Access assistance techniques in modern computer networks try to improve upon the interface that exists between a user at his terminal and a network based resource. For the terminal user of an interactive computer network the interface is two things. First, it is the physical equipment—the teleprinter or CRT terminal and the communications equipment connecting it to the computer. Second, at a higher and more complex level, the interface is the protocol that a user must know to communicate with the network and its computers—to express his needs or demands on the computer and to understand the produced results or errors from the computer.

These user protocols, unlike the "well defined" link protocols of computer-to-computer communications (such as the ARPA Network IMP-IMP, HOST-IMP, or HOST-HOST protocols,[1]) manifest themselves in the interactive dialog between the user and the computer. And, these user-computer protocols are not "well defined." They are typically machine dependent and often installation dependent.[2]

Interface and protocol standards groups are actively engaged in producing outputs directly related to the issue addressed here. At least one standards group in the Federal Government (FIPS Task Group 20) is studying low level user entry and exit protocols and procedures. The standards approach to access assistance represents a technique that is still in its infancy. With a three year projected completion date for the development and acceptance of the first entry and exit protocol standard for the Federal Government, the viability of this technique is yet to be realized. The beneficiaries of standards as an assistance technique will be the scientists, engineers, researchers, and those who work with them, who use or have the potential for using one or more computer services.

TECHNIQUES

These approaches to solving the problem of network access have been utilized by several groups in specific implementations of the access function. Pyke, in a recent paper,[3] reviews these efforts with special emphasis on presently operating and planned access support configurations. Categorizing these examples and other related devices as reported in the open literature reveals the trend that is evident in network access techniques—a trend toward improving the interface between the user and the computer through sophisticated assistance techniques and devices. By examining these devices—their methodology, their purpose, and their scope—this trend is brought more clearly into focus and up to date.

Basic communications assistance

Minicomputer based concentrators and packet or message switchers are well established solutions that provide the basic communications required of network users. Devices like the ARPA Network TIP[4] and the TYMNET Network TYMSAT[5] satisfy these requirements through data rate identification, terminal compatibility transformations including carriage delay timing functions and character set transformations, and host computer selection specifications.

Over the last few years these devices have been modified to reflect the needs and demands of the user community. They utilize software packages that map character sets and provide carriage delays to accommodate different user terminals. These devices continue to evolve in an attempt to follow manufacturers' terminal innovations. In response to new terminal innovations, devices like the TIP and TYMSAT recognize the user's terminal speed; while default terminal characteristics for other parameters—parity, full or half duplex, tab settings, etc.—are assumed, provisions to specify different settings are available. Many computer service providers and mainframe manufacturers have followed this trend by providing communications support for a large variety of terminals and by utilizing front end computers with appropriate software packages.

Resource identification

Access techniques only start with the basic communications assistance functions described above. Establishing connections to network host systems, logging into host systems, requesting resources, and initializing services or databases can be extremely complex and cumbersome. In one early ARPA Network attempt, a loose leaf notebook containing information on the resources available in the Network and on the access methods to these resources has met with only very limited success. The Network Information Center's ARPANET Resource Notebook[6] existed in both an on-line and printed form and contained entries for all of the resources available at each serving host on the network. Unfortunately, no attempt was made to facilitate access to these resources other than listing individuals to contact. (A more recent edition of this notebook has been published in paperback form[7] and includes enough information for a user to access the desired resource.) Resource identification techniques of a more substantive nature developed.

The REX system, an ARPA Network based on-line user assistance facility, provides resource-specific information.[8] This system, designed with the eventual goal of automating access to various network resources, finds the location of a resource on the network, provides information about the resource on the network, and describes the method for acquiring the resource on the network. REX provides a facility for dealing with a heterogeneous network as a coherent entity, regardless of the particular characteristics of the individual hosts.

A user language that provides commands to retrieve information about resources and to describe specific resources utilizes one of four keyword types—a resource name, a resource attribute, a resource category, or a host name—in conjunction with either a retrieval command—FIND or DESCRIBE—or the ACQUIRE command. An example is:

```
DESCRIBE FORTRAN AT MIT-MULTICS
```

The ACQUIRE command establishes a transparent connection to the resource without further action on the part of the user.

Resource connection

Connections to resources that are available in computer networks require cooperation between the connection initiator—the user or his surrogate—and the resource that ultimately provides the service—a coherent logical entity that exists in order to accomplish a specific task as viewed by the user. In a computer network environment it is not unusual for a multi-level hierarchy of access requests to occur to affect resource connection. Cooperation in traversing the network hierarchy may require several resource solicited identifications, passwords, and system or service names.

While the solicitation of user information occurs at the user level of interaction, many other protocols are used by the communications discipline employed. Usually these other disciplines are masked from the user and are transparent. In this way, a surrogate—usually a process knowledgeable in the protocol or line discipline employed—acts on behalf of a user to connect him to the requested service. For instance, users of the ARPA Network access resources with the cooperation of a TIP. It is feasible for the acquired resource to then request other resources on behalf of the user. In this example, the user level of interaction is the command language of the TIP; acting as a surrogate for the user, the TIP, knowledgeable in the IMP-IMP protocols, completes the resource connection for the user.

Hierarchical connections easily occur. In the ARPA Network, many host computer resources support a service known as FTP (File Transfer Protocol). This service establishes network connections to other resources on behalf of the user for the purpose of transferring files between host computers. Currently, the user need not identify himself to the TIP, however a user account is required for the host system to execute the service FTP. For FTP to access the file system of the other resource, the user level protocols require the user identification and password for the other resource.

Resource selection

Evidence in the published literature indicates that a trend in the use of intelligent terminals and their close cousins," "clustered" terminals, to assist users in the selection of resources is developing. A research program currently under way at the RAND Corporation aims to develop a prototype intelligent terminal system initially implemented on a minicomputer. The system, called the RAND Intelligent Terminal Agent (RITA), is based on sets of condition-action rules that encode complex sets of heuristics for handling interactions both with users and with external systems.[9]

RITA is capable of interacting with remote data systems, carrying out time-dependent tasks over extended periods of time in a semi-autonomous manner. The supposition that a rich set of heuristics for deciding communications levels of remote system interaction and for resource acquisition and graceful recovery from unexpected failure has in part motivated this effort.[10]

At the National Bureau of Standards a minicomputer-based device called a Network Access Machine (NAM) expands user-entered commands into command sequences executable on specific networks and host computers connected to that network.[11] The NAM analyzes system and network responses to assure agreement with those anticipated for specific commands. Conditional and parameterized expansions of user-entered commands are capabilities being added to the basic working NAM. This capability will allow the use of the same commands to permit access to resources on different host computers and different networks.[12]

Other extensions to the NAM are currently being implemented. One function is to predict the expected response time of a particular computer for use in a specific applications area—such as compute-bound FORTRAN jobs, small BASIC jobs, interactive editing sessions, or some other category. Good indicators of computer response time can be calculated by the NAM in the following way. The NAM automatically connects to the particular computer in question in order to execute a predefined benchmark job representative of the applications area. By having the NAM automatically time the response for the job execution the NAM can present to the user the results of the calculations in the form of a prediction of expected response time. Several benchmarks have been successfully tried—producing excellent predictions of expected response time.

One other intriguing function being added to the NAM is to provide the user with network wide tutorial assistance. A profile, maintained for each NAM user, reflects the disposition of the user with respect to any particular computer that he might use. Data are maintained in the profile concerning recent use of specific computers, the use of internal indicators, and help assistance indicators. Using this data base, the NAM acts on behalf of the computer in assisting the user.

An example of somewhat specialized access support to a network user employing a microprocessor is the development of a "line processor" by the Stanford Research Institute. This device interfaces a class of display terminals together with a pointing device called a "mouse" and a one-hand keyboard called a "key set" in such a way that the entire configuration can provide particularly effective access to a network-based interactive text manipulation system. The line processor has potential, however, for application beyond the initial intended use.

Service integration

An important trend, motivated by the desire to interface one user to multiple resources, is evident in the work done in the information services community by Marcus at MIT. He has developed a system that involves the coupling of two bibliographic data retrieval systems in such a manner that the user perceives a single homogeneous system.[22] Specific applications support built within the MULTICS system at MIT includes a master index and thesaurus that stores the vocabulary of the separate data bases along with index term interrelationships. The user is also provided with a common bibliographic data structure in which the data elements for bibliographic information are organized and interrelated among different data bases. This approach has been demonstrated experimentally using the ARPA Network for access to the National Library of Medicine Medline service and the MIT Intrex retrieval system.

Another example is the Resource Sharing Executive (RSEXEC) for the ARPA Network.[13] This executive system provides an environment for "inter-host" user-user interactions, for managing "multi-host" file directories, and for controlling multiple "jobs" on several hosts. In addition, the RSEXEC serves as a command language interpreter for the ARPA Network TIP users. Executing in any one of several available PDP-10 TENEX systems on the Network, RSEXEC can maintain communications through the Network with other TENEX systems. In this way the resources of all of the systems to which RSEXEC connects can be monitored and used. Facilities for monitoring status, logged in users, and load averages are available as well as the capability to build and create a composite file directory incorporating files from the various computers in the subnetwork. Provision is also available for initiating jobs at one or more cooperating sites at which valid accounts are maintained.

Distributed assistance

Distributed assistance—partially in host systems and partially in front end systems—can provide better network response at less cost. The National Software Works (NSW) motivated by a desire to provide users with access to a number of general or specialized software applications packages, resides on a PDP-10, but will also be available on a minicomputer such as the PDP-11.[14] NSW provides assistance in such a way so as to maintain a consistent user interface from package to package even across host systems. It is anticipated that heavily used common commands and grammars can be executed in the front end systems, thus increasing network response times and decreasing network communications costs.

Kimbleton and Schneider emphasize that the NSW is intended to be an environment for building software systems.[15] It is to include program preparation tools—cross assemblers and compilers, editors, simulators and emulators, performance analyzers, program formatters, flowcharters, test-data generators and other checking tools—that build software systems. These systems will usually be removed and run in a different environment, since the NSW is not intended to support the recurring execution of end-user applications.

Minicomputer hosts

A minicomputer installed as a network host computer can also perform substantial access functions for a community of users. The ELF system provides multiple, concurrent users with local computing and file capability including signal processing for speech applications as well as flexible access to ARPA network resources.[16] The ARPA Network Terminal System (ANTS) was a mini-host designed to facilitate use of the ARPA network by students at the University of Illinois. Use of this system promoted RJE use of the Burroughs 6700 at the University of San Diego as well as RJE use at the Campus Computing Network (CCN) at UCLA.[17]

At the University of Chicago, Ashenhurst has developed an interesting hierarchy of minicomputers and large scale computers to assist users in laboratories.[18] Minicomputers located in science laboratories throughout the campus are served by a larger minicomputer at a central site. Large compute-bound applications are served when the central minicomputer acquires resources on a large scale computer on behalf of the laboratory mini.

Other trends

The work of Wyatt at Harvard, in planning for an access system to couple users to multiple serving systems and networks, includes a call for automatic transformation of job control statements to match those of remote systems and for facilities to support "transparent connection" of local terminal facilities to various communications networks.[19] Wyatt also proposes that the "translation/communication system" perform comprehensive accounting and billing for multiple user accounts.

ARCHITECTURE

The preceding examples suggest that alternative solutions exist and that the access assistance functions can reside in a process executing in a host system, in a dedicated minicomputer, or in a single user "intelligent" terminal or terminal "cluster."

When supported on a large host computer, the access assistance functions utilize the sophisticated and extensive subsystems that are available—the file management systems, the language compilers, the utility processors and on and on. But, this type of application can be accomplished with less sophisticated resources. For instance, the ARPA Network TIP, in part motivated by a desire to move the basic communications support and low level access functions out of the large host computers and into smaller, less expensive minicomputers, eliminates much of the overhead required to handle access functions in a larger host system. Minicomputers are often used extensively for store-and-forward functions and other applications such as remote concentrators and message switchers; it might make good economic sense to put the access function in a minicomputer also.

The minicomputer, placed in the communications link between the user terminal and the serving computer network, can allow multiple users to access different hosts on one network or even different networks. The minicomputer seems ideally suited for such an application especially when several users or user groups require a moderate file storage capability for small files and a minimum computational capability for communications processing, signal processing or other requirements.

Intelligent terminals can support access to multiple hosts on a single network or to multiple networks, but file storage and other terminal resources appear to be too expensive at this time to dedicate to a single user terminal. Also, intelligent terminals may require cooperation with larger host systems for initial program loads; such cooperation may not be available from candidate networks or host computers. At this time, the intelligent terminal does not have as great a potential as the "cluster" supported minicomputer to perform the required access functions. Based on predictions that within five to eight years inexpensive interactive terminals will be available with the power of today's minicomputers, the use of intelligent terminals to support the access function will be feasible.

SUMMARY

Increased use of computer services by people in the routine performance of their jobs continues to grow steadily. To meet the demand, service providers design, implement, and market their services using the technologies and resources available to them. With the advent and growth of computer network technology it is not uncommon for people to use the resources of different computer systems. The non-uniformity in access to these resources and the services provided has led to the development of tools and techniques to assist the user.

Some of the tools and techniques that provide users with this access function have been described in this paper. By examining these devices—their methodology, their purpose, and their scope—and by discussing the current trends in network assistance architectures, a framework has been built for future discussions of this very important function that can be provided to computer network users.

The RAND intelligent terminal agent (RITA) as a network access aid

by ROBERT H. ANDERSON and JAMES J. GILLOGLY
The RAND Corporation
Santa Monica, California

ABSTRACT

An operational "intelligent terminal agent" system called RITA is described. RITA uses production systems to store heuristics about dealing with the interactive protocols of external information systems. The use of production systems allows RITA to operate in either a pattern-directed or goal-directed manner. By creating new production rules as part of their operation, RITA agents can exhibit learning. Advantages and disadvantages of production systems for creating intelligent terminal agents are discussed, and an annotated transcript of a session with a RITA agent is given to illustrate its ability to aid a user in handling File Transfer Protocol on the ARPANET.

INTRODUCTION

Until recently, most users of information systems have been either "computer sophisticates"—such as computer programmers—or else users of systems, such as airline reservation systems, with a very limited set of options. However, with the continuing rapid decline in the cost of computer hardware and data communications, many interactive computer-based information systems are becoming cost effective for much broader categories of users. These newer systems will greatly expand the number of people interacting with computers in their daily activities, and will give access to a complex variety of interactive protocols, interfaces, command languages, and remote computing systems. People are going to need assistance in tailoring this variety of options to their specific needs and especially in freeing them from routine interactions and protocols which are not directly relevant to the content of their task.

We assume the complexities of dealing with the interactive protocols of computer networks are familiar to this audience, and are sufficiently documented[1] not to require further elaboration. This paper describes one possible solution to the problem of complexity: user access to computer networks aided by an "intelligent terminal agent."

What is an intelligent terminal agent and why is it useful? The answer involves many aspects of the way people interact with computer systems as well as new alternatives becoming possible through advances in both hardware and software technology. The following observations concerning man/machine interaction and its supporting technologies form the basis for our design of such an agent:

1. Projected computer hardware cost trends and advances in microprocessor technology make it extremely likely that interactive computer terminals can be produced within five to seven years containing processing power and data storage equivalent to a present-day minicomputer, at a cost which is reasonable, assuming fairly intensive use of dedicated terminals by professionals as part of their job.
2. It is important to have certain information storage and handling capabilities locally*—most likely within the terminal itself—e.g., to provide "instantaneous" response to simple text manipulation commands and to simple error conditions.

Once local computing power becomes available within a terminal, it can be used to aid in interfacing with external information systems, such as the ARPANET or New York Times Information Bank, where much of the interactive protocol involves supplying standard responses which are not directly relevant to the task being accomplished. It is possible in the system described in this paper to teach an intelligent terminal to deal with such interactive protocols automatically, including instructions on dealing with certain error conditions, so that these details need not be remembered and handled manually by the user.

In addition, intelligent terminals should allow the user to define and set in motion "user agents". Such an agent could:

> Look at a calendar of events and start up services for the user automatically at certain times and dates. By manipulating calendar items, the human manager can progressively modify the plan

* "Locally" is used here to mean computing power and storage dedicated to the individual user and accessible via a very-high-bandwidth link—e.g., sufficient to rewrite a 3,000-character CRT display in 0.5 seconds.

being executed by the machine. For example, by changing the due date of a report, the schedule will be automatically altered for reminders and follow-up queries to be transmitted to persons making contributions.

Monitor the occurrence of various types of events, such as the arrival of a certain piece of network "mail", or the occurrence of a certain datum in a changing data base.

Deliver "interactive letters" to other users' terminals; these letters are capable of carrying on a dialog with the recipient, while in the process extracting information from him in a standard format suitable for further automated processing. Reference 2 contains an example of an interactive letter.

Manage transactions between a number of computerized services distributed on a computer network, monitoring their successful accomplishment.

We believe the desirability of the above list of services is a compelling reason to explore the design of intelligent terminal agents capable of running in present-day minicomputers. The remainder of this paper describes the design and operation of a system—the Rand Intelligent Terminal Agent (RITA)—which has been developed at Rand to meet all of the above requirements. RITA is currently operational on a PDP 11/45 minicomputer running the UNIX operating system.[3] The next section discusses "production systems" as the software technology underlying RITA. The third section contains examples of RITA's operation as an interface to computer networks. The fourth section concludes with a discussion of RITA's implementation status and some remaining research questions which have been raised by our work to date.

PRODUCTION SYSTEMS AS THE BASIS FOR A TERMINAL AGENT

The basis for our design of a system meeting the above requirements is the use of production systems. A production system consists of a set of production rules (having a pattern part and an action part), which operate upon a data base (which we call a context), according to the actions of a rule interpreter, or monitor.

For example, two production rules might be:

Rule 1

IF: there is a message whose status is "awaiting action" and the identification-field of the message is not in the action-items of the user

THEN: put the identification-field of the message into the action-items of the user;

Rule 2

IF: the latest-command of the user is "show action items" and the state of the system is "command unfulfilled"

THEN: send the action-items of the user to the user and set the state of the system to "command fulfilled".

These rules would be part of a larger set of rules governing a message-handling user agent. They might be interpreted by a monitor that continually tests the "if" conditions in each rule of the set, and executes the "then" actions in any rule whose conditions are all true. Assuming messages with various attribute values, such as an identification field and status, are placed in the data base by some external (and possibly asynchronous) process, the above rules would update a list consisting of the identification numbers of all messages awaiting action, and show that set to the user upon his request. Other rules would themselves, or permit the user to, take other actions and as a consequence change the status of the messages and remove their identification number from the set of action items.

There are a number of interesting options in the design of production systems. For example, production rules can be used in either a goal-directed or pattern-directed manner. A goal-directed system has a designated goal, and the objective is to execute rules whose actions help to achieve that goal. These two modes of operation are discussed further under the heading "Monitors," below.

A good discussion of design options in production systems is contained in a recent survey article by Davis and King.[4] That reference, as well as Reference 2, can be consulted for more details. A series of articles on the MYCIN system[5-9] by E. H. Shortliffe and associates at Stanford University describes a particular goal-directed production system which has significantly influenced the design of the RITA system.

Our design decisions in creating a production system for our particular needs are discussed below under four headings: data base, rules, monitors, and system architecture.

Data base

The data base upon which RITA rules operate is called a context; it consists of an unordered set of objects. Each object has a name, or type, and there can be more than one object in the context of the same type. There is neither an external structure imposed on the set of objects in the context nor a requirement that each object have a unique identifier associated with it. Each object can have one or more named attributes, and all attributes attached to an object must have names which are mutually distinct. Each attribute has an associated value, which is either a character string or an ordered list of values.

Objects, attributes, and values may be created or deleted dynamically by the actions of rules. If an attribute being tested by a rule's predicate does not exist, it is considered to be "not known." It is possible by a rule action (except within a goal-oriented monitor) to reset an attribute having a value back to the "not known" status. Goal-oriented monitors may not reset the value of any attribute; they may only set values which were previously not known. This restriction is necessary to preserve the integrity of information upon which chains of logical reasoning are based.

As an option, it is possible to attach a "level of certainty" to a string attribute value as it is being set. In this case, an attribute can have several different values associated with it, each with a different level of certainty. Levels of certainty are adjusted as additional positive or negative certainty factors for those values are asserted by the action of rules. Our use of certainty factors has been strongly influenced by their implementation in the MYCIN system, but differs in some details which will not be discussed here.

Figure 1 contains examples of object types and associated attribute names and values which might be used in a user agent within the RITA system.

The data structure we have chosen is not the most general one possible. As with other implementation decisions, we have chosen what we consider to be the simplest format and conceptual structure which allows the description of situations and heuristics related to intelligent terminal agents. With more experience in using the RITA system, some of these decisions are almost certain to change.

