical lithographic "footprints" for SO packages are illustrated below. Note that the 0.050" lead center-center spacing is not easily managed by commercially-available air pressure, hand-held dispensers.

Using a stainless-steel, wire-mesh screen stencilled with an emulsion image of the substrate pads is by far the most common and well-tried method. The paste is forced through the screen by a V-shaped plastic squeegee in a sweeping manner onto the board placed beneath the screen.

The setup for SO packages has no special requirement from that required by other surface-mounted, passive components. Recommended working specifications are:

- Use stainless-steel, wire-mesh screens, #80 or #120, wire diameter 2.6 mils. Rule of thumb: mesh opening should be approximately 2.5–5 times larger than the average particle size of paste material.
- Use squeegee of Durometer 70.
- Experimentation with squeegee travel speed is recommended, if available on machine used.
- Use solder paste of mesh 200–325.
- Emulsion thickness of 0.005" usually used to achieve a solder paste thickness (wet) of about 0.008" typical.
- Mesh pattern should be 90 degrees, square grid.
- Snap-off height of screen should not exceed $\frac{1}{8}$ ", to avoid damage to screens and minimize distortion.

SOLDER PASTE

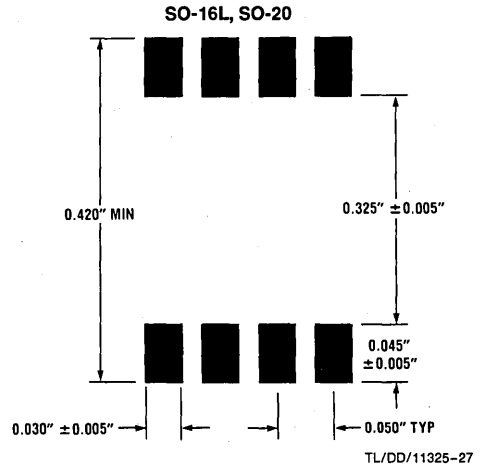

Selection of solder paste tends to be confusing, due to numerous formulations available from various manufacturers. In general, the following guidelines are sufficient to qualify a particular paste for production:

- Particle sizes (see photographs below). Mesh 325 (approximately 45 microns) should be used for general purposes, while larger (solder globules) particles are preferred for leadless components (LCC). The larger particles can easily be used for SO packages.

- Uniform particle distribution. Solder globules should be spherical in shape with uniform diameters and minimum amount of elongation (visual under 100/200 × magnification). Uneven distribution causes uneven melting and subsequent expulsion of smaller solder balls away from their proper sites.

- Composition, generally 60/40 or 63/37 Sn/Pb. Use 62/36 Sn/Pb with 2% Ag in the presence of Au on the soldering area. This formulation reduces problems of metal leaching from soldering pads.
- RMA flux system usually used.
- Use paste with approximately 88–90% solids.

CLEANING

The most critical process in surface mounting SO packages is in the cleaning cycle. The package is mounted very close to the surface of the substrate and has a tendency to collect residue left behind after reflow soldering.

Important considerations in cleaning are:

- Time between soldering and cleaning to be as short as possible. Residue should not be allowed to solidify on the substrate for long periods of time, making it difficult to dislodge.
- A low surface tension solvent (high penetration) should be employed. Solvents commercially available are:
 - Freon TMS (general purpose)
 - Freon TE35/TP35 (cold-dip cleaning)
 - Freon TES (general purpose)

It should also be noted that these solvents generally will leave the substrate surface hydrophobic (moisture repellent), which is desirable.

Prelete or 1,1,1-Trichloroethane
Kester 5120/5121

- A defluxer system which allows the workpiece to be subjected to a solvent vapor, followed by a rinse in pure solvent and a high-pressure spray lance are the basic requirements for low-volume production.
- For volume production, a conveyORIZED, multiple hot solvent spray/jet system is recommended.
- Rosin, being a natural occurring material, is not readily soluble in solvents, and has long been a stumbling block to the cleaning process. In recent developments, synthetic flux (SA flux), which is readily soluble in Freon TMS solvent, has been developed. This should be explored where permissible.