Rules

RITA rules are expressed in a finite syntax (technically, parsable by an LR(1) algorithm). We have chosen a syntax patterned after the specialized English output form generated to display MYCIN rules to a user. We believe that this syntax is simple enough to be read and written by a computer-naive user. Figure 2 contains several examples of clauses which can be used in RITA rules; more complete examples are contained in the transcript in a later section.

object type	attribute name	sample value
file	name	"foo.baz"
	directory	"jjg"
	site_id	"rand-isd"
	size	20000
	owners_name	"gillogly"
site	id	"rand-isd"
	operating_system_name	"unix"
	machine_type	"pdp-11/45"
	guest_account_name	"netguest"
	guest_account_password	"netguest"
	known-user-set	("jjg," "rha," "rsg")
known_person	name	"gillogly"
	primary_site_id	"rand-isd"
	primary_directory	"jjg"
	primary_password	"whumpus"
	secondary_site_id	"cmu-10a"
	secondary_site_directory	"g250a12"
	secondary_site_password	"foo"

Figure 1—Examples of RITA object types, attributes, and values

Left-hand-side predicate clauses

IF: the name of the system is "unix"

IF: the name of the system is the name of the desired_system

IF: the name of the system is not known

IF: there is a response whose arrival_time is less than the max_expected_delay of the system

Right-hand-side action clauses

THEN: set the name of the system to "net access program"

THEN: set the valid_id_set of the remote_site to the id of every site whose id is known

THEN: deduce the guest_account_name of the remote_site

THEN: create a remote_site whose id is "cmu-10a"

THEN: receive the next line from the system_IO_pipe as the value of the response

THEN: send "Which rule do you wish to see" to the user

THEN: return success

Figure 2—Examples of RITA rule clauses

Such facilities as string manipulation are provided in the RITA system by a set of primitive functions which may be called in the predicates or actions of rules.

Monitors

We have found that different types of monitors are necessary for various specific tasks and situations, and that no one monitor type is sufficient for our purposes. For example, interactions with an external information system to handle routine protocols are best handled by a LHS-scan monitor (one which tests the pattern part, or left-hand side, of rules against the context to determine the next rule(s) to be applied), acting in what might be called a "stimulus-response" mode. On the other hand, it is sometimes necessary for an intelligent terminal agent to make deductions (e.g., about the most likely site on the ARPANET for a particular person to have a mailbox, given that person's attributes). Deductions are best made by a RHS (right-hand side, or action part) scan, goal-driven monitor. In this form of monitor operation, one specific item of information (an attribute of an object) is designated as a goal. The monitor seeks to execute rules whose RHS set that attribute's value. To execute those rules, their LHS must be true when tested against the current context. If any such LHS is not true due to the lack of information about the value of some other object's attribute, that attribute becomes a (sub)goal of the system. This process recursively forms a tree structure linking the applicable rules in the system, until one of three situations occurs: (1) a rule's LHS evaluates as true, so that its corresponding actions can be performed and no new subgoals are formed; (2) a rule's LHS evaluates as false, which also terminates that branch of the goal tree; (3) one or more attribute values are needed for the evaluation of an LHS, but no new subgoals can be formed because there are no other rules in the rule set whose action parts set those attribute values. In this latter case, the system queries the user for the values as a last resort. The system therefore tends to ask questions which "make sense" because it is following a particular chain of logic, and asks only those questions it needs to reach a particular goal, given the current state of its information base.

We have implemented several different monitors as part of the RITA system:

- LHS scan, with ordered rule set
- LHS scan, with unordered rule set
- RHS scan with backward-chaining (implicitly, a rule set is treated as unordered)

Nothing in our implementation precludes the development of other monitors if the need arises. The top-level monitor in a user agent uses a LHS scan with an unordered rule set; however, it is possible for the following action clause of some rule to be executed:

DEDUCE attribute OF object.

This clause triggers the operation of the RHS scan backward-chaining monitor with the goal of deducing the value of the named attribute. Upon completion of a deduction, control reverts to the action clause of the LHS scan rule following the DEDUCE clause, or if there are none, to the next applicable rule chosen by the LHS scan monitor. It is not possible to invoke explicitly an LHS scan monitor during a goal-directed deductive operation. A discussion of the differences between our goal-directed mode and that employed in the MYCIN system is contained in Reference 2.

System architecture

RITA has been designed as three cooperating modules, so that only the currently active module need reside in core during the operation of a user agent. Such modularity is aided by the facilities in the UNIX operating system for communication between separate processes.

The user interface module gives the user one or more windows within which text can be displayed, with the facilities of the Rand Editor (a CRT-based text editor with two-dimensional editing features) available for text manipulation within those windows. It allows creation of rule sets and contexts in a symbolic English-like form, and passes rules and commands to the monitor to allow user control over its operation.

The syntax module contains facilities for compiling symbolic form rules and data descriptions into an internal list-structure form. The monitor module accepts these "compiled" rules and has facilities for decompiling internal forms back into symbolic form upon request. It uses one of the available monitors to apply a rule set to a context, and emits trace information to a history file for use by diagnostic and tutorial facilities.

Advantages and disadvantages of production systems

Why were production systems chosen as the basis for the RITA system? The following advantages are often cited as accruing from their use. We have listed them in what we believe is an approximate decreasing order of importance for the particular application for which RITA was designed: namely, the construction of intelligent terminal agents.

1. Their explanatory capability.

Production system rules are intended to be modular chunks of knowledge and to represent primitive actions. Thus, explaining primitive acts should be as simple as stating the corresponding rule—all necessary contextual information should be included in the rule itself. Achieving such clear explanations, however, evidently strongly depends upon the extent to which the assumptions of modularity and explicit context are met.[4]

The interested reader is referred to the MYCIN literature for an excellent example of the degree of explanatory power that can be achieved through careful design and implementation.

2. Simple control structure.

Due to the simple control structure of production systems, especially of the LHS scan type, we can imagine the following type of instructions being nearly sufficient to introduce a user to the operation of his terminal:

> This terminal operates according to a set of rules. Whenever it finds a rule that is true, it applies that rule. If you want to know why it is asking you for some item of information, or why it took some action, type "why?" and it will show you the rules it followed in taking that action.

If, in addition, the rules themselves are in simple English so that they are directly readable by a user, then we believe he will find the operation of this device quite understandable. Although the user will of course not understand all the nuances of its operation, he is at least not bewildered at the start, and can add incrementally to his understanding with experience. The user must realize, however, during this initial introduction to the system that there are nuances and that he should not be overly complacent or trusting of system behavior.

A RHS scan backward-chaining system, although more complex in its control structure, can give rational explanations of its behavior in a manner that makes the flow of control among rules understandable.

3. Incremental addition of knowledge.

With proper design, production systems can allow gradual, incremental addition of knowledge and heuristics in a top-down manner. If the set of rules is unordered, then new rules can be added to the set without concern for their placement. A particularly appropriate time for the addition of new rules to a system is when the system, in a goal-oriented mode of operation, has asked a question of the user. A possible user response is to give the system a rule for determining that item of information from other information it has; upon receipt of that rule, the system will no longer ask that question, since it can now form a subgoal by backward-chaining through the new rule. In this manner gradual evolution of the behavior of the system takes place to meet the needs of the user in his possibly unique environment.

4. Trainability and learning.

Assume production rules are stated in a constrained syntax so that their meaning is understandable by machines, and that each rule is, to the extent possible, a "noninteracting chunk of knowledge or behavior." It then becomes possible for a computer program to create rules in the proper format and insert them into existing sets of rules to change the behavior of a production system. For examples of such adaptivity in production systems, see References 10 and 11.

There are also some disadvantages in the use of production systems. The two major ones are:

1. It can be difficult to code an operation in the form of a production system, particularly for goal-oriented rule sets. Considerable thought must be given to the choice of objects, attributes, and values by which a problem area is represented. (However, the problem of choosing a good data representation is certainly not unique to production systems; the problem lies more in trying to fit all applications into this particular procrustean bed.) One must also carefully choose certain attributes of objects to represent "state variables" which encode the state of a computation or deduction. The values of these state variables are tested by various rules to trigger their potential applicability. In this manner, production systems encode explicitly that which in ordinary high-level programming languages is implicit in the nesting of control statements. For example, a traditional nested control structure such as:

```
if A then
   if B then C
      else  if D then E; else;
   else G;
```

might be encoded in a production system in the following manner:

```
if A                      then state_1;
if state_1 and B          then C;
if state_1 and not B      then state_2;
if state_2 and D          then E;
if not A                  then G;
```

Such explicitness in a production system allows the desired relative autonomy of individual rules, but at the price of requiring the programmer to create names for many intermediate states of his process.

In the RITA system, we hope to overcome this disadvantage by having system experts create initial systems and user agents having general applicability. Individual users are expected, at least initially, to make only rather minor modifications and enhancements to the basic system. Therefore, the vocabulary and overall design of a user agent will be established, providing many guidelines and examples for the individual user.

2. Production systems are often inefficient. It is quite easy to design systems in which the pattern parts of hundreds of rules are tested against the data base before a successful match is found; it is also easy in goal-oriented systems to pursue lengthy chains of reasoning which are not useful.

Our design of the RITA system has not been significantly influenced by efficiency considerations. The simple user agents which have been constructed to date (e.g., for handling File Transfer Protocol interactions on the ARPANET) have required only 30 to 40 rules and are not inefficient. As more complex agents are constructed, we believe there are a number of monitor enhancements than can increase efficiency (e.g., through hash-coded lookup tables to aid in finding applicable rules) which can be added as the need arises.

EXAMPLE OF RITA OPERATION AS A NETWORK ACCESS AID

The following is an annotated transcript illustrating the operation of a RITA user agent designed to assist in file transfers from remote sites over the ARPANET. The agent consists of 42 rules and a context having 14 objects. Several representative rules from this user agent are shown in the middle of the transcript. Annotations are indented and enclosed in square brackets. User interactions with the agent are shown italicized.

```
% file-agent
```

["%" is the UNIX system prompt. An executable UNIX file named "file-agent" contains commands to start a RITA agent with the rules to be read from a file called "ftp. rules".]

```
UFE: V21 Dec. 16
PARSER: V22 Dec. 8
MON: 17 Dec 75
```

[These three header lines are displayed by various RITA processes as they initialize themselves, as an aid to system developers should trouble arise during this session.]

ftp.rules: [Displayed by RITA to show this rule set is being loaded; any syntax errors, etc. would be printed at this time.]

* *run;* ["*" is the RITA user front-end prompt; the "run" command starts the agent.]

[The following 6 questions are generated by RITA during its backward-chaining deduction process.]

What is the name of the current-file?

draft2

What is the site-name of the current-file?

sumex

What is the host-id of the current-file?

[The file is being retrieved from a site that the agent has never encountered before, so it checks that the site-name given is really the official host id for that site. As will be seen below, it doesn't need to be told this again in a subsequent session.]

sumex-aim

What is the account-name of the current-file?

kowalski

What is the password of the current-file?

qwerty

What is the man-number of the current-file?

why

[At this point, the user doesn't know what data is being asked for, so he uses the reserved word "why" to ask the agent for the chain of logic that led it to ask this question.]

That's what I was supposed to deduce.

What is the man-number of the current-file?

[This is RITA's answer if it has executed the action clause "DEDUCE man-number OF current-file" in some rule, but no goal-oriented rules are relevant in helping it deduce that; therefore, there is no deeper chain of logic that got it here. The user wants to better understand how the man-number is used by the agent, so he interrupts the agent's operation and returns to its command level.]

* *display all goals that test the man-number of the current-file;*

[This question lets him see all goal-oriented rules (denoted by a prefix "GOAL") that test that attribute in their "if", or predicate, part.]

```
GOAL not-known:
      IF: the man-number OF the current-file IS
            NOT KNOWN OR the man-number OF
            the current-file IS " "
    THEN: SET the file-preface OF the current-file
            TO " "
          & SET the file-suffix OF the current-file
            TO " ";
GOAL before:
      IF: nsubstr (0, 1, the man-number OF the cur-
            rent-file) IS "<"
    THEN: SET the file-preface OF the current-file TO
            the man-number OF the current-file
          & SET the file-suffix OF the current-file
            TO " ";
GOAL after.:
      IF: nsubstr (0, 1, the man-number OF the cur-
            rent-file) IS NOT "<"
    THEN: SET the file-suffix OF the current-file TO
            the man-number OF the current-file
          & SET the file-preface OF the current-file
            TO " ";
```

[Having seen the above rules, the user thinks the system doesn't handle TENEX systems correctly, and decides to give it a rule which will allow it to deduce the man-number of a file from the account-number on such systems. He therefore reinitializes the agent and types in a new rule at the agent's command level.]

* *restart;*

* *goal tenex*

```
    if: the type of the system is "tenex"
  then: set the man-number of the current-file to
          concat ("<", the account-name of the cur-
          rent-file, ">");
```

[He then re-runs the agent to see how it will act with this new rule added.]

```
* run;
What is the name of the current-file?
draft2
What is the site-name of the current-file?
sumex
What is the host-id of the current-file?
sumex-aim
What is the account-name of the current-file?
kowalski
What is the password of the current-file?
qwerty
What is the type of the system?
tenex
```

[Note that instead of asking for the man-number of the current-file, the system asked for the system's type instead, through use of the newly-added rule.]

```
Will now attempt to retrieve file <kowalski>draft2
from the sumex-aim system
Sent: ftp
```

[Lines prefixed with "Sent:" and "Received..." are generated by the agent during its operation to show its interactions with the remote system on behalf of the user. The agent could easily be modified to be less verbose.]

```
Received from net: Host:
Sent: sumex-aim
Received from ftp: Connections established.
300 SUMEX-AIM FTP Server 1.44.0.0—at SAT 3-
JAN-76 14:22-PST
>
```

[">" is the ftp prompt character]

```
Sent: user kowalski
Received from ftp: 330 User name accepted. Password,
please.
>
Sent: pass qwerty
Received from ftp: 230 Login completed.
>
Sent: retrieve <kowalski>draft 2 ftpdata
```

[Note that this RITA agent automatically places retrieved files in a local file named "ftpdata"; through the addition of one rule, the agent's behavior could be changed so that it requests a recipient file's name from the user.]

```
File has been transferred
Received from ftp: 255 SOCK 3276899843
250 ASCII retrieve of <KOWALSKI>DRAFT2.;1
started.
252 Transfer completed.
Sent: bye
Job finished
done
%
```

[All ARPANET File Transfer Protocol interactions necessary to retrieve the desired file were successfully accomplished automatically by the RITA agent.]

[The next day, the user wants to retrieve that same file again, since he just received an ARPANET message stating that he should look at some late revisions. This gives us an opportunity to see how much this particular RITA agent has learned from the previous session.]

```
% file-agent
UFE: V21 Dec. 16
PARSER: V22 Dec. 8
MON: 17 Dec 75
ftp.rules
* run;
What is the name of the current-file?
draft2
What is the type of the system?
tenex
Will now attempt to retrieve file <kowalski>draft2
from the sumex-aim system
```

[Note that once it received the file name "draft2", it assumed all other attributes about the file from information received during the current session. All of this adaptive behavior is handled by several RITA rules which build new rules and data objects as their actions, then save the revised rule set on a disk file.]

[To tune this agent's operation better, it should also be given a rule telling it that the type of a system doesn't change; once it knows the type of a remote system, it can assume that it will stay constant. With that information, the agent would stop asking for the type of previously encountered systems.]

```
Sent: ftp
Received from net: Host:
Sent: sumex-aim
Received from ftp: Connections established.
300 SUMEX-AIM FTP Server 1.44.0.0—at SAT
  3-JAN-76 14:26-PST
>
Sent: user kowalski
Received from ftp: 330 User name accepted. Password,
  please.
>
Sent: pass qwerty
Received from ftp: 230 Login completed.
>
Sent: retrieve <kowalski>draft2 ftpdata
File has been transferred
Received from ftp: 255 SOCK 3276899843
250 ASCII retrieve of <KOWALSKI>DRAFT2.;1
  started.
252 Transfer completed.
>
Sent: bye
Job finished
done
* exit;
exiting.
%
```

[The "exit" command terminates execution of the RITA system, and returns the user to the UNIX command level.]

[As a last example, we show this RITA agent retrieving a different file from the same site.]

```
% file-agent
UFE: V21 Dec. 16
PARSER: V22 Dec. 8
MON: 17 Dec. 75
ftp.rules
* run;
What is the name of the current-file?
draft3
What is the site-name of the current-file?
sumex
What is the type of the system?
tenex
Will now attempt to retrieve file <kowalski>draft3
  from the sumex-aim system
```

[Note that this time it asked for the site-name, but once it received a previously known response, it automatically retrieved other needed attributes about that site, such as its formal ARPANET host id. As mentioned above, the "type of system" question is unnecessary, and should be eliminated through the addition of another rule.]

```
Sent: ftp
. . .
```

[We omit the remainder of this session transcript, since it proceeds in the same manner as the interactive protocols shown above.]

CONCLUSION

This paper has discussed the design of the RITA system. Within RITA, user agents consisting of sets of production rules can be created to operate either autonomously or in interaction with a user. One major application of such user agents is to aid in interactions with computer networks and remote information systems. RITA is currently operational on a PDP 11/45 minicomputer running under the UNIX operating system. It occupies about 58K bytes of core, allocated among two separate processes. User agents comprising about 50 rules are now in use, and can, for example, handle ARPANET file transfer operations and interactions with the New York Times Information Bank.

This is, however, a report on work in progress. Some of the questions that remain unanswered at this stage of the research project are:

- Will a computer-naive user really be able to modify the operation of a user agent by adding or modifying rules? If so, how long a prior familiarization period is required?
- At what level of size or complexity of a user agent will speed of operation and efficiency become important considerations?
- What about system security? Knowledge about passwords, access keys, data formats, and account numbers for external systems might well reside within RITA user agents, making the intelligent terminal itself a valuable target for compromise. Even with physical security, such as restricting access to the room containing the terminal, often

there will still remain external communication paths to the machine that allow possible access to data. We need to understand more about the constraints which must be placed on access to intelligent terminals containing sensitive data in representative user environments.

We are encouraged by our initial experimentation in the use of production systems to represent heuristics governing intelligent terminal behavior. Their ability to provide explanations of that behavior, to be modified and incrementally extended by a user, and to operate in either a pattern-directed or goal-directed manner are all potentially valuable features. We believe the RITA system, whose design we have discussed here, provides a good testbed for the demonstration and evaluation of these intelligent terminal agent capabilities.

ACKNOWLEDGMENTS

Bob Greenberg designed and implemented many key features of RITA's user interface and syntax modules. The particular RITA agent whose operation created the transcript presented earlier was created by Dr. Don Waterman. The support and encouragement to date of our prior ARPA program manager, Dr. Craig Fields, and our current program manager, Steve Walker, are gratefully acknowledged.

Network interface systems—An evaluation by simulation*

by JOE B. WYATT and VINCENT I. POLLEY
Harvard University
Cambridge, Massachusetts

ABSTRACT

The availability of low-cost digital communication services has made it productive for computer users to remotely access multiple computer resources. This is a particularly sound strategy for accessing complex resources that are infeasible to relocate. At the same time, the availability of low-cost and reliable minicomputer systems which can accommodate sizable numbers of terminals has enabled a shift of some interactive programming and information processing to these small, standalone systems. Although these small systems are powerful and can be configured flexibly, there are a number of opportunities to expand the scope of an individual user by relating the small system directly to other host computers via a network. In accomplishing this feat, however, there are a bewildering number of technical and economic alternatives.

This paper addresses one of the issues surrounding the development of such systems namely the relative performance and cost characteristics of a minicomputer system in the role of both a standalone processor and a network interface. The methodology for the evaluation is stochastic simulation. The basic measurements for the base line simulations and model validation is a DEC PDP-11/45 computer system operating under the UNIX operating system in the Science Center at Harvard University. The paper describes the simulation methodology and the individual experiments in some detail. Several conclusions are drawn about the performance and cost characteristics of such systems and also about the use of simulation to evaluate these characteristics.

INTRODUCTION

One of the principal problems confronting a user when contemplating the use of a computer network is the variety and complexity of the system resources encountered. Conventions for system log-in, user command languages and terminal hardware interfaces vary from system to system. For someone who is neither skilled at nor interested in computer technology, it can be a frustrating confrontation. It has appeared that interfacing user terminals through a mini-computer system programmed to accommodate some of the interface functions might increase user productivity substantially. This possibility is particularly attractive since it has been demonstrated that small mini-computer, time-sharing systems are also highly cost effective for basic computer tasks; e.g., program development, management of small data bases and the like.[1]

In this paper a network interface system (NIS) is hypothesized in two configurations. The first configuration is a relatively large mini-computer which provides, in addition to the network interface functions, basic programming and language capabilities as well as file storage and retrieval facilities. The second NIS is a minimum configuration for handling network functions only.

The basis for both evaluations is the PDP-11/45 computer system operating under the UNIX operating system. Such a system is installed and operational at Harvard University. This system was used to develop the parameters for a simulation model and to validate the simulation results for the initial NIS configuration. The simulation model was developed using OSSL, a macro-level, stochastic language and processor developed for simulating operating computer systems.[2]

THE EXPERIMENTAL SYSTEM

The base case for the initial simulation model is the time-shared mini-computer facility located in the Science Center at Harvard University. This system is available for undergraduate teaching and research and provides basic hardware and software capability for several programming languages, information storage and retrieval systems, and a number of basic mathematical systems used in teaching programs.[3] The configuration consists of a PDP-11/45 processor with 120K words of executable memory (90K available to users jobs), a fixed head disc unit (used for swapping), two secondary storage disks available for user files, and two magnetic tape units. The system has available 33 ports for interactive user terminals (mostly 1200 baud CRT terminals) and a high-speed line printer for large vol-

* This work was supported by NSF Grant GJ40586.

ume hard copy output. It costs about $150,000. The system supports several language processors, a file system and editor, and a host of specialized processors operating under the UNIX operating system (supplied by Bell Laboratories).