The dangers of an inadequate cleaning cycle are:

- Ion contamination, where ionic residue left on boards would cause corrosion to metallic components, affecting the performance of the board.
- Electro-migration, where ionic residue and moisture present on electrically-biased boards would cause dendritic growth between close spacing traces on the substrate, resulting in failures (shorts).

REWORK

Should there be a need to replace a component or re-align a previously disturbed component, a hot air system with appropriate orifice masking to protect surrounding components may be used.

When rework is necessary in the field, specially-designed tweezers that thermally heat the component may be used to remove it from its site. The replacement can be fluxed at the

Hot-Air Solder Rework Station

TL/DD/11325-34

Hot-Air Rework Machine

TL/DD/11325-35

lead tips or, if necessary, solder paste can be dispensed onto the pads using a varimeter. After being placed into position, the solder is reflowed by a hot-air jet or even a standard soldering iron.

WAVE SOLDERING

In a case where lead insertions are made on the same board as surface-mounted components, there is a need to include a wave-soldering operation in the process flow.

Two options are used:

- Surface mounted components are placed and vapor phase reflowed before auto-insertion of remaining components. The board is carried over a standard wave-solder system and the underside of the board (only lead-inserted leads) soldered.
- Surface-mounted components are placed in position, but no solder paste is used. Instead, a drop of adhesive about 5 mils maximum in height with diameter not exceeding 25% width of the package is used to hold down the package. The adhesive is cured and then proceeded to auto-insertion on the reverse side of the board (surface-mounted side facing down). The assembly is then passed over a "dual wave" soldering system. Note that the surface-mounted components are immersed into the molten solder.

Lead trimming will pose a problem after soldering in the latter case, unless the leads of the insertion components are pre-trimmed or the board specially designed to localize certain areas for easy access to the trim blade.

The controls required for wave soldering are:

- Solder temperature to be 240–260°C. The dwell time of components under molten solder to be short (preferably kept under 2 seconds), to prevent damage to most components and semiconductor devices.
- RMA (Rosin Mildly Activated) flux or more aggressive OA (Organic Acid) flux are applied by either dipping or foam fluxing on boards prior to preheat and soldering. Cleaning procedures are also more difficult (aqueous, when OA flux is used), as the entire board has been treated by flux (unlike solder paste, which is more or less localized). Non-halide OA fluxes are highly recommended.
- Preheating of boards is essential to reduce thermal shock on components. Board should reach a temperature of about 100°C just before entering the solder wave.
- Due to the closer lead spacings (0.050" vs 0.100" for dual-in-line packages), bridging of traces by solder could occur. The reduced clearance between packages also causes "shadowing" of some areas, resulting in poor solder coverage. This is minimized by dual-wave solder systems.

Mixed Surface Mount and Lead Insertion

TL/DD/11325-36

A typical dual-wave system is illustrated below, showing the various stages employed. The first wave typically is in turbulence and given a transverse motion (across the motion of the board). This covers areas where "shadowing" occurs. A second wave (usually a broad wave) then proceeds to perform the standard soldering. The departing edge from the solder is such to reduce "icicles," and is still further reduced by an air knife placed close to the final soldering step. This air knife will blow off excess solder (still in the fluid stage) which would otherwise cause shorts (bridging) and solder bumps.

AQUEOUS CLEANING

- For volume production, a conveyerized system is often used with a heated recirculating spray wash (water temperature 130°C), a final spray rinse (water temperature 45–55°C), and a hot (120°C) air/air-knife drying section.
- For low-volume production, the above cleaning can be done manually, using several water rinses/tanks. Fast-drying solvents, like alcohols that are miscible with water, are sometimes used to help the drying process.
- Neutralizing agents which will react with the corrosive materials in the flux and produce material readily soluble in water may be used; the choice depends on the type of flux used.
- Final rinse water should be free from chemicals which are introduced to maintain the biological purity of the water. These materials, mostly chlorides, are detrimental to the assemblies cleaned because they introduce a fresh amount of ionizable material.