The PDP-11/45 system first became operational in September of 1974, and was used primarily to teach the introductory computer science course at Harvard. The language used in this course was developed at Harvard and goes by the name of PPL (polymorphic programming language). The students using this language constituted over 60 percent of the system load during 1974-75. In addition to PPL there are also four other principal processors supported on the system. These include ECL (extensible coding language), another Harvard designed language, and also a lightly used BASIC compiler. The BASIC compiler functions very similarly to PPL and for simulation purposes was considered to be equivalent. An EDIT processor, which includes a file storage and retrieval system, is reasonably heavily used. Since the system is also used to teach a course which involves assembly level programming, the PDP-11/45 Assembler processor also receives some use, and is modeled in the ASEM submodule.

For the simulation of the basic functions of the system, a mix of typical terminal activities was determined from the set of processors above including an additional job to represent the execution of a compiled or assembled program. This TEST procedure simulates the execution of a job which accepts some user commands, executes a relatively large number of processor instructions, and produces a message back to the user terminal.

The load simulated was a very heavy one so that the dynamics of the PDP-11/45 system could be studied under some stress relative to the system scheduler. Data was collected from the system during a period of intensive use and used to verify the accuracy of the simulation model. The basic representation of the Harvard UNIX operating system was simulated by a submodel developed over a period of a year during which the structure and code of the system were closely examined and a relatively large number of measurements were made of system functions in an attempt to assure a valid model.

In addition to the fundamental processors described above, five functions for network interface were considered for the simulation model. These include NAM, a network access processor; FTP, a file transfer protocol; TRAN, a job control language translator; an accounting function processor; and an information storage and retrieval processor.* The latter two processors were treated in a special manner. The accounting functions were assumed to be absorbed in the "overhead" of the UNIX system (as indeed most are), since the system offers relatively complex capability for job accounting as implemented at Harvard. The information storage and retrieval functions which would be associated with obtaining network information are represented as EDIT jobs in the system (the EDIT jobs rely on the UNIX file system for storage, retrieval and processing). The former three network functions were simulated by discrete submodels.

The NAM is one of the most complex of the network submodels. It simulates the activities of a software machine extant at the National Bureau of Standards in Gaithersburg, Maryland.[4] The NAM is designed to effect log-on and subsystem access procedures for the user by assuming his duties in the necessary exchange of requests and information required while logging onto a network computer resource. NAM accepts a line of text from a user calling the NAM into operation. It then initiates communication with a remote host computer, exchanging between 6 and 18 lines of text in order to effect the requested access, and finally passes on to the user a "welcome aboard" missive from the same remote host. NAM also operates optionally as a character Store-and-Forward processor.

The submodel for the File Transfer Protocol (FTP) emulates the shipping of a word package from one host to another. The protocol being simulated is much like the ARPAnet FTP, wherein the data being shipped across the net is broken up into packets (here, of length 512 words), with receipt of a packet being acknowledged only after full error-detection software scans of it have finished. This FTP is different from ARPA's FTP in that the data shipped from Host A to Host B is stored at an intermediate machine (in this case at the **N**etwork **I**nterface **S**ystem) instead of travelling directly between the two machines. The NIS performs such functions as data transliteration and translation, coordination of device speeds (i.e., it buffers the transmission), and generally makes the whole procedure as transparent to the two hosts as possible. As far as they are concerned, they are outputting data to a standard I/O device.

The Translation submodel (TRAN) simulates a software package operational at Harvard's Office for Information Technology. This program effects translations of IBM's Job Control Language from one IBM system to another. For example, a job designed to be run on MIT's IBM 370/168 is passed through the Translator to acquire compatibility with the JCL conventions extant at Princeton University's IBM 360/91 Computer System. The TRAN Procedure simulates the table-driven translation of a medium-sized JCL deck, and is thought to be general enough in conceptualization to represent other types of simple translation, not merely JCL-type control cards.

These three Network functions, NAM, FTP, and TRAN, taken with the five previously discussed production jobs, make up the eight job types whose impact (in various combinations) upon the performance of

* The NAM model was developed from the programs and data supplied by the National Bureau of Standards Institute for Computer Sciences and Technology.

the PDP-11/45 UNIX computer will be the subject of the rest of this paper.

The OSSL developed simulation model consists of Procedures to represent the previously mentioned eight processes representing the eight basic system tasks, and one main Procedure (called SCHED) which simulates the actions of the UNIX Operating System. Procedure SCHED simulates the scheduling of system tasks, and coordinates the running of the other eight Procedures.

The UNIX method (simply stated) for determining which process shall be swapped into executable memory goes as follows:

(0) if a job is ready for swap-in, go to (2) else go to (1)

(1) enter a wait state and remain in it until signalled that a job is ready to be swapped in and then go to (2)

(2) find the job which has been swapped out the longest and which is runnable (i.e., it is waiting to use the processor) and then go to (3)

(3) if there is enough core available, swap the job found in step (2) into core and go to (1) else, go to (4)

(4) check to see if any jobs now in core are doing terminal I/O. If so, swap the first found out and go to (2) else, go to (5)

(5) if the job requesting swap-in has been out for 3 seconds or more, and if any job has been in core for more than 2 seconds, then swap the oldest such out and go to (2) else, go to (6)

(6) since either the oldest job on disc is less than 3 seconds old, or the oldest job in core is less than 2 seconds old, no job is eligible for swap-in. go to (1)

For simulation, procedure SCHED receives "requests" from the other eight procedures, asking that the jobs they represent be swapped into core (executable memory). It then steps through the above algorithm and, when it has finally "swapped the job in," notifies the relevant Procedure that its particular part of the simulation may continue.

THE SIMULATIONS

The subject system under analysis as the base case consists of the PDP-11/45 processor, 90K words of executable memory (available to user jobs), a fixed head disc operating at 250,000 words/sec transfer rate, and a secondary storage disk (available for user storage) operating at 150,000 words/sec with an 8 msec latency and a 25 msec seek time (the latter being an optimized 32 msec seek). The operating system is UNIX, and the job mix* is as follows:

five	PPL	jobs
two	ECL	jobs
three	EDIT	jobs
one	TEST	job
one	ASEM	job
one	NAM	job
one	FTP	job
one	TRAN	job

Each of these jobs is under the control of a hypothesized user (i.e., there are 15 people actively using the system) at his own 120 character-per-second CRT. Each is represented by an OSSL submodel. It should be noted that as each of the jobs in the standard job mix incurs completion, another of the same type is started up. Several "sensitivity" experiments were performed as baseline tests of the OSSL simulation model. The results of each sensitivity analysis from the simulations have been summarized, with two types of parameters presented. The first type includes internal *system performance* measurements, e.g., component scheduling and use measurements. The second type includes *use performance* measurements of response and throughput, e.g., the response times for individual interactions, and the completion rate for jobs. The description for each of the two types of parameters is shown in the following tables (Tables I and II).

Basic 11/45 system

After having run a basic set of models without the network interface system functions to validate the "stand alone system," the first new configuration was simulated with the network interface functions incorporated into the currently installed PDP-11/45 at the Harvard Science Center. The previously defined standard job mix was used in the base line simulation. In order to further exercise the base case in an evaluation of sensitivities, the system configuration was altered in several ways and simulated for the same time period with the identical job mix. Since the initial simulations indicated a processor intensive (and processor limited) system execution, the base line cases were tested on a configuration with four different processor configurations. The first was the basic PDP-11/45 processor, the second was a PDP-11/45 processor with Cache memory, the third was a PDP-11/70 processor with Cache memory, and the fourth was a dual PDP-11/45 processor system. The results of the base line simulations for the system performance and use performance parameters (previously described) are shown in Table III and Table IV.

One of the principal purposes of the four base line cases was to examine the sensitivities indicated by the model as the configuration was changed in order to determine the extensibility into further analysis of various network interface system configurations. It can be seen from the data in Table III that the performance of

* This mix (hereafter referred to as the "standard job mix") reflects a heavy load upon the system. Indeed, the system is functioning in its very worst case when supporting such a user distribution. However, such a load is a frequent occurrence at the end of the academic term.

TABLE I—Internal System Performance Parameters

CPU Busy —the percent of total time the processor has been active

CPU Rejection —the rate at which the processor has been requested but has been busy. The new request is then queued, and the queue residency time is the next figure cited (CPU Wait).

CPU Wait

mean —the average residency time of a queued processor request

σ —the standard deviation of the residency times

maximum —the maximum residency time of a queued processor request

CPU Wait Until

50% —the median residency time

66% —the time spent in queue by 66% of the requests

95% —same as above but for 95% of the requests

PRFR —The Processor Request Failure Rate (PRFR) is calculated as follows: of those requests for the processor which were queued, the percentage which were not met until 2 or more seconds had passed is multiplied by the fraction of requests for the processor which were queued. Thus, the PRFR reflects the chance that a random request for the processor will be kept waiting for more than 2 seconds. Since the UNIX scheduling algorithm allows a job to be swapped out of executable memory after it has been there for 2 seconds, the PRFR is a barometer reflecting about how many jobs will get into core, request the processor, and get flung from core before the request is met.

Swapping Disc Busy —the percent of total time the swapping disc has been active

Disk Busy —the percent of total time the disk storage unit has been active

Core Rejection —the percent of swap-in requests which could not be met the first time due to insufficient free core (required queueing)

Total Swap-in —the total number of jobs swapped-in

Average Core Life —the average time a job spent in core in any one swap

Average Core Used —the average amount of core in use by user jobs. (Also given as a percent of total available core.)

Note: In these reports, unless otherwise stated all times shall be in units of seconds, and all sizes will be in units of words (16 bits to each word).

TRAN
—the counts reflecting the number of completions of the associated Procedure. If none have finished, the count will read zero. If none were started up in the first place (i.e., a particular simulation is not concerned with the relevant Procedure) then a dash (—) will appear.

the PDP 11/45, given the heavy work load for fifteen active terminals, was CPU (processor) limited. The CPU was busy almost 95 percent of the time and barely four requests in five could be met (the fifth had to be queued). The mean time in CPU queue was .87 seconds, with a standard deviation of 1.153 seconds and a maximum wait greater than five seconds. Since the UNIX operating system allows a process to reside in core normally for two seconds before being eligible to be swapped out, the results would indicate that 10 percent of the processes were eligible to be swapped out of core memory by the scheduler before they emerged from their wait for CPU service. None of the other performance parameters are particularly alarming. The swapping disc, core memory and disk storage are relatively modestly used. One might expect that their use was limited by the lack of processor capacity.

The use performance results from the simulation model are equally indicative of sluggish system response and throughput. For example, the mean response time for an EDIT command was in excess of five seconds with a standard deviation of over five seconds as well. The maximum recorded wait was 22 seconds. The NAM MACRO response is even more indicative of the processor bottleneck since MACRO requires the execution of a substantial number of instructions. The mean response time for MACRO was 196.7 seconds with a standard deviation of 56.1. The throughput counts for the assembler and the network interface sys-

Note: The ECL, PPL, EDIT and TEST jobs are of sufficient length (5 to 15 minutes each) that none complete in the 10 minute base line simulations. A subsequent simulation of longer duration demonstrates throughput for these jobs.

tem jobs indicate a relatively modest completion rate for these functions.

From an examination of the results of the initial simulation it appears that the configuration is sensitive to the availability of processor bandwidth and possibly the amount of available executable memory (since the average core used was 89 percent). There is also the hint that prioritizing the scheduling algorithm in some different manner might affect system performance and use performance for a particular type of job.

11/45 cache processor

The relatively clear indication for a subsequent sensitivity run is to improve the processor bandwidth. As a result, the second of the base line simulations incorporated the use of a Cache memory added to the PDP-11/45 processor. The results from the effective improvement in the processor capacity can be observed from the results in Tables III and IV. The processor busy time has dropped from 95 percent to 92 percent. The processor wait time has been approximately halved with the standard deviation dropping from 1.15 to .64. It is also indicated that for half of the processes the residency time in the CPU wait queue dropped from .6 to .2 seconds. The improvement in CPU bandwidth has also resulted in more efficient use of the swapping disc and the risk storage unit (increased 5 percent and 9 percent respectively). The PRFR has also sharply reduced as expected.

Use performance of the system with the Cache has improved dramatically. For example, the mean EDIT response time has dropped from 5.61 seconds to 3.47 seconds (standard deviation dropped from 5.12 to 2.87) and the maximum dropped from 22 to 12 seconds. Throughput improvements average around 60 percent as characterized by the FTP job turnaround, which increased from 41 completions to 69 completions.

11/70 processor with cache

The indications from the prior simulation of the system with the 11/45 processor and Cache supported the notion that the CPU was and remains the limiting component. A third simulation replaced the 11/45 processor and Cache with an 11/70 processor and Cache leaving all other characteristics of configuration and workload constant.

This change also significantly improved the performance of the system. Throughput improved by about 60 percent and interactive response times also dropped. For example, the mean EDIT response was reduced to 2.27 seconds (σ of 1.87) and the maximum to 10.0. The NAM MACRO response improved from a mean of 192.0 seconds to 92.9 seconds. Internal system performance also reflected the improvement with CPU Busy time dropping from 91.6 percent to 88.0 percent and CPU queuing appreciably reduced. Memory swap-ins continued to increase for the period and both the swapping disc and the disk storage unit busy times jumped appreciably.

Dual 11/45 processors

The final sensitivity test in the baseline series accommodated dual 11/45 Processors to replace the single processor configuration. In this case, processor queuing was eliminated but some response times showed no gain over the uniprocessor 11/70 Cache system, reflecting the mixed blessing of two slower processors versus one faster processor in a processor intensive environment. In general, however, both use performance and internal performance were improved over the fastest uniprocessor configuration. It should be noted that no allowance was made for any increase in operating system overhead which might result from the dual processor configuration. The UNIX system used at Harvard does not accommodate other than a uniprocessor configuration and estimates vary about the consequences of a multiprocessor modification to UNIX.

Base line simulation conclusions

The four base line simulation experiments bolstered faith in the capability of the model to represent the

NIS system. The isolation of the processor as the constraining component in the system and the demonstration of the sensitivity of the model to improvements in processor performance seemed in keeping with expectations. Moreover, the subtle changes in the internal system performance of the other major components, e.g., executable memory, swapping disc, and disk storage, increased confidence in the model as well. Use performance data was also within predicted limits although priority modifications in the scheduler might have altered the performance of individual processors substantially.

It was particularly interesting in the simulation to note the continual improvement of the uniprocessor configurations as processor performance improved followed by the somewhat discontinuous improvement of the dual processor configuration which utilized the slowest processor. In particular, although overall performance indicated substantial improvement for the dual processor configuration, some individual processes did not perform as well on the dual processor configuration as on the fastest uniprocessor. Although in retrospect the result was not surprising, the ability of the model to accurately reflect the mixed blessing of the dual processor configuration supported the notion that the model was sufficient for more useful analyses.

TABLE V—Relative Effect on Internal Performance

* From Table III for comparison.

WORKLOAD SENSITIVITY ANALYSIS

The second part of the simulation experiment dealt with the evaluation of the relative effect of network interface functions combined with basic functions on the standalone processor. Specifically it was of some interest to learn whether the network interface functions had more or less impact on system performance than the basic "standalone" processors. More specifically, it seemed meaningful to understand whether the addition of n terminals to engage in network access activity would have more or less effect on the PDP-11 UNIX configuration than the addition of the same number of terminals for standalone tasks involving PPL, ECL, BASIC, and the like. As a result, several simulation experiments were conducted to attempt to evaluate the sensitivity of the model to these alterations in workload. For these experiments the PDP-11/70 Cache configuration was selected. The use of this configuration rather than any of the others provides a level of processor power sufficient to make either an increase or decrease in processor demand more obvious and more realistic.

Twelve terminal standalone system

The first simulation consisted of the PDP-11/70 Cache configuration with the job mix altered to remove the network interface functions. In other words, all use of NAM, FTP and TRAN was eliminated from the workload. In the first case this was accomplished by simply reducing the number of terminals from 15 to 12, removing those three that were engaged in the network interface functions.

The effect of this change in workload upon internal performance is shown in Table V. It can be seen that there is a general shift toward more processor-intensive use of the configuration and less efficient use of both the swapping disc and the disk storage units. Even though the total number of active terminals has dropped from 15 to 12, the processor has jumped from 88 percent to 93.5 percent, and the processor rejection rate (percent of requests which must queue for processor use) has soared from 14.4 percent to 59.5 percent. Other processor performance parameters, including the queue waiting statistics, further imply a relative increase in processor demand. On the other hand, the rejection rate for memory use has actually dropped from 55 percent to 47 percent. The total number of swaps has reduced dramatically and the average life of a process in memory has more than doubled. At the other end of the spectrum the swapping disc busy time has dropped from about 40 percent to 12 percent, and disk storage unit use has dropped precipitously to only slightly over 10 percent of its former use level.

From the perspective of system utilization, the results are limited but significant (see Table VI). The interactive response time as measured by the EDIT processor has remained relatively constant. The mean response time for the EDIT is at about 2.3 seconds with a standard deviation of about 1.9 seconds, for both simulations. The maximum response time has increased slightly for the non-network configuration. Throughput as indicated by the assembler has increased only slightly—from 17 to 19 jobs.

It can be concluded from this initial experiment that removal of the network interface functions slightly im-

TABLE VI—Relative Effect on Use Performance

	Fifteen Terminal (Standalone & Nis)*	Twelve Terminal (Standalone)	Fifteen Terminal (Standalone)
EDIT—mean response	2.27	2.3	2.59
—σ	1.87	1.9	1.81
—max.	10.0	12.0	8.0
ASEM	17	19	17

* From Table IV for comparison.

proves the throughput of the configuration for the other jobs but does not substantially alter the response time for interactive tasks. From the internal performance data, however, it is obvious that the system is unbalanced in the sense that the processor is intensely busy while other critical parts of the configuration, including executable memory, the swapping disc, and disk storage units, are performing well below their most efficient levels. Hence, the first indication would be that the network interface functions fit into the workload environment, for the most part consuming resources that are otherwise not critical.

Fifteen terminal standalone system

A second experiment to measure the relative effect of the network interface functions was conducted with a fifteen terminal system. In this case, the network interface functions NAM, FTP, and TRAN were replaced by standalone jobs representing PPL, EDIT, and TEST. This configuration brought the number of terminals up to equal the combined configuration tested first, but eliminated any network access functions. In this way, an indication of the relative effect of the network interface functions could be ascertained directly.

A summary of the results is shown in Table V for internal performance and Table VI for use performance. It can be observed that the use performance varied only slightly from the other 15 terminal configuration. The EDIT interactive response indicated both a slight change in the direction of improvement (maximum response dropped from 10 seconds in the combined system to 8 seconds) and a slight degradation (mean response time rose from 2.27 seconds to 2.59 seconds). Morcover, the throughput count for the assembler (ASEM) was the same. As a result, the relative effect of the network interface functions on system use performance is negligible.

The internal performance data indicates some change. The CPU busy rate rose from 88 to 93 percent, and the rejection rate soared to 69 percent from 14 percent. In addition, the mean wait time for the processor ready queue doubled, the standard deviation increased from .35 to .55 and the maximum increased by about one third. The use of executable memory became less contentious, however. The core rejection rate dropped slightly, the total number of swaps was cut almost in half and the average core life jumped from .45 seconds to .81 seconds. Most notably, however, the uses of the swapping disc and disk storage were only about forty percent and eleven percent respectively of the combined configuration! The clear indication from the internal performance data is that the network interface functions tend to balance the use of major system components more efficiently, reducing processor congestion significantly and using the idle resources of the swapping disc and the disk storage unit. Thus, the relative impact of the network interface functions appears to be at worst breakeven (use performance) and at best favorable (internal performance).

TABLE VII—Incremental Effect on Internal Performance

* From Table V for comparison.

Eighteen terminal combined system

The third and final experiment in this series was to determine the *incremental* effect of the network interface functions. This experiment was performed by simply adding three terminals with the three network interface functions to the fifteen terminal standalone configuration previously simulated. The results of this experiment are shown in Table VII and VIII. From Table VIII it can be observed that the throughput performance of the system was reduced only slightly for

TABLE VIII—Incremental Effect on Use Performance

	Basic+3* 11/70 CACHE	Basic+3+NIS 11/70 CACHE

FTP	—	94
TRAN	—	34

* From Table VI for comparison.

the assembler while 94 FTP transactions were performed and 34 program translations (TRAN) were performed. The EDIT response times did not significantly change. Hence it would appear that the network interface functions were performed at a minute incremental expense. From the internal performance in Table VII it can be seen that the network interface functions place almost all of the incremental load on the disk storage unit with a noticeable increase on the swapping disc and executable memory use as well. Since the network interface functions are significantly less processor intensive, the average use of the processor has dropped modestly and the processor rejection rate has dropped dramatically (to 1/3 of its former level).

Conclusions about the combined NIS and standalone system

It appears that the network interface functions mesh well with the characteristics of the standalone UNIX system. On a relative basis, replacement of standalone functions with network interface functions tended to balance the use of the major components of the computer system configuration more evenly, thus reducing the processor intensivity. This would indicate that the configuration becomes relatively much less congested in the case where some terminals are engaged in network activities. On an incremental basis it appears that a few additional terminals could be added for network access to a standalone configuration with a very modest impact on the standalone functions. In addition, the incremental effect would be a more efficient use of all of the components in the system. Hence, insofar as system performance is concerned the network interface function can be integrated into the PDP-11 UNIX system at a negligible sacrifice in performance of the standalone functions and with substantial improvement in the relative efficiency of the major components in the system. This result is, of course, more useful with the assumption that the Harvard UNIX system is typical of other standalone mini-computer system configurations.