Dual Wave

TL/DD/11325-37

CONFORMAL COATING

Conformal coating is recommended for high-reliability PCBs to provide insulation resistance, as well as protection against contamination and degradation by moisture.

Requirements:

- Complete coating over components and solder joints.
- Thixotropic material which will not flow under the packages or fill voids, otherwise will introduce stress on solder joints on expansion.
- Compatibility and possess excellent adhesion with PCB material/components.
- Silicones are recommended where permissible in application.

SMD Lab Support

FUNCTIONS

Demonstration—Introduce first-time users to surface-mounting processes.

Service—Investigate problems experienced by users on surface mounting.

Reliability Builds—Assemble surface-mounted units for reliability data acquisition.

Techniques—Develop techniques for handling different materials and processes in surface mounting.

Equipment—In conjunction with equipment manufacturers, develop customized equipments to handle high density, new technology packages developed by National.

In-House Expertise—Availability of in-house expertise on semiconductor research/development to assist users on packaging queries.

Plastic Leaded Chip Carrier (PLCC) Packaging

General Description

The Plastic Leaded Chip Carrier (PLCC) is a miniaturized low cost semiconductor package designed to replace the Plastic Dual-In-Line Package (P-DIP) in high density applications. The PLCC utilizes a smaller lead-to-lead spacing—0.050" versus 0.100" - and leads on all four sides to achieve a significant footprint reduction over the P-DIP. The rolled under J-bend leadform separates this package style from other plastic quad packages with flat or gull wing lead forms. As with virtually all packages of 0.050" or less lead spacing, the PLCC requires surface mounting to printed circuit boards as opposed to the more conventional thru-hole mounting of the P-DIP.

History

The Plastic Leaded Chip Carrier with J-bend leadform was first introduced in 1976 as a premolded plastic package. The premolded version has yet to become popular but the quad format with J-Bend leads has been adapted to traditional post molded packaging technology (the same technology used to manufacture the P-DIP). In 1980 National Semiconductor developed a post molded version of the PLCC. The J-bend leadform allowed them to adopt the footprint connection pattern already registered with JEDEC for the leadless chip carrier (LCC). In 1981 a task force was organized within JEDEC to develop a PLCC registration for package I/O counts of 20, 28, 44, 52, 68, 84, 100, and 124. A registered outline was completed in 1984 (JEDEC Outline MO-047) after many changes and improvements over the original proposals. This first PLCC registration covers square packages with an equal number of leads on all sides. A second registration, MO-052, was completed in 1985 for rectangular packages with I/O counts of 18, 22, 28 and 32. Since 1980 many additional semiconductor manufacturers and packaging subcontractors have developed PLCC capability. There are now well over 20 sources with the number growing steadily.

Surface Mounting

Surface mounting refers to component attachment whereby the component leads or pads rest on the surface of the PCB instead of the traditional approach of inserting the leads into through-holes which go through the board. With surface mounting there are solder pads on the PCB which align with the leads or pads on the component. The resulting solder joint forms both the mechanical and electrical connection.

ADVANTAGES

The primary reason for surface mounting is to allow leads to be placed closer together than the 0.100" standard for DIPs with through-hole mounting. Through-hole mounting on smaller than 0.100" spacing is difficult to achieve in production and generally avoided. The move to 0.050" lead spacing offered with the current generation of surface mounted components, along with a switch from a dual-in-line format to a quad format, has achieved a threefold increase in component mounting density. A need to achieve greater density is a major driving force in today's marketplace.

MANUFACTURING TECHNIQUES

Learning how to surface mount components to printed circuit boards requires the user to become educated in new assembly processes not typically associated with through-hole insertion/wave soldering assembly methods.

Surface mounting involves three basic process steps:

- 1) Application of solder or solder paste to the printed circuit board.
- 2) Positioning of the component onto the printed circuit board
- 3) Reflowing of the solder or solder paste.

As with any process, there are many details involved to achieve acceptable throughput and acceptable quality. National Semiconductor offers a surface mounting guide which deals with the specifics of successful surface mounting. We encourage the user to review this document and to contact us if further information on surface mounting is desired.