NETWORK INTERFACE SYSTEM PERFORMANCE

The third and final analysis of the investigation deals with the development of a mini-computer configuration exclusively for network interface functions. The objective is to provide adequate performance capability for network access alone at a minimum cost. For this analysis both the job mix and the computer system configuration were altered substantially. The job mix represented was felt to be typical of an individual user accessing a computer network resource via the facilities of the network interface system.

The essential flow goes as follows:

(1) A user, having logged on to the NIS system, enters the editor (EDIT) and edits a file of length 3K words, invoking 20 to 30 edit commands.

(2) Having prepared his file, he next uses the NAM to open a connection and log him in to a remote host.

(3) Ready to send his file (constructed in step 1) across the network to the remote host, he first must make its "JCL" compatible with the receiving institution's conventions. He thus translates it using TRAN.

(4) With the file ready to go and the network connections complete, he uses a File Transfer Protocol (FTP) to ship the translated file over the net.

(5) With his program ready to run on the remote host, he now uses the NAM, in its character store-and-forward mode, to send from 6 to 12 lines of text (receiving the same on a one-for-one exchange basis) to the remote host, setting the job up for running, and finally initiating execution by the remote host.

(6) Execution completed (in zero elapsed time for purposes of this analysis) on the remote host, the user uses FTP to ship his results home.

(7) And finally, now that he's finished with the remote host, he uses the NAM to close his network connections.

This seven-step terminal session is simulated for each terminal by the sequential execution of the procedures indicated with a variety of use parameters. Upon completion of the seven-step sequence, it is reinitiated for each terminal. The sequence is started at a random point for each terminal in order to more quickly reach steady state in the simulation.

Four hardware configurations are examined relative to the specified workload. Each configuration is simulated for a period of thirty minutes operation. The basic hardware configuration includes a PDP-11/20 processing unit (to replace the prior PDP-11/70 and 11/45 processing units) and a reduced executable memory configuration. The same swapping disc and disk storage devices from previous simulations are used. The configurations remain constant for the four simulation experiments except for the size of executable memory and the number of active terminals on the system. The operating system simulated was UNIX even though the PDP-11/20 processing unit has a slightly smaller instruction set which would require some modification to UNIX should it actually be used. In the four simulations, the following combinations of active terminals and executable memory were examined:

(1) Ten terminals and 20K executable memory.

(2) Fifteen terminals and 20K executable memory.

(3) Fifteen terminals and 32K executable memory.

(4) Eighteen terminals and 32K executable memory.

The ten terminal 20K system was chosen as the base line configuration. It was hypothesized from the early experiments that the PDP-11/20 processor, which is approximately one-fourth the speed of the PDP-11/70 with Cache memory, would be adequate to support a ten terminal configuration given the seven-step sequence of operations defined. The 20K word memory was estimated in size from the memory use statistics gleaned from prior simulations for the network interface function processors. Since there was some feeling that the availability of executable memory might be more sensitive in the NIS system than for the prior combined systems, additional statistics were collected from the simulation model for the queueing relative to the availability of executable memory. These statistics called "core wait" (mean, standard deviation and maximum) and "core wait until" (50 percent, 66 percent, 95 percent) are analogous to the same statistics collected for the central processing unit in prior simulations.

Base line NIS system (ten terminals and 20K memory)

The summarized results for the four simulation experiments are shown in Tables IX and X. Table IX indicates the internal performance of the NIS and Table X indicates use performance. From the use performance statistics it appears that the base line system is performing within reasonable limits relative to system use. The response time for the EDIT processor is about 3 seconds with a standard deviation of slightly over 2 seconds. The MACRO NAM processor response time is a mean of 31 seconds and a standard deviation of about 11 seconds (a performance superior to any of the prior configurations). Throughput for the base line configuration appears to be respectable although it cannot be directly compared to the prior combined system simulations because of the difference in the characterization of the network interface system workload.

TABLE IX—NIS Internal Performance

Total Swap-in	484	1158	596	918
Average Core Life	3.72	1.55	3.02	1.96
Swapping Disc Busy	1.45	3.41%	1.7%	2.5%
Disk Busy	4.16	6.22%	5.4%	5.7%
PRFR	0	.24%	0	.485%

The internal system performance for the NIS indicates that the processor is only about 50 percent busy with a very low request rejection rate and a very minimal amount of processor queueing. The rejection rate for initial requests for executable memory is about 50 percent, however the mean wait for executable memory is relatively high with a mean of .4 seconds and a standard deviation of 1.15 seconds. The additional statistics for executable memory use indicate that 2/3 of the queued requests were processed within .19 seconds and 95 percent were processed within 2.75 seconds, still relatively long waits for executable memory in a computer system. Offsetting the queueing is the indication that the average core life of a process once swapped into memory is 3.72 seconds. Both the swapping disc and the disk storage are trivially active, indicating about 1 percent and 4 percent busy respectively.

Fifteen terminal and 20K memory NIS system

In the second experiment the number of terminals was increased by 50 percent to a total of 15 with the remainder of the configuration constant. As a result of this increase the throughput of the system increased about 33 percent ranging from 27 percent improvement for the edit and 42 percent improvement for the NAM. This improvement in throughput was accomplished, however, at some sacrifice in interactive response time. The mean response to EDIT transactions increased from 3 seconds to over 4 seconds and the mean response for MACRO increased from 31 seconds to 49 seconds. These responses are within reasonable limits, but are approaching that state which the user might call "sluggish."

An examination of the internal performance data indicates that the processor is substantially more busy, reaching 72 percent with a rejection rate leaping from

TABLE X—NIS Use Performance

	10 Term	15 Term	15 Term	18 Term
	20K	20K	32K	32K
EDIT—mean	3.04	4.39	4.34	6.23
—σ	2.36	3.63	3.73	5.4
—max.	14.	18.	20.	28.0
MACRO (NAM)—mean	31.	49.2	42.9	52.6
—σ	10.7	18.9	18.2	21.7
—max.	60.	100.	90.	120.
EDIT	11	14	12	9
FTP	18	24	22	19
NAM	26	37	30	35
TRAN	9	12	10	11

19 percent to 60.5 percent for initial processor service requests. Queueing times, however, have not substantially increased for the processor. The availability of executable memory appears reasonably critical with a rejection rate jumping to 61 percent from about 54 percent and the mean wait in queue more than doubling. In addition, the total number of swap-ins more than doubled to 1158 from 484 and the average core life dropped from 3.72 seconds down to 1.55 seconds. It is significant to note, however, that the swapping disc and the disk storage unit continue to be hardly taxed at all with busy times of 3.4 percent and 6.2 percent respectively.

Fifteen terminal and 32K memoryNIS system

Since the second experiment which held the configuration constant and increased the number of terminals to 15 seemed to indicate that executable memory was in short supply, the third experiment held the number of terminals to 15 and increased executable memory to 32K words. This resulted in almost negligible change in use performance. Response times stayed about the same as the second configuration for the EDIT and showed very slight improvement for the MACRO processor. The throughput statistics remained virtually level for each of the four processors (with the exception of NAM which showed a somewhat anomalous drop due to the sequence in which the 15 different seven-set processes completed). In terms of internal performance the processor continued busy (74.7 percent) and the processor wait in queue times increased slightly.

The executable memory statistics clearly reflect the improvement concomitant with greater memory size. The rejection rate dropped from 61 percent to 54.2 percent and the queueing times dropped as well with the mean reduced to .361 seconds from .91 seconds. Total swapping was also cut approximately in half and average core life improved back to above 3 seconds from 1.5 seconds. One might conclude, however, on the basis of the use performance, that the investment in the additional 12K words of executable memory was not returned in visible performance to the user.

Eighteen terminal and 32K memory NIS system

As a final sensitivity test, the configuration of the system was again held constant and the number of terminals increased to 18 from the 32K word memory. The increase in terminals from 10 to 18 for the PDP-11/20 processor begins to show symptoms of a debilitating nature in this experiment. The processor busy time has increased to about 87 percent and the rejection rate has jumped up to 63 percent. Queueing times for the processor are at an all-time high mean of 43 milliseconds with a standard deviation of 332 milliseconds. As might be expected, the executable memory statistics are approximately the same for memory queueing but the number of swap-ins has increased from 596 to 918 and the average core life has dropped from over 3 seconds to 1.96 seconds. Hence the contention for the central processing unit has affected the use of executable memory to some degree.

Conclusions about the NIS system

For some of the network interface functions, the processor is a limiting factor as the number of jobs increase. For example, the EDIT processor is adversely affected as the number of terminals on the system increase and the processor remains constant. On the other hand, the NAM processor appears considerably less affected by the availability of processor power, although some constraining does occur.

It is apparent from all of these results, however, that a relatively small mini-computer configuration can accommodate a sizeable number of terminals performing network interface functions. For example, the configuration with 15 terminals operating on the 20K word PDP-11/20 system provides a superior use performance. There is also a reasonable balance of internal performance activity between the processing unit and executable memory. In all of the cases, however, the swapping disc and disk storage units appear excessively powerful for the need. It is reasonable to expect that the units simulated could be replaced by others, somewhat less sophisticated (and less expensive). Should swapping become a problem, it has been demonstrated that modest increases in executable memory size can reduce the amount of swapping and hence the dependence on a high performance swapping device. In addition, the range of performance characteristics for disk storage units available for mini-computers allows for a great deal of configuration "tuning."

These two hypotheses were in fact tested by simulating the substitution of a single, relatively slow disk storage unit for both the swapping disc and the disk storage device. The replacement disk storage unit contains two removable "packs" with capacity of three million bytes each operating through a single disk control unit. The essential performance characteristics of the replacement disk unit are:

Average Seek Time	—35 milliseconds
Average Latency	—12.5 milliseconds
Transfer Rate	—2.5 million bits/second

The disk replacement was the only alteration to the fifteen terminal, 20K executable memory system previously simulated (Tables IX and X).

The result confirmed the hypothesis that the lower performance disk storage unit could replace the separate swapping disc and disk storage units with modest sacrifice in performance (Tables XI and XII). As hypothesized, the addition of 12K memory reduced the

swapping considerably. The use performance statistics of the system would indicate that a single disk with lower total access time might completely restore the performance level. From this result, the configuration for the NIS system seems relatively well balanced to workload. It is comforting to know, however, that a variety of mini-computer system components (processors, Cache memories, executable memories, disks, etc.) are currently available at relatively low cost for incrementally configuring such systems.

CONCLUSIONS

On the basis of current computer system pricing, it is clear that a computer system configuration approximating that of the final network interface systems simulated could be purchased for under $40,000. This would include 32K word executable memory, floating point arithmetic, a 6 million byte disk storage unit and controller, a processor equal or more powerful than the PDP-11/20, and a communications interface controller and line controller for 16 terminals. The simulation analyses indicate that this would provide a system with adequate performance capability for network interface only, for standalone use only, or for a combination depending on the specific character of the workload mix. In fact, all of the simulations have been conducted with very intensive workload characteristics and have assumed that all of the terminals simulated were simultaneously heavily active. Hence, it seems likely that local use patterns for such systems would be less demanding than those simulated. Moreover, it is relatively easy to visualize the price of small computer systems on the order of those simulated to continue to drop dramatically.

If one amortizes the purchase price of such a system over a period of three years, the incremental cost per terminal for the network interface system and substantial standalone capability already comes to less than $1000. It might reasonably be expected that this investment could be recouped several times over in reduced networking costs (connect time, etc.) and in more effective use of the human user's time. Considering the capability promised by a combination of the small standalone computer system in conjunction with a hierarchical interface to a variety of network host computers, it seems likely that such an investment might be wise.

An overview of the distributed computer network*

by DAVID L. MILLS
University of Maryland
College Park, Maryland

ABSTRACT

The Distributed Computer Network (DCN) is a resource-sharing computer network which includes a number of DEC PDP11 computers. The DCN supports a number of processes in a multiprogrammed virtual environment. Processes can communicate with each other and interface with this environment in a manner which is independent of their residence within a particular computer. Resources such as processors, devices and storage media can be remotely accessed and shared so as to provide increased reliability, flexibility and system utilization.

The DCN now supports several programming languages and applications packages. Programming languages such as SIMPL, LISP, BASIC and others, along with an extensive library of interactive graphics procedures, can be executed in processes which take full advantage of the distributed architecture of the network. Many of the components of the Disk Operating System (DOS) for the PDP11 can be executed in a special emulator-type virtual process now being constructed for this purpose. In this manner the PDP-11 assembler, FORTRAN compiler and various system utilities can be supported in the network environment. In cases which exceed the processing power of the network, connections are available to two large Univac 1100-series machines.

INTRODUCTION

A resource-sharing computer network is a collection of computers and communication facilities in which resources resident on one computer can be accessed remotely from another.[9] A distributed computer network is a resource-sharing network in which resources are managed on a global scale so that files and processes can migrate throughout the network as determined by user requirements and the current system loading. In distributed networks individual users need not necessarily be aware of the physical location of their resources.

The Distributed Computer Network (DCN) project started at the University of Maryland in 1973 with a single PDP 11/45 which could be connected to either a dual-processor Univac 1108 or a single-processor Univac 1106. The PDP11 was to be used to develop a virtual-processor based operating system suitable for operation on a number of PDP11 computers. The 1106 and 1108 (hereafter referred to collectively as the 1100) were to be used for data-base residence and as a computational resource. Other papers and reports[11,12,14–18,25] have described original design objectives for the DCN and the operating systems developed for it.

The DCN has since grown to include several PDP11 computers and peripherals interconnected by a variety of interprocessor links and data communication devices. The operating system which controls the resources of the DCN exists in two versions. One of these, called the Virtual Operating System (VOS), supports virtual-processor emulation of standard PDP11 programs and requires the storage management features of the PDP11/45 or the PDP11/70. The other, called the Basic Operating System (BOS), supports special-purpose dedicated applications in PDP11 models without these features, including the GT40 Display Processor and the LSI-11 Microprocessor.

Design objectives

The DCN was originally intended as a research tool for the development and evaluation of resource allocation and management techniques suited to the distributed environment. Although intended to be used by students and faculty, it was not anticipated that the DCN would replace other operating systems like RSX11[4] and UNIX[21] in all, or even most, applications. The foremost objectives in the DCN design are summarized below:

1. The supporting network software must be able to run in a wide variety of equipment configurations and hardware options. In particular, it must be

* This research was supported in part by Contract N00014-67-A-0239-0032 from the Office of Naval Research and Grant GK-41602 from the National Science Foundation.

possible to support intelligent terminals such as the GT40 and LSI-11 without requiring major system redesign or loss of critical features.

2. The environment of a process must be uniform throughout the network. Requests for network services such as activation of programs, access to storage media, communication with other processes and interface with the network data base must be standardized so that program and data files can be moved between processing sites with a minimum of reprocessing.
3. The network data base must be accessible to every process, regardless of its location. At least in the case of simple sequential access, the process should not need to be aware of its own location in the network or that of a requested file. The data base cannot be rendered unusable to all users if a single catalog or dictionary fails.
4. Input/output devices such as card readers, line printers and terminals must be accessible from anywhere in the network, either directly or through a spooling facility. An access method must be available for special-purpose resources such as array and transform processors, digital and analog input/output devices, and channels to other machines.
5. A comprehensive capability for performance monitoring and functional control must be built into the network. Using these capabilities it must be possible to experiment with and evaluate a wide spectrum of resource-allocation techniques and methodologies. Systems for data-base access, processor scheduling and process residency should be modular and separable, so that experimental substitutions can be made.
6. Finally, the system should be well-structured and capable of exploitation by graduate students and research workers. Design principles should be widely applicable and consistently applied. To the fullest extent practicable it should be possible to incorporate existing system and application software into the network without modification and to incorporate new hardware and software without extensive system redesign. Reasonable insulation and protection from software bugs should be provided.

Several systems now in existence or under development share some of these objectives. RSEXEC,[9,23] which operates as a subnetwork of the ARPA network, provides capabilities for remote file and device access. As in RSEXEC, the structure of the DCN is based on a virtual-storage and virtual-processor organization. Processes, devices and files can be accessed from anywhere in the network by a standard communication protocol. System integrity is enhanced by a hierarchical collection of loosely-coupled service processes which monitor user requests and poll each other for system status.

DCS,[5-8,22] which includes special-purpose hardware and communications facilities, incorporates a network-wide standard process naming and accessing protocol. As in DCS, DCN processes are named and given a unique identity within the network. Resources are identified and accessed with processes. Critical information is maintained in multiple copies and system damage due to lost system components, such as catalogs, is minimized by use of a standard set of recovery procedures.

Network configuration

The current configuration of the DCN, shown in Figure 1, includes six PDP11 CPU's with a total of about 360K bytes of processor storage and 13M bytes of direct-access storage. Communication bandwidths between the machines vary from 30 bytes/sec to about 300K bytes/sec, depending upon the facilities available. The three PDP11/45 machines, some of which cannot be dedicated to DCN use at all times, constitute the principal supporting resource for the other machines in the network. One of these machines includes special hardware for picture processing, another includes special hardware for real-time signal processing and a third includes interactive and remote-batch connections to the Univac machines. The GT40, PDP11/40 and LSI-11 are used for specialized terminal support and as test beds for the evaluation of small systems. Any of these machines can be connected by asynchronous lines at speeds to 9600 baud.

The 1100 machines provide all program preparation facilities available at present, including the cross assembler, cross compilers and cross link-editor. They are connected to the PDP11 network by either a 1200-baud asynchronous interactive port, by a 9600-baud synchronous remote-job entry port or by both at the same time. This provides facilities for exchanging program and data files between the 1100 machines and the PDP11 network.

SYSTEM ARCHITECTURE

Most DCN operations are performed in the context of a process. A DCN process includes procedure code, data storage and an interface for communicating with other processes and components of the network. Management of this environment is performed by the kernel (see Figure 2), which includes mechanisms for input/output device interface, storage allocation, process scheduling, interprocess communication and other similar functions. A hostel is an abstraction of a virtual environment in which a set of processes can interact with the kernel. An operating system for a hostel includes certain components of the kernel resident in the hostel (the supervisor) and, in addition, certain processes to manage system resources such as input/output devices, catalogs and files.

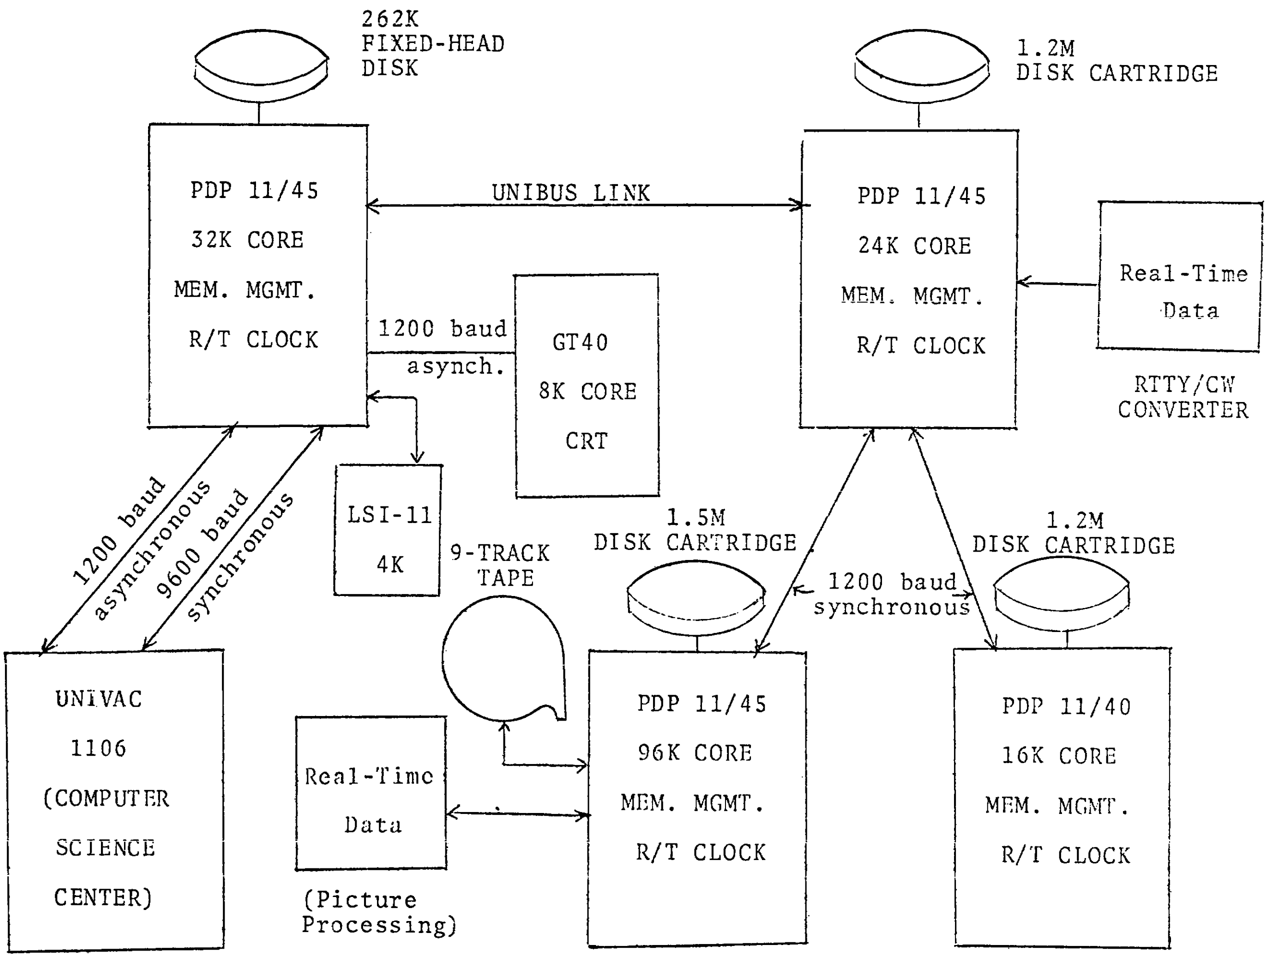

Figure 1—System configuration

There are at present two multiprogrammed operating systems for DCN hostels. One of these, called the Virtual Operating System (VOS), provides full capabilities for user processes in a general-purpose program development and execution system. The other, called the Basic Operating System (BOS), provides a limited subset of these capabilities for special-purpose data collection and processing systems. Both systems can be intermixed in the network and cooperate in providing the services to maintain the distributed environment.