Benefits of the PLCC

There are four principle advantages offered the user by switching from P-DIP to PLCC. These four advantages are outlined below as follows:

1. Increased Density—
 - Typically 3-to-1 size reduction of printed circuit boards. See *Figure 1* for a footprint comparison between PLCC and P-DIP. This can be as high as 6-to-1 in certain applications.
 - Surface mounting allows components to be placed on both sides of the board.
 - Surface mount and thru-hole mount components can be placed on the same board.
 - The large diameter thru-holes can be reduced in number, entirely eliminated, or reduced in size (if needed for via connection).
2. Increased Performance—
 - Shorter traces on printed circuit boards.
 - Better high frequency operation.
 - Shorter leads in package. *Figure 2* and Table I compare PLCC and P-DIP mechanical and electrical characteristics.
3. Increased Reliability—
 - Leads are well protected.
 - Fewer connectors.
 - Simplified rework.
 - Vibration and shock resistant.
4. Reduced Cost—
 - Fewer or smaller printed circuit boards.
 - Less hardware.
 - Same low cost printed circuit board material.
 - Plastic packaging material.
 - Reduced number of costly plated-through-holes.
 - Fewer circuit layers.

Package Design Criteria

Experience has taught us there are certain criteria to the PLCC design which must be followed to provide the user with the proper mechanical and thermal performance. These requirements should be carefully reviewed by the user when selecting suppliers for devices in PLCC. Some of these are covered by the JEDEC registration and some are not. These important requirements are listed in Table IV.

Reliability

National Semiconductor utilizes an assembly process for the PLCC which is similar to our P-DIP assembly process. We also utilize identical materials. This is a very important point when considering reliability. Many years of research

and development have gone into steadily improving our P-DIP quality and maintaining a leadership position in plastic package reliability. All of this technology can be directly applied to the PLCC. Table V shows the results of applying this technology to the PLCC. As we make further advances in plastic package reliability, these will also be applied to the PLCC.

Sockets

There are several manufacturers currently offering sockets for the plastic chip carrier. Following is a listing of those manufacturers. The listing is divided into test/burn-in and production categories. There may be some individual sockets that will cover both requirements.

TABLE IV. Package Design Criteria

Criteria	Required to Comply with JEDEC Registration
Minimum Inside Bend Radius of Lead at Shoulder Equal or Greater than Lead Thickness—to Prevent Lead Cracking/Fatigue	Not Required
Minimum One Mil Clearance Between Lead and Plastic Body at all Points—to Provide Lead Compliancy and Prevent Shoulder Joint Cracking/Fatigue	Not Required
Copper Leads for Low Thermal Resistance	Not Required
Minimum 10 Mil Lead Thickness for Low Thermal Resistance and Good Handling Properties	Not Required
Minimum 26 Mil Lead Shoulder Width to Prevent Interlocking of Devices During Handling	Yes
Maximum 4 Mils coplanarity Across Seating Plane of all Leads	Yes

TABLE V. Reliability Test Data
(Expressed as Failures per Units Tested)

Device/Package	OPL	TMCL	TMSK	BHTL	ACLV
LM324/20 Lead	0/96	0/199	0/50	0/97	0/300
LF353/20 Lead	0/50	0/50	—	0/45	0/100

LINEAR APPLICATIONS HANDBOOK—1991

The purpose of this handbook is to provide a fully indexed and cross-referenced collection of linear integrated circuit applications using both monolithic and hybrid circuits from National Semiconductor.

Individual application notes are normally written to explain the operation and use of one particular device or to detail various methods of accomplishing a given function. The organization of this handbook takes advantage of this innate coherence by keeping each application note intact, arranging them in numerical order, and providing a detailed Subject Index.

Databook User Information

The following product variations are listed in this book as Preliminary Information only. Unless otherwise stated, they are not currently scheduled for production release. These variations relate to specific packaging and temperature combinations.

COP98X, 94X, 92X, Family (Scheduled for Q3, 92 Release)

COP988 (Scheduled for Q4, 92 Production Release)

COP68X Family

COP688 Family