The BOS is designed to operate in a minimum PDP11 configuration including at least 4K words of storage, an operator's console and a communications device for connection to the DCN. The VOS is designed to operate in a PDP11/70 or PDP11/45 configuration including at least 16K of storage, the memory management (hardware relocation) unit, an operator's console and a communications device. A rather extensive set of direct-access storage devices and communication devices can be supported in either system by simply including the appropriate modules at system generation time. Examples of supported devices include fixed and moving head disks, magnetic tapes, synchronous and asynchronous serial communications devices and high-speed interprocessor links.

The VOS and BOS are structured in a similar manner. They consist of the supervisor, a set of user processes and a set of system processes. The supervisor consists of a number of routines to schedule processes, dispatch device interrupts and coordinate interprocess communication. User processes are designed to execute one or more application programs, depending on the particular system configuration. System processes include device processes, which manage the set of input/output devices configured in a particular installation, and service processes, which perform network management functions.

In the VOS, which requires the memory management unit, there are two types of processes: real and virtual. Real processes share a subset of the virtual address space of the supervisor and are designed to

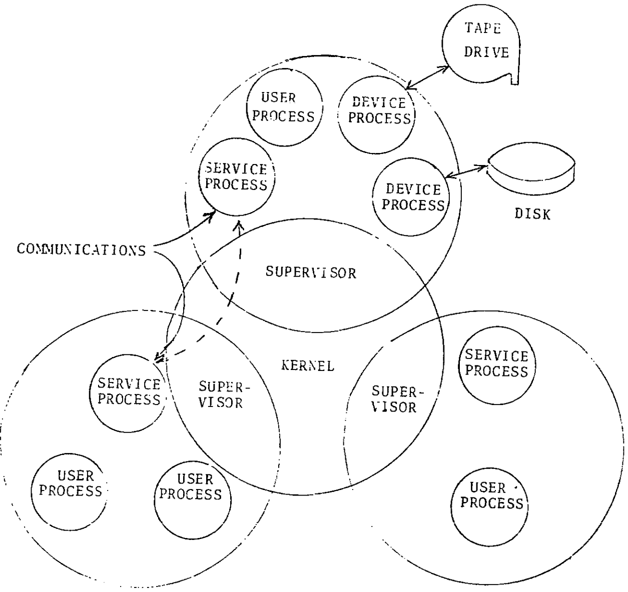

Figure 2—System structure

support peripheral devices, such as the operator's console, communications lines, and direct-access storage devices. Virtual processes have individual virtual address spaces and are designed to support application programs and network management programs. In the BOS all processes are real, including those which support application programs and network management functions.

Figure 3 shows the hierarchical relationships between the various components of the VOS. The BOS is constructed the same way but does not have all of the functions shown. Level zero, consisting of the resident supervisor, provides management of process scheduling, interprocess communication, processor storage and interrupt dispatching. Level one consists of the port dictionary process, which provides access to named interprocess communication channels, or ports. (The port dictionary process itself is accessed by a predefined or well-known-port.) Level two, consisting of a set of device processes, provides an abstraction of the physical devices as a set of processes in which all data transfers are in the form of standard messages. Level three, consisting of a set of swapper processes, manages the virtual-storage operations in the system and supervises segment transfers between processor and direct-access storage. Level four consists of a set of dictionary processes providing access to named virtual files.

The supervisor and levels zero through four are specific to each hostel in the network. Processes at higher levels are free to migrate throughout the network driven by user requests and network management policies. Level five consists of the catalog system, a hierarchical set of processes which provides access to volume and port dictionaries by means of a sequential decomposition of file and port names. Level six, consisting of a set of stream-demon processes, provides sequential access to virtual files. Level seven consists of a set of user processes. Each of these uses the services provided by the preceding levels to create an environment in which a conventional application-oriented program can operate.

Level	Component	Services
0	Supervisor (resident)	message buffering system initialization interval timer process scheduling and timeslicing process synchronization (P, V) processor storage allocation and mapping swap queue management interrupt vectoring
1	Port Dictionary (resident)	port name/address translation

7	User Process (swapped)	message interface file-system interface catalog-system interface interrupt management virtual-storage management

Figure 3. System Hierarchy

Virtual storage management

The PDP11/45 equipped with the memory management unit provides a hardware relocation facility which can be used to realize a virtual storage system. The memory management unit provides three sets of relocation registers, one set corresponding to each of the user, supervisor and kernel states. Each of these states is associated with a distinct processing environment: the kernel state is associated with the basic process scheduling and processor storage mapping functions; the supervisor state is associated with a set of supervisor processes used to manage the input/output and swapping functions; the user state is associated with all other processes, including those for resource management and application programs.

Processor storage mapping functions are handled differently in the three states. In kernel state the mapping is fixed, since all segments are resident in processor storage. In supervisor state the mapping includes the particular segment which contains the process procedure and, in addition, certain procedures of the kernel which can be called by the process. In user state the mapping includes only those segments which have been explicitly requested by the process using a set of supervisor primitives constructed for the purpose.

The virtual storage space available in the three processor states is shown in Figure 4. The segments accessible in kernel state are resident at all times in processor storage. Segments accessible in supervisor state for procedure code are made resident as each process is installed, which can occur dynamically as part of normal system operations. Segments in user space are swapped from direct-access storage to processor storage according to a demand-fetch policy, in which the transfer occurs only upon actual reference. Segments are removed from processor storage according to a modified least-recently-used policy.

All segments in processor storage except those used for message buffers, etc., have images on direct-access storage as segments of files. The remainder are used by the supervisor for scheduling, buffering and message-transmission operations. Associated with every process is a control segment, which contains space for scheduling parameters, general registers, storage-mapping registers, and so forth. As each process is scheduled its control segment is mapped into kernel space, but not into user space. This provides an exceptionally clean and secure interface, since there is no way that a virtual process can access any segment other than those validated by the supervisor.

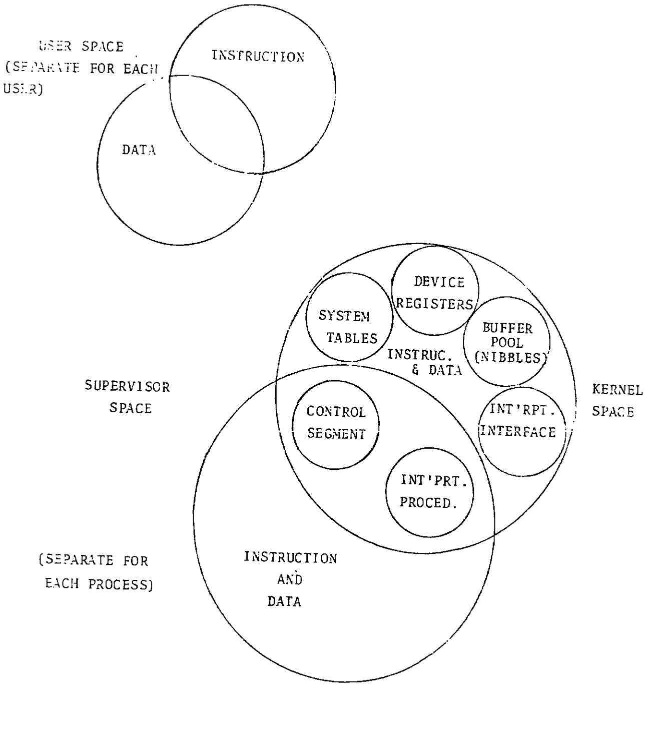

Figure 4—Storage mapping

Interprocess communication and synchronization

Due to the distributed nature of the DCN, processes cannot in general communicate by means of shared storage. Instead, a highly-developed stream-oriented interprocess communication and synchronization facility is provided. This includes the capability for transmitting variable-length messages from any process in the network to any other and provides for the automatic routing of messages between hostels, so that the sending and receiving processes are not in general aware that their correspondent is in the same or a different hostel.

Functional control over message formatting, flow control and routing is provided by the supervisor, together with a set of system processes. The supervisor includes primitives for sending and receiving messages on a byte-by-byte basis. A set of system processes formats them for transmission over a communication circuit or interprocessor link as required. A common buffer pool is maintained in each hostel so that separate buffers for each process are unnecessary.

A message, consisting of a string of bytes preceded by a header, is sent by a process to a named connector called a port. The concept of port, as used here, is similar to those of Walden,[24] Farber[5] and Carr[2] (although called by different names). One or more named ports can be allocated to a particular process on request. A port is always allocated to the receiving process, although any number of processes can send to it. A port name is accessed in the same fashion as a file name. The catalog system (see below) provides access to a port dictionary maintained at the hostel in which the port is allocated. Each entry in this dictionary includes the name of the port, its address and a pointer to the process to which it is allocated.

Ports are identified according to a 16-bit integer called the port address. For efficiency in message transmission and routing, the port address is split into two 8-bit fields: the hostel ID (HID) and the process ID (PID). System processes which transmit messages between hostels use the HID to determine the routing, while the supervisor within each hostel uses the PID to determine the particular port within the hostel.

The use of HID and PID fields in the port address would seem to constrain the mobility of ports. In fact, as shown in Reference 17, recovery from transient system failures requires that all processes with knowledge of a port address be able to correct the address if the process to which it is allocated moves unintentionally. This is a special case of capability revocation (see below). Since in the DCN design intentional process movements are not expected to occur very often, the same correction mechanism is applied in both cases.

THE CATALOG SYSTEM

Files and ports are accessed by a hierarchical set of catalogs in a manner similar to DCS.[6,7] Each catalog is associated with a process which provides the name of another process when given the fully qualified name (see Figure 5). The chain of processes accessed in this way terminates either at the dictionary process for the volume on which the file resides or the port dictionary for the hostel in which the port is allocated. The catalog and dictionary structure is such that each catalog and its access process can be re-created (perhaps on another volume or hostel) if the storage media used to store the catalog or the processor or process which services it fails.[18]

At least one volume at each hostel contains the system catalog, which is at the top of the catalog system hierarchy. This catalog is replicated in each hostel so that failures do not compromise accesses to files in other hostels. Other catalogs may be replicated as well in the interest of efficiency and reliability. A system of continuous consistency checks is now in implementation[17] to insure that the catalog system remains intact in the face of transient system failures.

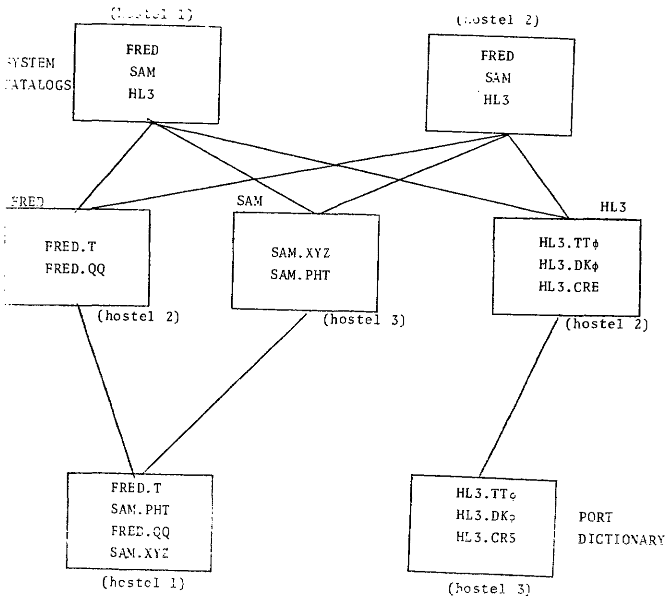

Figure 5—Catalog system

THE VIRTUAL FILE SYSTEM

A file consists of a number of variable-size segments, each of which can be assigned one of several access keys. The segments can be used in any way required—sequentially or randomly—according to the needs of the process. A dictionary is maintained on each direct-access volume in the VOS hostel. Each file on the volume is represented by an entry which includes the fully qualified name of the file and the location, length and access key of each of its segments. The dictionary is maintained by a special process, called the volume dictionary, which responds to requests for additions and deletions of dictionary entries and for accesses to files on the volume.

The segments of a file are accessed by first opening the file and then mapping the specified segment into the virtual storage of the requesting process. A file is opened by sending a message through the catalog system to the appropriate volume dictionary, which returns its port address to the requesting process. A segment is mapped into virtual storage by sending another message to the indicated volume dictionary process, which returns the address of the segment on the volume. When the segment is referenced this address is sent to the swapper, which transmits the segment to processor storage. A service process called the stream demon provides for the connection of a sequentially-structured file to a selected port for input or output. This provides a simple sequential access method for use by system translators and utility programs. More sophisticated access methods are currently being considered.

PROTECTION MECHANISMS AND CAPABILITIES

The environment accessible to a process is completely determined by the set of port addresses and segment addresses known to the process. Each of these are protected quantities and cannot be inspected or changed directly by the process. A new port assignment or segment mapping can occur only as a result of a designated supervisor primitive in which each port address and external address has a local name (or table index) known only to the process.

In order to send a message to a port, a process must first obtain its address from the catalog system and then obtain authorization from the process which is allocated that port. In both of these cases access can be controlled by means of a password or key. In order to access a virtual file segment the file must be opened and the segment mapped into virtual storage. This requires obtaining the port address of the dictionary process, the address of the segment and the segment access key. In addition, every virtual storage segment can be assigned a storage access key. An access generated by an application program is checked against these keys and is permitted only if validated by both of them. Thus, access to a virtual storage segment can be controlled by the file system, using a password required to open the file or change the segment access key, or by the user process, using the same mechanism to change the storage access key.

These mechanisms can be readily generalized and interpreted as capabilities.[3] In a very real sense a port address is a capability which provides access to a port. Only one kind of access permission is implied by this capability—that of sending messages to the port. A segment access key of the appropriate type is a capability which implies permission to read, write or execute the segment. In this context the ability to obtain either capability depends upon the knowledge of the name of the port or file and the password procedures involved.

NETWORK FACILITIES

The mechanisms described so far provide for a uniform treatment of hostels, processes and interprocess communication. It remains to build on this base to show how the operations of the network are organized. It will be most illuminating to consider the appearance of the network from the user's point of view and then describe how his requests are processed by the supervisor and system processes.

The user process

The DCN appears to a user as an hierarchical collection of user processes. A user process can be viewed as a region of processor storage into which can be loaded or mapped one of a number of application programs. In the VOS the region consists of one or more segments of virtual storage as necessary to contain the procedure and data segments of the application program. In the BOS the region consists of permanently resident fixed-size blocks of storage containing shared re-entrant code.

The storage management policy of the user process is characterized by a hierarchical overlay structure. In the VOS most of the 65K-word virtual space is available for the application program. Each overlay consists of a program file, which can contain procedure and data segments. An overlay is initiated by mapping these segments into the virtual storage of a user process and allocating a segment of the process file as a stack. When one overlay calls another, the virtual storage mapping of the calling overlay is saved on the process stack, the virtual storage mapping of the called overlay replaces that of the calling overlay and a new process stack segment is allocated. When the called overlay terminates, the process stack segment and virtual storage mapping of the calling overlay is restored and the stack space released.

Network operations

When the user process is first invoked a simple command language interpreter (CLI) is mapped into storage. The CLI is capable of responding to a number of operator commands, including the following:

1. A set of commands to link to another user process and to return to an old user process.
2. A set of commands to establish an association between a named port and logical port number as used by the application program.
3. A set of commands to send data and control messages to other processes.
4. A set of commands to select an application program (possibly from a library) for execution.

Additional commands are available in some user processes for debugging and auxiliary storage management. A typical set is summarized in Figure 6.

When a user logs on the system he is connected to a system process called the logger. During the log-on procedure a user profile is constructed which contains such information as the default user name to be used in file-access operations and the default hostel name to be used in some port-access operations. Following the log-on procedure the user specifies the name of the user process in which his application program is to run. This is presently done by specifying

Command	Function
ASG <lpn> <portname>	assign a port to a lpn
SEND <lpn> <message> EOF <lpn> <message> ATTN <lpn> <message> CTRL <lpn> <message>	send various types of messages to processes identified by lpn
DISPLAY <bgnadr> <nwords> ALTER <bgnadr> <value> . . . SENSE <lpn> TEST <nlines> <code> RESET	commands used for debugging and system testing
FORK <lpn> <message> JOIN <message> END <message>	commands to initiate and terminate user processes and to control synchronization between calling and called processes
LOAD <lpn> START <adr> <parameters>	commands used to load application programs and initiate execution
LOGON <parameters> PROFILE <parameters> LOGOFF	commands to log on and off and establish user profile (defaults)
RUN <portname> <parameters>	combination of ASG, LOAD and START
LINK <portname> <message>	combination of ASG, CTRL and FORK

(<lpn> is logical port number)

Figure 6—Command Summary

a hostel name (possibly remote) together with a user process name in that hostel.

Connections to the specified user process are established by searching the catalog system for the process name. If found the user is connected immediately to that process; if not, a new user process is created in the hostel indicated in the user profile and the user connected to it. In either case, the user profile is transmitted to the new process, so that it has access to all the files and ports of the old one. In a similar manner a user process can initiate another user process to perform some function while the old process either continues or is suspended until the new process terminates. When communications are terminated between the user and the original user process, the logger once again assumes control and the user can either log off or select a new user process.

APPLICATIONS SUPPORT CURRENTLY AVAILABLE IN THE DCN

The development of the DCN has reached the point where many application programs can be supported in the network environment. In a complex system such as this, confidence in the utility and capability of the system is gained only through user experience. The facilities described below were developed primarily to test the suitability of the DCN for their operation.

A special emulator, now in development, provides a virtual-processor environment in which programs written for the manufacturer's Disk Operating System (DOS) can execute. The emulator includes a set of supervisor-call interpreters compatible with DOS and with which commands can be entered into input/output devices and sequential files. Only those programs which are "well behaved" in the DOS sense can be supported (i.e., do not reference device registers directly). Although load modules produced by the DOS assembler, FORTRAN compiler and linker are well behaved in this sense, some of the system components within DOS, in particular the FORTRAN compiler itself, require direct file access, which is not supported in the DCN. In the FORTRAN compiler direct file access is required only to accomplish an overlay function, which is provided in a different fashion by the VOS itself. Work is under way at the moment both to provide direct file access and to change FORTRAN to call the VOS overlay facilities rather than its own.

Several cross assemblers and cross compilers are available on the 1100 machines, including the assembler, link editor, and the SIMPL and ULP compilers.[1,13,19] Programs in these languages are usually compiled and link-edited on the 1100 machines and then transmitted to the PDP11 network by means of real-time or remote-batch facilities. In addition, a PDP11 version of the ULP compiler and real-time interpreters for LISP[10] and BASIC are available on the PDP11 network.

Several application packages have been constructed for use in the DCN. These include two and three dimensional graphics transformations (which can be used in real-time by the GT40),[20] an interactive instruction-trace monitor and paging simulator, a VOTRAX speech synthesizer driver and various signal processing and recording routines for satellite tracking and telemetry.

SUMMARY AND CONCLUSIONS

The facilities of the DCN are now being used to develop several applications packages, including interactive graphics and image-processing systems, real-time data collection and processing systems and interactive calculator systems. These tools are also being used to study program behavior in the distributed environment. The distributed nature of the network and the organization of the VOS and BOS operating systems have greatly facilitated these tasks and have aided in the refinement of the DCN concepts.

At present many of the original design goals for the DCN have been realized. Still remaining to be developed are additional mechanisms to aid in a strategy for automatic file and process migration, load leveling and performance monitoring. These mechanisms are of course at the heart of the concept of the distributed network and indicate the direction of future research. The most important aspect of the DCN at its present level of development is that it forms the basis of a set of tools to study operating systems architecture, data-base organization and communications strategies as applied to networks supporting distributed resources.

A network-oriented multiprocessor front-end handling many hosts and hundreds of terminals

by W. F. MANN, S. M. ORNSTEIN and M. F. KRALEY
Bolt Beranek and Newman Inc.
Cambridge, Massachusetts

ABSTRACT

The authors discuss the design of a large-scale front-end computer in terms of system requirements, available technology, and the authors' experience with the ARPANET. The design is contrasted with that of the ARPANET TIP. Issues discussed include the choice of hardware configuration (CPU requirements, reliability, modularity, terminal interface units), what facilities to provide in the front-end, the communications protocol between front-end and Host, flow control on various inter-computer data paths, and data buffering strategies. The resulting system is being installed at the Research Computer Center at Bolt Beranek and Newman Inc.

INTRODUCTION

In recent years there has been a tremendous increase in the use of computer terminals and other types of remote access facilities. Part of this increase can be attributed to the proliferation of time-sharing systems, which by their nature require multiple terminal access. But more generally, the growth of data communications has gone hand-in-hand with increasing remote usage and with the interconnection of remote facilities to form various kinds of computer networks. Servicing access ports, since it can consume a significant fraction of the main computer's power, has been off-loaded both to specialized I/O channel processors and to more general "front-end" processors. As time has passed, and because of the somewhat specialized nature of the job, the design of such machines has evolved into an independent art form.

Our group at Bolt Beranek and Newman has been deeply concerned with the evolution of this sort of machine through our work in the development of the ARPANET.[1] Designing the Interface Message Processors (IMPs)[2] and Terminal Interface Message Processors (TIPs),[3] both based on the Honeywell 316 line of computers, and later the Pluribus IMP,[4] has involved us in many issues of communications processing. Recently we have built yet another front-end computer to provide connections among several on-site Host computers, a number of shared peripheral control computers, several network ports, and a large (and increasing) number of terminals of various types. As such requirements are becoming increasingly common, we felt it would be useful to discuss some of the design issues we have confronted and the particular solutions we have chosen.

Because requirements have varied widely from one site to another, many front-end processors have developed as *ad hoc* solutions to particular problems (e.g., Reference 5). It has often proved difficult to estimate how much computer power will be required and to anticipate how fast requirements will increase, and in a number of instances the resulting systems have not proved terribly satisfactory.[6] In some cases the front-end processor was underdesigned for the known requirements and eventually ran out of processing bandwidth, memory address space, I/O ports, or memory channels; in other words, the system reached some sort of growth limit. In other cases one or more of these limits was reached because the requirements expanded much more rapidly than expected.

One solution to these difficulties is a system capable of relatively easy expansion. Over the past several years we have been developing just such a line of machines, known as Pluribus, and have reported on this work at earlier National Computer Conferences.[4,7] The Pluribus is a modular minicomputer-multiprocessor which cannot only meet expanding requirements through a smooth process of growth, but can also provide extreme reliability when used with an adaptive program able to utilize redundant hardware resources. In the following paragraphs we provide a brief update to our earlier reports.

A number of Pluribus machines have been built and are now working in a variety of environments. One is installed in the ARPANET as a high-speed IMP; it is currently connected to four Hosts as well as to five network lines, a configuration larger than could be handled by previous IMPs.[4,7] A second machine, of approximately the same size but with different I/O equipment and with high reliability requirements, has been installed as a Host to provide pre-processing of seismic data collected through the network.* Two Satellite IMPs (with special time-keeping interfaces and a program which implements a broadcast capability) are being used in a development program,[8,9] and several small, single-processor, Private Line Interface (PLI) machines[10] have been built which can provide an ARPANET user with (secure) communication over what appears to him to be a point-to-point private line. Finally, a large 13-processor version of an IMP is undergoing testing and evaluation.[11]

In general, our ideas concerning modularity and reliability appear to be holding up very well, and this has encouraged us to consider further applications. We have proposed using Pluribus machines in a number of other computer networks now being considered, and we are presently engaged in a study to consider the suitability of using a large version of the machine as the basis for a person-to-person message-handling system. In addition we are beginning to explore the extension of the basic architectural notions to the next generation of multiprocessors.

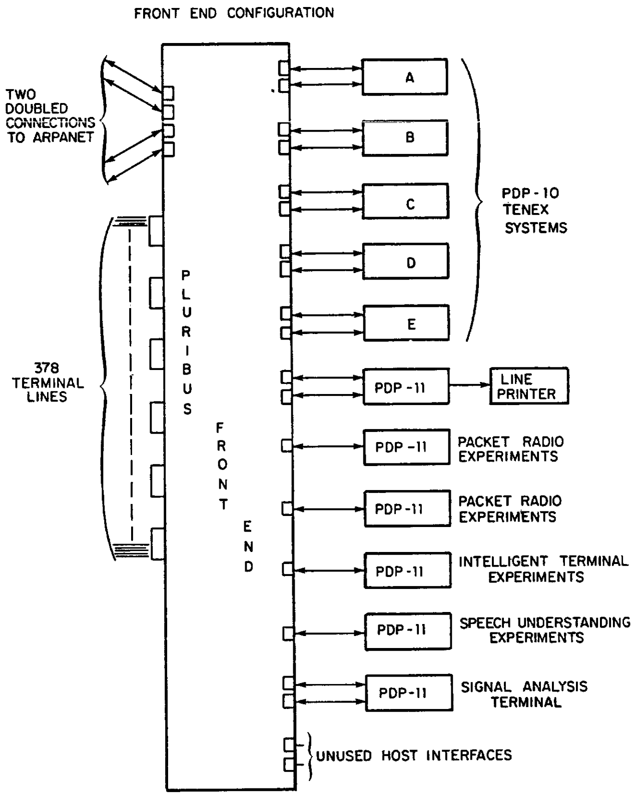

Figure 1

FRONT-END REQUIREMENTS

The growth of the ARPANET has created increased demands on a number of network sites which provide resources useful to many people. Our own Research Computer Center[12] is an example of such a resource and both the central facility and its accessing mechanisms have rapidly been reaching saturation. The central (PDP-10) TENEX facility has grown by replication so that several TENEX systems are now housed in a common center; this only intensifies the accessing and inter-communication problems, however, since it is desirable for all terminals to be able to attach to any of the Host systems, for the Hosts to be able to communicate with one another, and ideally for the Hosts to share access to I/O devices such as high speed printers. Figure 1 shows the configuration we have chosen to provide the required interconnections.

Terminals are currently connected to our TENEX time-sharing systems in one of two basic ways: either via a more-or-less traditional route using a terminal scanner connected to a PDP-10 I/O bus (through a characteristically messy patch panel), or via network access. Terminals that come in through the network either connect to a local Terminal IMP (TIP) or are associated with some remote network site. We wanted to find a solution which provided a homogeneous method of access to multiple Hosts for all local terminals, i.e., all those that previously connected through either the patch panel or a local TIP. Manual patching of terminals was recognized as a severe operational problem. The number of terminals being serviced was already in the hundreds, and may eventually grow to as many as a thousand. Furthermore the number of Host computers at the site was being enlarged to handle increasing demands and it was clear that we should be able to attach at least fifteen or twenty Hosts of various sorts. Finally, if a single element was to be used to connect everything together, it had to be extremely reliable since all communications would pass through it. A list of these communications includes the following:

1. All intra-site traffic between local TENEX systems.
2. All traffic between local TENEX systems and remote sites in the network.
3. All traffic between local TENEX systems and various local specialized Hosts (e.g., a PDP-11 which runs a shared line printer facility for the TENEXs.)
4. All terminal traffic (both local and remote) to all of the TENEX systems.
5. All local terminal traffic to access remote Hosts.

* The seismic Communications and Control Processor (CCP) is a four-processor six-bus Pluribus system that serves as the central data switching and control node in the ARPA-sponsored seismic data collection network. The CCP is installed at the Seismic Data Analysis Center in Alexandria, Virginia.

MACHINE SELECTION

In keeping with our desire to off-load user accessing tasks from the Hosts, we first considered connecting all local terminals through regular 316 TIPs. We needed to handle over 350 terminals to begin with and since a TIP can handle at most 63 lines in terms of hardware, buffering, and processor capacity, this solution would have required six TIPs. That seemed very expensive, not particularly reliable, and would have required many interconnections among the TIPs. Furthermore the 316 TIP suffers from being limited to fixed device-buffers and to a set of rigid protocols, both TIP-to-user and Host-to-Host, and also suffers from lack of adequate flow control between TIP and user.[13] Its total bandwidth is limited by the 316's CPU and memory channel hardware, and by the TIP-IMP interface software. Most of these limitations are directly due to the amount of memory which can be addressed by the 316. This memory limitation cramps the current TIP software: new features are difficult to add, device buffers are inadequate, and major improvements are extremely difficult and time-consuming. Finally, the TIP protocols for dealing with terminals via network connections were designed with network-wide generality in mind and as such are costly in terms of Host bandwidth.[14] We felt that something much simpler would be more suitable for local terminals. For all of these reasons we decided to look for a better solution.

Although there was some temptation to make use of front-end technology already developed for such machines as the PDP-11,[5,6] it was clear that the mass of the problem (number of lines, quantity of traffic, etc.) precluded the use of a single such machine. At best, a collection of such machines would be required, with many interconnections; and since we had already developed such a multiple machine, we next turned our attention to the Pluribus as a possible solution. Perhaps not surprisingly, we found that the Pluribus could meet all of our requirements. It is modular and can be expanded in a variety of domains: more memory can be added as required for additional programs, buffers, etc.; more processors can be added to increase processing bandwidth without reprogramming; a large address space, combined with a modular physical structure, power, and cooling permits enormous expansion of I/O facilities.

This meant that we could start with a reasonable set of hardware and expand as requirements increased. In addition the Pluribus had already been programmed as an IMP and could handle all required Host connections with plenty of room for expansion. Finally, a great deal of attention had been given to matters of reliability.[7] We had accepted the idea that parts of the machine would gradually and inevitably break, and had striven to produce a machine that was totally fail-soft and which could be repaired while it continued to work. This unique capability is extremely desirable in such a central element of the computer center.

The Pluribus thus offered an attractive point of departure for a solution. A number of ingredients were missing, however. In particular, none of the TIP features (hardware or software) existed. For the hardware we decided that we could adapt our own 316 Multi-Line Controller[15] to the Pluribus and use as many as were needed to service the desired number of lines, a choice discussed at some length below. The absence of TIP software was not such a serious drawback as it might appear since we would have wanted to rework the algorithms in the old TIP anyway to improve their efficiency and capacity. We therefore decided to proceed with a design based on the Pluribus.

DESIGN ISSUES

Dedicated function machines

One of the issues discussed at the time of the 316 TIP design was whether to provide terminal handling and servicing functions in the same machine that housed the store/forward IMP functions, or whether to perform these functions in a separate machine that would deal with the IMP as a regular Host does. We opted at that time for the single machine solution, arguing that the efficiencies of intra-machine communication would reduce overhead to the point that a single machine could do the job. Debate has nonetheless continued, a strong counter-argument being that the IMP code is relatively unchanging and that the perpetual modifying and tuning required of the user-interfaced TIP code can endanger the more central IMP functions. Bugs in new TIP releases can more easily affect the IMP program if both programs reside in the same machine.

This argument, though still true to a certain extent, was outweighed by the cost savings and enhanced reliability provided by a single large Pluribus machine. Under the Pluribus philosophy all functions are combined into a single carefully partitioned program and all processors work separately at whatever needs to be done. This approach facilitates load sharing under shifting workloads and *enhances* reliability. In the event of a processor failure, the other processors continue doing all necessary jobs. If a memory unit fails, another memory unit is pressed into service until the first unit can be repaired. In contrast to the usual state of affairs, we expect larger Pluribus machines to be more reliable than smaller ones, since more resources are available to be redistributed in case of trouble. The Pluribus approach to reliability is based on redundancy and self-checking. Bugs of all sorts are anticipated, including lingering software and hardware bugs, and mechanisms are included both for detecting trouble and for correcting the symptoms.

Terminal interface hardware

Another design issue was selection of the hardware to provide the actual terminal connections. When we began, we assumed that the technology had improved since 1970, when we had been forced to design our own Multi-Line Controller. We thought that a convenient off-the-shelf solution would be available and in particular we were hoping to find a multiplexor or concentrator whose high speed output we could bring directly (without demultiplexing) into our machine. We wanted to do demultiplexing within the machine, through a combination of hardware and software, in order to eliminate the need for a large number of individual line interfaces. Using a multiplexor would also permit us, later on, to install multiplexors at remote locations, near remote terminal clusters, thereby saving on line costs.

Unfortunately we had to deal with at least three terminal types: Teletypes, TI Silent 700s, and 1200-baud scope terminals. Furthermore we had to be able to connect any of the three types of terminals to any system port, and this meant dynamic programmable configuring of the multiplexor. We found that the flexibility in commercially available multiplexors was, for the most part, limited to strapping options. While "Autobaud" features are available, they do not reduce the part of the high speed line bandwidth used by the port's subchannel. Thus with Autobaud we would have had to allocate 1200 baud to all ports even though typically a third of the terminals in use at any one time are 110-baud Teletypes. If we took the multiplexor high speed line directly into the Pluribus, it would have meant either more sophisticated hardware demultiplexing, or a large amount of wasted processor and memory bandwidth.

Thus our review of the multiplexor-concentrator field was disappointing. More and more intelligence is being added to these systems but they are still being treated as subsystems separate from the computers which must eventually service the lines. From our point of view, inadequate industry attention is being given to allowing demultiplexing to be carried out directly within the recipient computer system and allowing it to control the multiplexors themselves.

The 316 TIP's Multi-Line Controller is, in fact, a local concentrator. It is completely programmable as to individual port line characteristics and reports character/line number pairs to the TIP. It is designed to interface directly to a computer, fetching characters from and storing characters into memory, and has all the necessary features to permit program control of line characteristics. In short, the MLC seemed eminently suitable for use with our local terminals and datasets, so we adapted its 316 interface to attach it to the Pluribus.

The communications protocol

A third major design question was how to control the terminals. In the 316 TIP, a quite general set of protocols was provided whereby a terminal user could carry on a single control dialogue directly with a Host-like program in the TIP. By talking to this "mini-Host" a user could specify information about what network Host he wished to be connected to, what transmission modes he wanted, etc. Furthermore the "mini-Host", by implementing a modest version of the general network-wide Host-to-Host protocol,[16] in particular the terminal-handling function (known as the TELNET protocol),[16] permitted a user to communicate directly with any Host in the network that also implemented the TELNET protocol. Unfortunately, server Hosts have found the standard Network Control Program (NCP)[16] to be expensive in terms of machine cycles, and the harmful effects of this clearly increase with the number of terminals in operation. We therefore decided on a simplified form of communication between our terminal-handling code and the TENEX Hosts. At the Host-to-Host level we use a special protocol which provides only for buffering and passing characters between the terminals and the Hosts. It does not include the capacity to recognize escape characters in the data stream and thus deflect some of the stream to its own intelligent mini-Host system; instead, the character stream is treated transparently.

The user's interface to local Hosts

The decision to put all of the character interpretation functions in the Host raises the issue of how the terminal-Host connection is established. Since escape characters are not provided, a user cannot specify, in a subset of his character stream, such things as where he wishes to be logically connected. Instead, when he starts to use his terminal, he is automatically connected to some local Host. Some terminals are "soft-wired," via the front-end, to particular Hosts. The other terminals are defined as "wild," which means they are automatically connected to any suitable local Host. Furthermore, if the Host to which a particular terminal is normally soft-wired is inoperative when the user starts to use his terminal, a suitable alternate can automatically be chosen. The point is that initial logical connection is made to a particular real Host, not a mini-Host in the TIP. When a user first starts typing he is talking to that Host just as with a more traditional direct connection. This avoids the sort of double login (first to the TIP and then to the Host of choice) that we have experimented with (somewhat unhappily) in the ARPANET.[17] It furthermore removes the more sophisticated (space consuming but not bandwidth consuming) functions from the front-end to the larger Host which is better suited to handle them.

The user then talks directly to a command interpretation system in the Host. If he needs to switch his logical connection to a different Host, he uses the specific Host commands defined for such purposes. If the switch is to a different *local* Host, then a command is returned from this Host to the front-end instructing it to switch the user's logical connection to the new Host. Thereafter his character stream passes through the front-end directly to the Host of interest without occupying the initial-connection Host at all. All of this is in the spirit of Reference 18.

Interfacing to remote sites

The approach described above is intended to satisfy the needs of a local user on one of our local Hosts. Users of the Pluribus front-end who desire to access remote network Hosts will initially have to pass their character streams through TELNET on a local Host (since the front-end has no such facility). This is a burden on the local Host which the 316 TIP does not impose.

To relieve the local Hosts of this burden, we intend to add the NCP and TELNET functions to the Pluribus front-end. This in no way interferes with the simplified protocols described above for local users of local facilities. The front-end software currently consists of four logical modules: an IMP module, a terminal handler, a front-end protocol handler, and a Host/IMP protocol handler (see Figure 2). Together these provide the usual IMP functions and, in addition, act as a very large terminal scanner for the collective TENEX systems. With the addition of a fifth, NCP-TELNET, module, the front-end could connect its terminals directly to remote Hosts, eliminating the need for a user to log onto TENEX merely for the purpose of running TELNET in order to gain access to a foreign system.

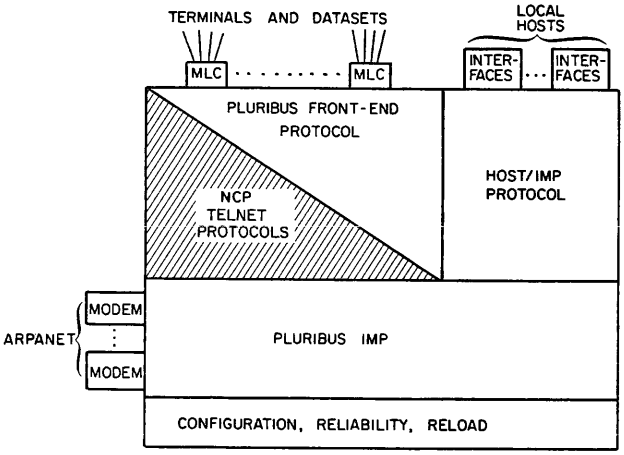

Figure 2

More generally, the advent of an enlargeable front-end machine opens up the possibility of off-loading still more of the communication-handling function from the Host computer. Once we have the NCP-TELNET module we plan to use it to accept incoming TELNET connections and serve as an interface between *remote* users and our TENEX Hosts. The remote user would establish a TELNET connection to the Pluribus front-end, and would from then on appear to be a local terminal to the TENEX Hosts. This kind of facility is the main thrust of several other ARPANET front-end projects.

Flow control—Host to IMP

Flow control is an issue in the design of all communications systems. One way to stop unwanted flow of traffic over an interface is simply to block it until such time as we want it to resume. This expedient has the advantage that it allows a very simple set of rules for the users of the interface. Its major drawback, however, is that a single electrical "pipe" is treated as a single logical path. In fact, some types of connection, such as the one between a Host and an IMP, provide for many concurrent logical paths. While blocking one or more of them from time to time may be necessary, having only one blocking mechanism for the entire pipe is clearly undesirable.

In particular, if we consider the connection as providing only two paths, one for terminal-Host access and one for other Host-network traffic, then we can see that while it may become necessary to block network traffic (due, let us say, to momentary lack of some network resource such as buffer space or traffic control blocks), it is certainly not desirable to let this interfere with terminal traffic which does not require the temporarily depleted resource at all.

We discussed the possibility of using two separate hardware interfaces between the Pluribus front-end and the TENEX Hosts, one for regular network messages (including intra-site Host-to-Host traffic) and the other for front-end traffic. This was motivated by blocking problems observed at the 316 TIP-Host interface. This issue is somewhat similar to the one-or-two-machines question and here again we opted for the shared path solution, modifying the software to provide an extended, non-blocking IMP-Host protocol. The essential idea of this protocol is that the receiver will always remove his messages from the pipe, thereby guaranteeing that the pipe will keep flowing. If for any reason the receiver is unable to process a message, he merely throws it away. This of course requires an acknowledgment/retransmission protocol to properly account for messages. This protocol is being implemented as a new ARPANET standard.[19]

Flow control and buffering—Front-end to TENEX

Flow control is also an issue at the terminal level. As a terminal user types, characters flow to the Host and eventually into some buffer in the Host memory which is associated with that particular user. The program in the Host takes characters out of the buffer, inspects them, and processes them. The buffer is required because the program does not check each line constantly but only in turn as determined by the swapping algorithm. The larger the buffer, the more leisure is permitted to the program, but the greater is the cost in space (and response time).

A flow control mechanism is required to guarantee that the flow of characters will stop should the buffer ever fill up. In TELNET the mechanism works as follows. Initially the receiver allocates some amount of buffer space to the line and informs the sender of this space allotment. Each time the sender sends off characters to the receiver, it reduces the space it believes is still available at the receiver by an equivalent amount. Correspondingly, as the receiver removes characters from the buffer it informs the sender of the change, and this increases the receiver's available space count accordingly. Since only changes are reported, precautions are required to assure that the sender's and the receiver's notions of available space do not become permanently separated through some communications error.

In addition to this buffering in the receiver (the Host for input and the TIP for output) there is additional buffering in the sender. For input, this allows the user to continue typing even when his characters cannot be sent off immediately because of lack of space in the Host. In the 316 TIP fixed buffering is used, and the amount of space available for this sender buffering is small. So, if the remote Host is at all sluggish in taking the characters, the buffers quickly fill and the user receives an alarm indicating that some of his typing has been thrown away. Even worse, by the time he actually stops typing, the blockage will generally have cleared up and the last few typed characters may be accepted, leaving a gap where the momentary blockage occurred. The user must then delete back to the missed section and resume from there, an awkward procedure at best.

The Pluribus's ability to incorporate a large memory and a large number of terminals makes a buffer pool arrangement more sensible. In the Pluribus front-end, if space has been allocated for the user in the receiving Host, the user's characters go directly into a message for the Host. If the space allocated in the Host becomes momentarily used up (because the Host does not empty its buffer rapidly enough) then sender buffers are borrowed as required from the buffer pool in the Pluribus to hold any input typing until the Host empties the "pipe" at its far end. The buffer pool is large and is shared not only among all users for such backup of input buffering but also, as we will see below, for buffering of output.

With this scheme, given a sizable buffer pool, the user should never see any blockage. Occasionally a user will see a delay in remote echoing (from the Host) as the Pluribus stores up input while waiting for the Host. A person's natural tendency not to type on blindly until he sees echoing will restrain him from typing too far ahead and thus depleting the pool. For controlling paper tape readers, etc., we plan to provide flow control of the XON/XOFF type.

Flow control and buffering—TENEX to front-end

If we now consider output from the Host to the terminal we see a somewhat different problem. Output typically consists either of slow character-by-character echoing of user input or of substantial bursts of output characters. The output burst rate is typically many times the input rate. Terminals vary in the speed at which they can accept output and some (such as line printers) may periodically refuse characters for some time (e.g., during a page eject). In the TELNET protocol, output flow control is handled exactly the same way as input flow control, through the use of allocated space in the receiver (TIP). The buffers used for output are typically larger but the mechanism is the same. Buffer sizes vary depending upon the type and speed of terminal and are fixed when the terminals are installed.

In the Pluribus front-end a different approach is used which takes advantage of increased buffering capability to simplify procedures and to virtually eliminate sender buffering requirements in the Host. The Host simply sends output *ad libitum* to the Pluribus. The Pluribus allocates (50-character) buffers from its pool, as required to hold the output that comes in, until it can be sent to the terminal. If the rate of Host output exceeds a terminal's rate for a period, the amount of buffering required will eventually rise above some pre-defined clip level for that terminal. At that point a "stop sending" message is sent to the Host. Output for the terminal will continue to be accepted and may absorb further buffers from the pool. When the Host heeds the request to halt output this "overshoot" process stops. As the terminal catches up, buffers are released back into the pool and when the queue of output buffers drops below a second, lower clip level, a "resume sending" message is sent to the Host. This sort of "servo" operation allows the front-end to maintain terminal output flow over a wide range of Host behaviors. It also means that the Host sees only occasional "wait-a-minute" and "O.K.-to-resume" messages instead of an allocate message for each small set of output characters.*

* One might ask, why not make changes similar to all of these in the 316 TIP? The answer is threefold. First, TELNET is a network-wide standard and changing it would require corre-

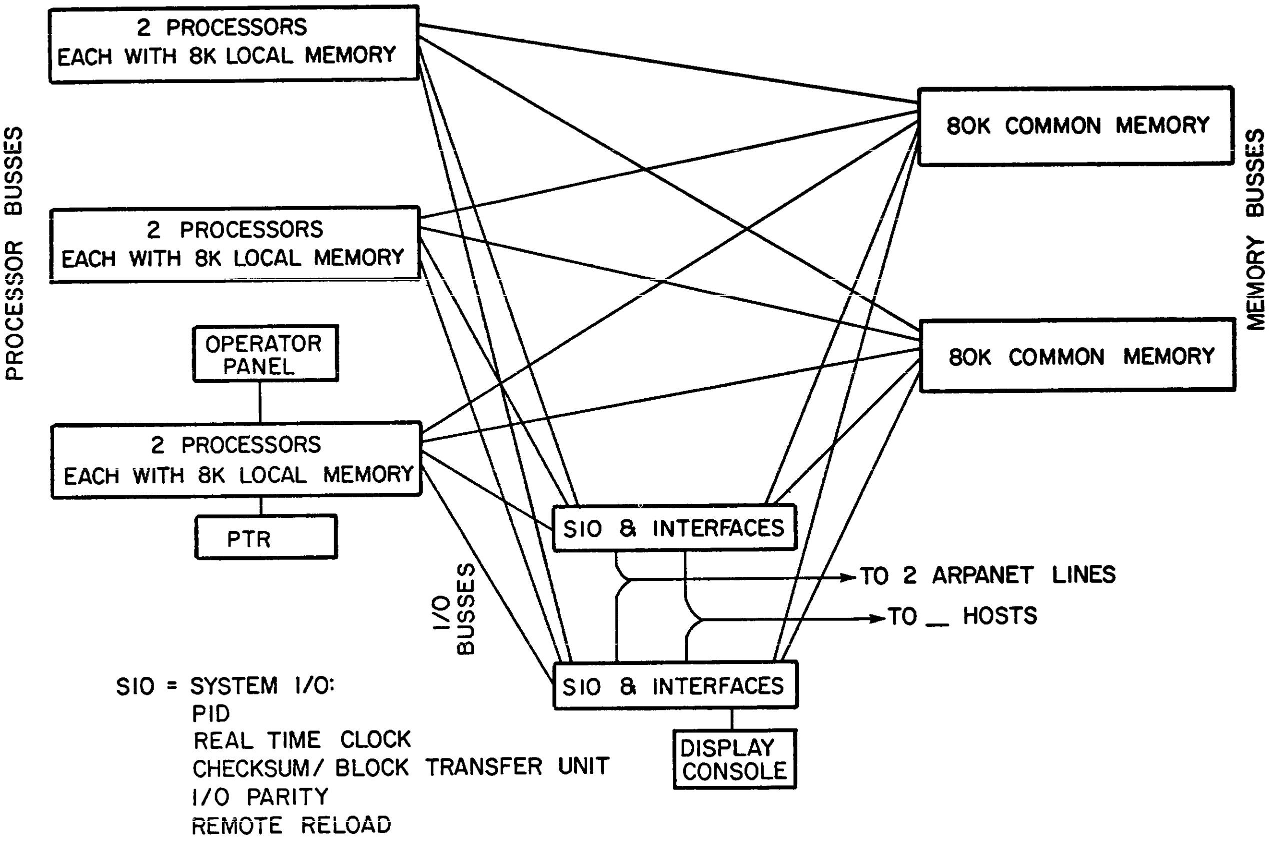

Figure 3

HARDWARE CONFIGURATION

The Pluribus front-end physically occupies eight racks, six for the central machine and two to house individual line interface units (see Figure 3). Six BBN Multi-Line Controllers (MLCs) are included in the initial system, providing interfaces for up to 378 terminal lines. The Host, high-speed network lines, and MLC interfaces are mostly duplicated, on separate I/O busses, for increased reliability. Our bandwidth calculations indicated that four processors were more than sufficient to handle the load of the entire system; reliability considerations led us to include three processor busses, each with two processors. The configuration includes enough memory (80K words on each of two memory busses) to allow for ample buffering, both for store-and-forward and for terminal traffic. There is also room to expand the code to provide many features, such as the improved user interface to TELNET, long desired in the 316 TIP but unimplemented due to lack of space.

The system design takes full advantage of the reliability features of the Pluribus. Sufficient resources of each type are provided so that, in the event of any single failure (hardware or software), the system will continue to run without objectionable degradation, and without human intervention. In case of a hardware fault, the offending component may be diagnosed, debugged, removed, or replaced while the remainder of the system continues to run. The system will automatically incorporate newly fixed components back info the system.

We did not provide any redundancy in the case of the actual terminal concentrator, the MLC. We felt justified in this because of the extremely low failure rates of the MLC in our network experience. Since there are six MLCs in the configuration, a total MLC failure would only knock out a sixth of the TIP's capacity. The I/O bus to MLC interfaces are duplicated, so failures within the Pluribus, or maintenance activities, will not knock out MLCs.

Since this machine is an IMP, it has all of the usual network remote debugging aids such as DDT, reload, verification, and restart facilities. A local display terminal, programmer's console, and paper tape reader augment these capabilities.

sponding changes everywhere else in the Network. Second, our protocol does not address all the issues involved around the Network. Third, the techniques we use would require more main memory than the 316 TIP can address.

THE FUTURE

As discussed above we plan to implement NCP and TELNET functions in the Pluribus front-end in order to off-load these tasks from our TENEX Hosts. Plans for the future also include the development of a flow control procedure for externally clocked terminals, and support for various exotic terminals. While the MLC will handle most if not all asynchronous terminals, we see a pressing need to handle devices such as IBM 2780s, 2260s, and 3270s, which communicate in assorted synchronous line protocols. The Pluribus hardware already includes interface cards which can handle synchronous lines, and an earlier project in which an RJE terminal was tied to an IMP through a Pluribus-based mini-Host has demonstrated the operation of a 2780 using this interface.[20] We see no particular problems in incorporating this approach directly into our front-end eventually, although there are no immediate plans to do so.

ACKNOWLEDGMENTS

A number of people have contributed to the work described herein. Front-end requirements were largely motivated by discussions with Robert Clements (who also made the required modifications to TENEX), Stephen Chipman, and Theodore Strollo. Bernard Cosell and Eric Roberts helped design the front-end protocol, and Martin Thrope built the Pluribus-MLC adaptor. Many other members of the Pluribus group also made significant contributions. We would like to thank Robert Brooks and Sally Schindler for their help with the manuscript.

Design issues for mixed media packet switching networks*

by D. HUYNH, H. KOBAYASHI** and F. F. KUO†
University of Hawaii
Honolulu, Hawaii

ABSTRACT

In this paper we present some of the important design issues for packet switching networks with both satellite and terrestrial components—which we call *mixed media* packet switching networks. Satellite packet switching has considerable promise for low cost, high bandwidth data communications. However there is inherent high delay in satellite links which does not appear in ground links. Therefore a mix of the two communications media offers the advantages of low-cost/high bandwidth together with low-delay communications where required. In this paper we examine a number of tradeoffs which offer guidelines for the design and optimum utilization of mixed media networks.

INTRODUCTION

In 1968 the Advanced Research Projects Agency (*ARPA*) of the U. S. Department of Defense began implementation of a computer-communication network which permits the interconnection of heterogeneous computers at geographically distributed centers throughout the United States. This network has come to be known as the *ARPANET*,[1,2] and has grown from the initial four node configuration in 1969 to almost forty nodes (including satellite nodes in Hawaii, Norway, and London) in late 1974. The major goal of ARPANET is to achieve resource sharing among the network users. The resources to be shared include not only programs, but also unique facilities such as the powerful ILLIAC IV computer and large global weather data bases that are economically feasible when widely shared.

The ARPANET employs a distributed store-and-forward packet-switching approach that is much better suited for computer-communication networks than the more conventional circuit-switching approach. Reasons favoring packet switching include lower cost, higher capacity, greater reliability and minimal delay. The CCITT (Comité Consultatif International Télégraphique et Téléphonique), an international standards organization, defines a packet as "a group of binary digits including data and call control signals which is switched as a composite whole. The data, call control signals and possibly error control information are arranged in a specific format."

Multi-access satellite channels

Communication satellites operating in packet mode are becoming increasingly important for consideration in the design of large computer communication networks. In particular, most possess the following characteristics which are of special importance: the satellite's antenna coverage allows any of a large number of ground stations to access it at any time (multi-access), and its transmissions can be received by all of these stations at all times (broadcast).

Up to the present, packet switched computer networks have mainly utilized terrestrial communications links. Recently, Telenet Communications Corporation, one of the new value-added carriers[3] announced plans to offer public packet switched data service in which terrestrial and satellite links will be available. *ARPA* has also planned to augment its terrestrial links with satellite communications and has commissioned several satellite IMPs or SIMPs[4] built by Bolt Beranek and Newman Inc. (BBN). In mid 1975, BBN and the British Post Office jointly conducted a multi-access satellite experiment using the Atlantic INTELSAT IV satellite with SIMPs located at the ETAM ground station in the U.S. and the Goonhilly Downs ground station in England.

The basis of this experiment is the work on the

ALOHANET of THE ALOHA SYSTEM project at the University of Hawaii.[5,6,7] The multiplexing technique that is used by the ALOHANET is a multi-access packet switching method that has come to be known as the *ALOHA* technique.

Based upon the ALOHA multiplexing method or variations thereof, a number of techniques have been proposed for the utilization of a satellite channel in a packet-switched data network in a way which allows all stations to dynamically share the channel capacity.[8,9,10,11,12,13,14] All are based on the division of the channel into time slots approximately equal to a packet transmission time. The approach described by Roberts[8] and Kleinrock and Lam in References 12 and 13 makes use of a technique called "slotted ALOHA random access" or "slotted ALOHA." The channel capacity of a slotted ALOHA channel was estimated to be $1/e \simeq 36\%$.[8]

Goals of this paper

In this paper we will examine a number of key issues in the design of a packet-switched communication network composed of a terrestrial store-and-forward packet switching component combined with a multi-access/broadcast satellite as depicted in Figure 1.

The factors involved in the design optimization of a packet switched network are:[15]

- Node location and traffic matrix
- Topology of links
- Capacity of links
- Routing
- Flow control, other network design, etc.

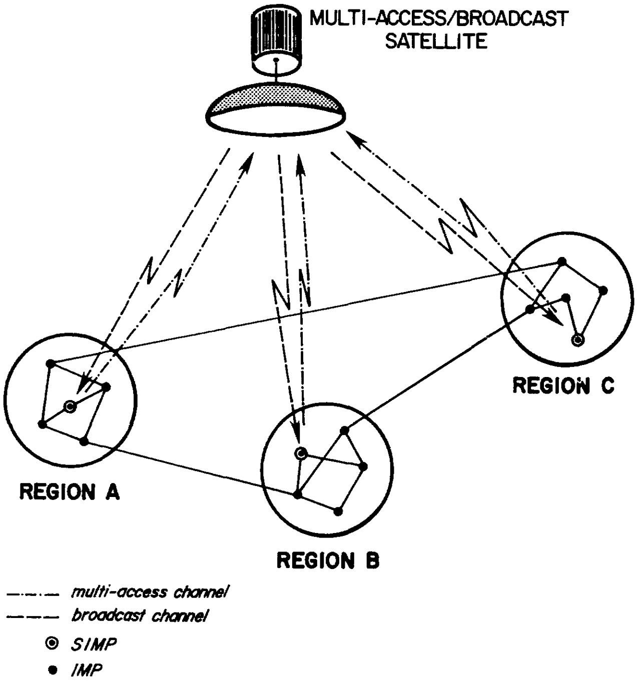

Figure 1—The proposed network model

To attempt to optimize any one factor, such as the capacity of links, it is necessary to assume that the factors higher in the list must be given. However, to decide optimum choices for the factors high on the list may require detailed calculations of all the lower ones. Fortunately, such factors as node location are usually not design variables, being fixed by practical considerations. Frank, Frisch and Chou[16] have developed sub-optimum procedures for the topological layout of a packet switched network. Thus we will concentrate on the following problems in our paper.

1. Routing of packets via ground or satellite
2. Capacity assignments for ground and satellite channels
3. Retransmission strategies

In this paper we will concentrate on the discussion of design issues such as throughput, delay, cost, etc., rather than dwell on the theoretical development of the design equations which is given in a companion paper to be published elsewhere.[17]

THE NETWORK MODEL

The network model under consideration consists of a terrestrial store-and-forward packet switching network referred to here as the *ground subnet*, and a multi-access/broadcast satellite which together with the SIMP ground stations is the *satellite subnet.*

For the ground subnet we will use the model given in the paper by Crowther, et al,[18] and will reproduce the succinct definitions of network terminology given in that paper:

Nodes—The nodes of the network are real-time computers, with limited storage and processing resources, which perform the basic packet-switching functions.

Hosts—The Hosts of the network are the computers, connected to nodes, which are the providers and users of the network services.

Lines—The lines of the network are some type of communications circuit of relatively high bandwidth and reasonably low error rate.

Connectivity—We assume a general, distributed topology in which each node can have multiple paths to other nodes, but not necessarily to all other nodes. Simple networks such as stars or rings are degenerate cases of the general topology we consider.

Message—The unit of data exchanged between source Host and destination Host.

Packet—The unit of data exchanged between adjacent nodes.

Acknowledgment—A piece of control information returned to a source to indicate successful receipt of a packet or message. A packet acknowledgment may be returned from an adjacent node to indicate successful receipt of a packet; a message acknowledgment may be returned from the destination to the source to indicate successful receipt of a message.

Store and Forward Subnetwork—The node stores a copy of a packet when it receives one, forwards it to an adjacent node, and discards its copy only on receipt of an acknowledgment from the adjacent node, a total storage interval of much less than a second.

Packet Switching—The nodes forward packets from many sources to many destinations along the same line, multiplexing the use of the line at a high rate.

Routing Algorithm—The procedure which the nodes use to determine which of the several possible paths through the network will be taken by a packet.

For the satellite subnet we use the finite population model of the slotted ALOHA channel developed by Kleinrock and Lam,[13] which we call *Scheme 1* and we also consider a multi-access channel model in which there is no retransmission via satellite. This model which we denote as *MASTER* or *Scheme 2* is described in a later section of this paper.

The combination of a system that operates in contention mode (the satellite) and one that operates in queueing mode (the terrestrial store-and-forward net) into an overall system model presents many interesting problems. These problems are mainly due to the fact that with contention systems the throughput increases to a maximum and then decreases as system load increases while for queueing systems the throughput increases to one as system load increases.[13] The model of a multi-access slotted-ALOHA channel is typical of a contention model, and to use the channel optimally the system load on the channel must be carefully controlled. We have tried to develop an analytical model of the overall system so that we may predict and optimize its performance. Our network model thus consists of:

A. A set of store-and-forward IMP-like devices interconnected by capacity limited ground channels (a distributed subnet). For the sake of reliability this subnet is at least 2-connected.

B. A set of SIMP-like devices directly connected to satellite ground stations. These SIMPs are usually geographically scattered and relatively far apart from each other.

C. A multi-access/broadcast satellite transponder linking all SIMPs in a star configuration.

A SIMP is usually co-located with an IMP at a node and both devices have buffering and scheduling capabilities. We assume that the ground net is regionalized. That is, the ground net is partitioned into regions. Every region has a SIMP and the IMPs in that particular region can only go through one and only one SIMP. The regionalization is determined by the closeness of an IMP to a SIMP in terms of the number of hops and the distance between them. Such a structure is shown in Figure 1.

ROUTING

With a mixed media network the issue of routing is a major concern. With two possible courses to choose from—one via satellite and one via ground, the issue is to choose the set of routes so as to minimize the overall average network delay. The tradeoffs to consider are these: the satellite channel has an inherent minimum delay of .26 seconds. However, satellite capacity is less costly than ground channel capacity for medium to long distances, and therefore more satellite capacity is available at less cost than comparable facilities on the ground. The ground channels are inherently faster than the satellite channel, but because of capacity limitations, are subject to queueing delays, which combined with the store-and-forward nodal processing delays may, in heavy traffic situations, result in larger overall delays than the satellite delays. To summarize, satellite channels have greater delays but also more cost effective channel bandwidth than ground channels.

The routing procedure used in the ARPANET is a distributed adaptive algorithm in which each node has a routing table which is periodically updated with minimum distance estimates from its immediate neighbors.[19] Unfortunately the distributed adaptive algorithm is extremely difficult to describe analytically and could not be applied to our analytical model. Instead we have chosen a deterministic split traffic (bifurcated) routing strategy [19] which because it allows traffic to flow on more than one path between a given source-destination node pair gives a better balance than a fixed routing procedure. It should be noted that our analytical model does not require any specific routing algorithm, but can accommodate any routing algorithm that can be modelled mathematically.

Optimal routing of packets

Using the network model of Figure 1 the main problem in packet routing is to route packets from one region to another via either ground or satellite links in such a way as to minimize the overall average delay of the network. Given the topology of the network and the capacities of the ground and satellite links, we assume a demand matrix $[\gamma_{ij}]$ where γ_{ij} is the average Poisson input in packets/sec from node i to node j. Let us define the *routing index* g_{ij} as the fraction of γ_{ij} sent through the ground net and let $\bar{g}_{ij}=1-g_{ij}$ be the fraction of γ_{ij} sent through the satellite net by first routing to the SIMP in the region where IMP i resides, then transmitting through the satellite channel to the SIMP in the region where IMP j resides. As a result, $g_{ij}=1$ if both IMPs i and j are in the same region.

Let us define T as being the overall average delay of the network, averaged over all source-destination node pairs and all routes dictated by the routing algorithm. The optimal routing strategy for mixed media networks can be stated as:

$$\min_{g_{ij}} T; \text{ subject to } \{0 \leq g_{ij} \leq 1 \text{ for all } i,j\}$$

For our analysis, we define the following notation:

$\gamma=\sum_{i,j}\gamma_{ij}$ total traffic in the net

τ_{ij}= average delay for a packet travelling from IMP i to IMP j

$\sigma(i)$ = index of the region (hence that of the corresponding SIMP) to which IMP i belongs

τ_s= average delay for a packet transmitted from one SIMP to another via the satellite channel

T_{ij}= overall average delay for a packet travelling from IMP i to IMP j (averaged over ground and satellite links)

We can readily derive the following relationships:

For the ALOHA scheme

$$T_{ij}=g_{ij}\tau_{ij}+\bar{g}_{ij}(\tau_{i\sigma(i)}+\tau_s+\tau_{\sigma(j)j}) \quad (1)$$

and

$$T=\frac{1}{\gamma}\sum_{i,j}\gamma_{ij}T_{ij}$$

$$=\frac{1}{\gamma}\sum_{i,j}\gamma_{ij}[g_{ij}\tau_{ij}+\bar{g}_{ij}(\tau_{i\sigma(i)}+\tau_{\sigma(j)j})]+\frac{1}{\gamma}\sum_{i,j}\bar{g}_{ij}\gamma_{ij}\tau_s \quad (2)$$

For the MASTER scheme, in order to obtain an expression analogous to Equations (1) and (2), we further introduce the notation:

P_σ= probability that a packet transmitted from SIMP σ into the satellite channel is successful

Then we obtain

$$T_{ij}=g_{ij}\tau_{ij}+\bar{g}_{ij}[\tau_{i\sigma(i)}+\tau_s+P_{\sigma(i)}\tau_{\sigma(j)j}+(1-P_{\sigma(i)})\tau_{\sigma(i)j}] \quad (3)$$

and

$$T=\frac{1}{\gamma}\sum_{i,j}\gamma_{ij}T_{ij}$$

$$=\frac{1}{\gamma}\sum_{i,j}\gamma_{ij}\{g_{ij}\tau_{ij}+\bar{g}_{ij}[\tau_{i\sigma(j)}+P_{\sigma(i)}\tau_{\sigma(j)j}$$

$$+(1-P_{\sigma(i)})\tau_{\sigma(i)j}]\}+\frac{1}{\gamma}\sum_{i,j}\bar{g}_{ij}\gamma_{ij}\tau_s$$

In Equations (2) and (4) the terms with g_{ij} represent the portion of traffic from IMP i to IMP j routed entirely through the ground net and those terms with $\bar{g}_{ij}$ represent the portion routed from node i to the regional SIMP $\sigma(i)$, from $\sigma(i)$ to $\sigma(j)$, the regional SIMP in which IMP j resides and then from $\sigma(j)$ to IMP j. Thus even in the satellite routing, there is some associated ground traffic to get to and from the regional SIMPs. Our mathematical model is flexible enough to permit SIMPs at every node, and if this were the case, obviously the $\tau_{i\sigma(i)}$ and $\tau_{\sigma(j)j}$ terms would be zero. The term τ_s is derived from the finite population model of a slotted ALOHA channel as originally given in Lam [13] and in a slightly different form by the authors.[17]

Let λ_l be the traffic on link l. We can derive λ_l as a function of g_{ij}, the traffic demand γ_{ij} and the routing algorithm. Since the equation is fairly complex we will not give it here but refer the reader to a companion paper for its derivation.[17] Given λ_l and neglecting the delay due to transmission errors and nodal processing and ground propagation time, the average delay along any ground link can be described by the M/M/1 queueing model by virtue of the well-known independence assumption and Jackson's decomposition theorem.[22]

$$T_l=\frac{1}{\mu_l C_l-\lambda_l} \quad (5)$$

where C_l is the capacity of channel l and $\frac{1}{\mu_l}$ the average packet length on that channel. The overall average delay can be expressed in terms of the link traffic λ_s, $\{\lambda_l\}$ and link delays τ_s, $\{T_l\}$ as

$$T=\frac{1}{\gamma}\left[\sum_{l=1}^{L}\lambda_l T_l+\lambda_s\tau_s\right] \quad (6)$$

where L = total number of links in the net, and λ_s the total traffic rate on the satellite channel, i.e.,

$$\lambda_s=\sum_i\sum_j\bar{g}_{ij}\gamma_{ij}$$

We can show that T in Equation (6) is convex with respect to g_{ij} so that we can obtain a minimum overall delay by varying g_{ij} according to a selected optimization algorithm. The optimum choice of g_{ij} depends also upon the topology of the network, the location of the SIMPs, the capacities of the ground and satellite links, the specific terrestrial routing algorithm, as well as the traffic demand matrix $[\gamma_{ij}]$, all of which must be specified in advance of the optimization computation.

Since the optimum selection of g_{ij} is not critically dependent upon a particular optimization procedure, we used the algorithm known as the BOX COMPLEX procedure [20] since this is one of the optimization algorithms which does not require derivatives of the objective function.

As an example, consider the network model in Figure 2 in which the two regions consist of nodes {1,2,3,4} and nodes {5,6,7,8}, and the regional SIMPs are located at nodes 1 and 7. The traffic demand matrix assumed to be uniform with $\gamma_{ij}=20$ packets/sec. $i \neq j$ and $\gamma_{ij}=0$

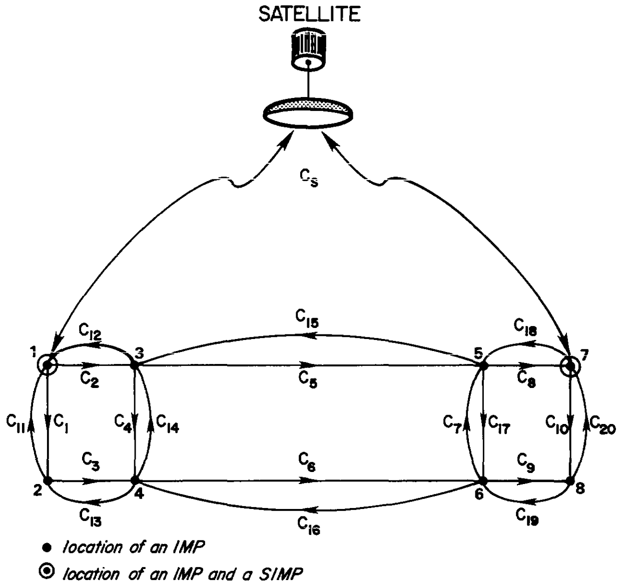

Figure 2—The network model considered in numerical examples

for $i=j$. The average packet lengths is assumed to be 512 bits on all ground channels. The packet length on the satellite channel is fixed and equals 1 K bit. The ground link capacities are all assumed to be $C_g=50$ K bits/sec and the satellite capacity to be $C_s=1500$ K bits/sec. With this information as input to the routing optimization program, the inter-regional g_{ij} are computed and are given in Table I. Note that we assume $g_{ij}=1$, for i,j in the same region.

LINK CAPACITY ASSIGNMENTS

In the packet routing studies above we assume that the ground link capacities are given. We also assume as given the capacity of the satellite channel. The capacity assignment problem is: for each channel l the capacity C_l must be found which minimizes the total average message delay T. The problem is most difficult if the capacities must be chosen from a discrete set of options. Following Kleinrock[21] we assume that the capacities of ground links and satellite channel are continuous variables and use analytic procedures involving Lagrange multipliers to obtain C_l. A general discussion of our approach follows.

TABLE I—The Routing Indices for Traffic from Region 1 to Region 2

	3	1	1	0	.315
	4	1	1	0	1

Note: The Routing Indices for traffic from Region 2 to Region 1 are symmetrical to those given in Table 1. For instance, $g_{82}=g_{28}=.706$; $g_{72}=g_{18}=0$; etc.

We assume as given the topology of the network including SIMP locations. We also assume a given demand matrix $[\gamma_{ij}]$. Let λ_l be the traffic on link l. The (continuous) capacity assignment problem can be formulated as

$$\min_{C_l, C_s} \quad T=\frac{1}{\gamma}\left[\sum_{\ell=1}^{L}\lambda_l T_l+\lambda_s T_s\right]$$

subject to the constraint that the overall budget B is specified where B is

$$B=\sum_{\ell=1}^{L} b_l C_l+b_s C_s$$

and b_l and b_s are cost functions of the capacities C_l and C_s respectively.

In solving the capacity assignment problem, we need to know the total allowable budget and unit cost of ground and satellite channel capacities. We assume the unit cost of ground channel capacities are the same, so we can normalize all costs by a unit cost of ground channel capacity. In obtaining the following results, we further assume a ratio of *1* to *10* for satellite and ground channel capacity costs, i.e.,

$$\frac{1 \text{ unit cost of}}{\text{ground channel capacity}} = \frac{10 \text{ unit cost of}}{\text{satellite channel capacity}}$$

Our program is sufficiently general so that we can assume any ratio between satellite capacity and ground capacity costs. Perhaps a more realistic ratio to use today is a 1 to 3 proportion.

Without going into the details of the capacity assignment optimization scheme, which is quite similar to the work of Kleinrock[21] and which is described elsewhere,[17] let us discuss a computer program we have written which combines the routing and capacity assignment algorithms in an overall procedure. The program first obtains a solution for the routing assignments including overall average delay T_R, the routing indices g_{ij} and the channel traffic rates λ_s and λ_l. Then with the λ_s and λ_l from the routing calculations and with a given total budget B and the assumed unit costs of satellite and ground channel capacities b_s and b_l as inputs to the capacity assignment routine, we obtain the capacity assignments C_s and $\{C_l\}$ and a new figure for overall average delay T_C. If $T_C \leq T_R$ then the entire procedure is repeated with the previously computed values of C_s, $\{C_l\}$ and g_{ij} used as input to the routing subroutine.

The process is iterated until $T_C = T_R$ to within a specified accuracy or until the maximum time limit allowed for the optimization procedure is reached.

Using the output data from the routing subroutine run given in the previous section, the iterative cycle is carried out for the network in Figure 2. The input data consists of the original demand matrix, initial values of $C_l = 50$ K bits/sec and $C_s = 1500$ K bits/sec and an assumed total budget B in cost units and $b_l = 1$ and $b_s = 0.1$. The final results for $\{C_l, C_s\}$ and $\{\lambda_l, \lambda_s\}$ after 8 iterations for B = 1,700,000 cost units are given in Table II, and those for B = 950,000 cost units after 4 iterations are given in Table III. For the total budget B = 1,500,000 the minimum overall average delay was T = .037 sec. whereas for B = 950,000, T = 1.435 secs. We have performed a number of runs with different values of budget B and the results show that as total allowable budget increases the overall average delay decreases as seen in Figure 3. Also the optimum satellite capacity decreases and the ground channel capacities increase as the total allowable budget increases. This is because we have assumed a 10 to 1 ratio between the cost of unit ground capacity to unit satellite capacity. As the total budget grows we have more money to spend on the relatively more expensive ground channel capacities. As ground channel capacities become large, packets tend to go via ground subnet since the minimum satellite propagation delay is high (0.26 secs). We can show in general that the T vs B curve is a hyperbola and have derived formulas for the asymptote S which are given in a companion paper.[17]

THE MASTER SCHEME

In this section we will describe a scheme in which retransmission traffic from a multi-access channel is sent via the ground net. This scheme will be denoted here as the MASTER (**M**ulti-**A**ccess **S**atellite With **TE**rrestrial **R**etransmission) plan. Under the MASTER plan, the up-link of the satellite channel is a slotted multi-access channel and the down-link is a broadcast channel. Unlike slotted ALOHA, whenever a packet collision occurs in the multi-access channel, the MASTER scheme does not use the satellite channel for retransmission of the rejected packet. Instead the rejected packet is sent via the ground net from the source SIMP directly to the destination IMP without having to first go to its regional SIMP. By sending retransmitted packets via the ground net, overall average delay can be reduced significantly especially if the traffic on the satellite channel is heavy. Moreover, the MASTER plan eliminates all possibilities of instabilities that might occur in a slotted ALOHA channel under very heavy traffic situations.[13] Thus we see that the MASTER channel has no retransmitted packets. Since on the down-link broadcast channel each SIMP can hear its own transmissions, if a packet collision occurs, the source SIMP could reroute the rejected packet through the ground net without waiting for an acknowledgment from the destination SIMP. Moreover, after sending a packet, a SIMP can immediately send again in the next slot without waiting for the results of previous transmissions.

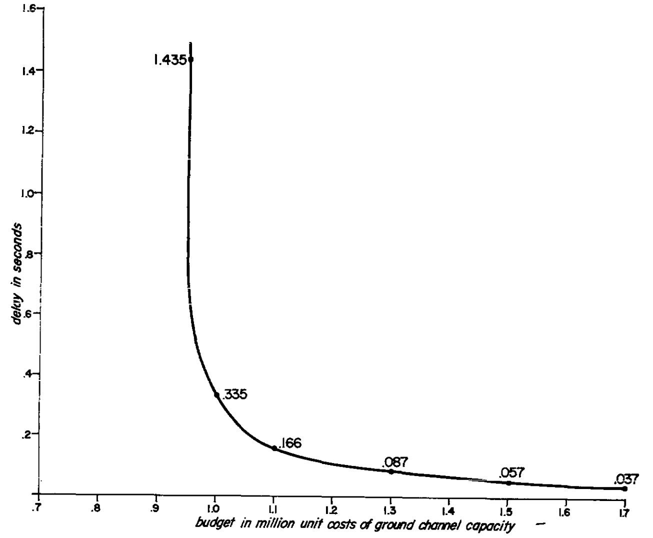

Figure 3—Delay-cost trade-offs

Now let us turn our attention to a more detailed discussion of the MASTER plan. Consider the satellite channel model depicted in Figure 4. Let λ_σ [pkts/sec] be the average input rate from SIMP σ to the satellite channel. The probability q_σ that a packet will be transmitted from SIMP σ in a given time slot, or equivalently the traffic rate in a given time slot is:

$$q_\sigma = \frac{\lambda_\sigma}{\mu_s C_s}$$

where C_s [bits/sec] is satellite channel capacity and $1/\mu_s$ [bits/sec] is the packet length.

We define random sequences $X_\sigma(k)$ and $Y_\sigma(k)$ as

$$X_\sigma(k) = \begin{cases} 1 \text{ if SIMP } \sigma \text{ transmits in time slot k} \\ 0 \text{ otherwise} \end{cases}$$

$$Y_\sigma(k) = \begin{cases} 1 \text{ if SIMP } \sigma \text{ successfully transmits in time slot k} \\ 0 \text{ if otherwise (i.e., no transmission or collision)} \end{cases}$$

Then it follows that

$$\Pr[X_\sigma = 1] = q_\sigma$$

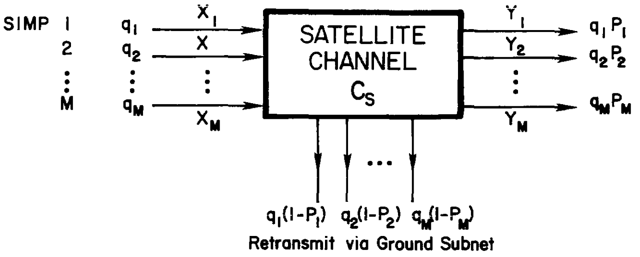

Figure 4—The satellite subnet model under Master

By assuming that the streams $X_\sigma(k)$ from different SIMPs are independent we readily obtain

$$\Pr[Y_\sigma = 1] = q_\sigma P_\sigma$$

where $P_\sigma = \prod_{\tau \neq \sigma} \bar{q}_\tau$, with $q_\tau = 1 - \bar{q}_\tau$, is the probability of success of a packet from SIMP σ. The normalized throughput S or successful transmission per slot time, of the satellite channel is thus

$$S = \sum_\sigma \Pr[Y_\sigma = 1]$$
$$= \sum_\sigma q_\sigma P_\sigma$$

Note that packets from SIMPs traverse the satellite channel once and only once under this operational scheme. If we assume the satellite channel transmission errors and nodal processing delay to be small, and buffer storage to be sufficiently large, then the average delay incurred by a packet when going through the channel can be found by using response time formulation of an M/D/1 queueing system plus the satellite propagation delay $\tau_{\min}$ of approximately .26 secs. The result of a deterministic service time system is used, since in a slotted channel all packets are of fixed length, any messages with length less than a specified full packet size are filled with blank characters to form a full size packet. Thus the average delay experienced by a packet travelling from SIMP σ through the satellite channel is

$$T_\sigma = \tau_{\min} + \frac{1}{\mu_s C_s}\left\{1 + \frac{\lambda_\sigma}{2(\mu_s C_s - \lambda_\sigma)}\right\}$$

The overall average packet delay of the satellite channel τ_s [secs/pkt] can be obtained by averaging over all T_σ's

$$\tau_s = \frac{1}{\lambda_s}\sum_\sigma \lambda_\sigma T_\sigma$$
$$= \tau_{\min} + \frac{1}{\mu_s C_s} + \frac{1}{2\lambda_s}\sum_\sigma \frac{q_\sigma^2}{1 - q_\sigma} \qquad (7)$$

where

$$\lambda_s = \sum_\sigma \lambda_\sigma$$

and

$$q_\sigma = \frac{\lambda_\sigma}{\mu_s C_s}$$

It can be shown that for a given total traffic rate $\lambda_s = \sum_\sigma \lambda_\sigma$ [pkts/sec] τ_s takes on its minimum when $\lambda_\sigma = \lambda_s/M$, for all $\sigma = 1,2,\ldots,M$. We can also show that the condition $\sum_\sigma q_\sigma = 1$ is necessary to achieve the maximum throughput S. From these conditions we immediately see that the best throughput delay trade-off is attained for $q_\sigma = 1/M$, $\sigma = 1,2,\ldots,M$.

This condition, although the optimum operating point, is difficult to attain, since the traffic rates from SIMPs are most likely not equal. It is difficult to study the trade-off for cases with a large number of heterogeneous SIMPs. We can obtain some understanding of how S varies by investigating the case of M=2. For this case, the throughput rate of the satellite channel is

$$S=q_1(1-q_2)+q_2(1-q_1)=q_1+q_2-2q_1q_2 \qquad (8)$$

A plot of the throughput S versus the traffic rates q_1 and q_2 is given in Figure 5. In the throughput as shown in Figure 5, the surface takes the form of a saddle with the valley located on the plane $q_1=q_2$ which includes the S-axis and is at a 45° angle from the planes $q_1=0$ and $q_2=0$ (the slashed, diagonal plane shown in Figure 5 and ridge located on the plane $q_1+q_2=1$ which is perpendicular to the plane $(q_1=q_2)$ and passes by upper-corner end points (1,0,1) and (0,1,1) of the throughput surface). Note that the condition

$$q_s=q_1+q_2 \qquad (9)$$

corresponds to a straight line of slope −1 on q_1-q_2 plane. As stated above if

$$q_1+q_2=q_s=1 \qquad (10)$$

we obtain the maximum boundary of the throughput S. The ridge of the saddle surface of the throughput S is thus the maximum boundary. For this simple case, we can further prove that, given the condition in Equation (9), S attains its minimum for

$$q_1=q_2 \qquad (11)$$

which is the line with slope 1 on q_1-q_2 plane (the line at 45° degree angle with q_1-axis and q_2-axis). The valley of the saddle surface of the throughput is thus the minimum boundary. Also, the overall average packet delay, τ_s, of the satellite channel for m=2 case is

$$\tau_s=\tau_{min}+\frac{1}{2\lambda_s}\left(\frac{q_1^2}{1-q_1}+\frac{q_2^2}{1-q_2}\right)+\frac{1}{\mu_s C_s} \qquad (12)$$

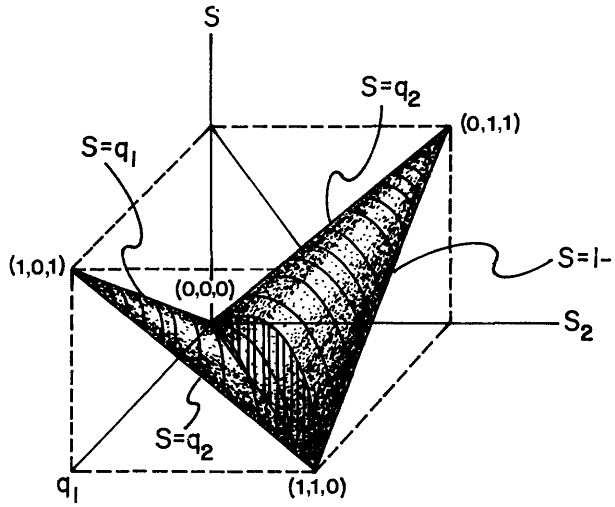

Figure 5—Throughput surface given by equation (8)

Again, the delay τ_s is symmetrical with respect to q_1 and q_2. In Figure 6 we show the level curves of the delay surface in the (q_1,q_2) plane. Given the condition in Equation (9) the delay τ_s reaches its minimum for $q_1=q_2$. The minima are shown by a dashed line intersecting the level curves.

The above results are preliminary. We have not computed numerical examples for the MASTER scheme. These will be given in a companion paper by the authors.[17]

CONCLUSIONS

In this paper we have presented some of the important design issues for mixed media packet switching networks. Satellite packet switching has considerable promise for low cost, high bandwidth data communications. However there is inherent high delay in satellite links which do not appear in ground links. Therefore a mix of the two communications media seems to offer the best of both worlds. In this paper we have examined a number of trade offs which offer guidelines for the design and optimum utilization of mixed media networks.

We have introduced a new communications scheme called MASTER (Multi-Access Satellite with TErrestrial Retransmission). We believe that the MASTER scheme offers significant advantages over slotted ALOHA especially when the multi-access satellite channel is heavily loaded.

We have not explored the possibility of sending network control information along the ground and using

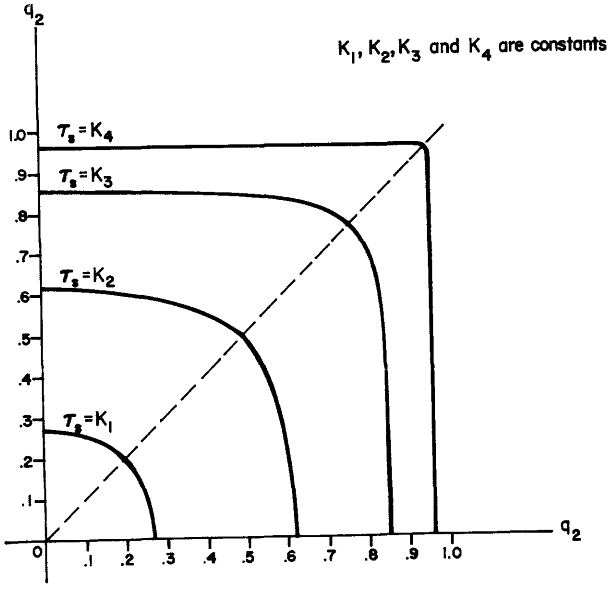

Figure 6—Level curves of delay surface given by equation (12)

the satellite for bulk data transmission. However the extension is logical and not difficult to analyze. Another logical extension of the MASTER scheme is to use the satellite channel on a reservation basis, such as suggested by Crowther, et al,[10] Roberts[11] and Binder,[14] but use the ground channel to set up reservations. We plan to explore this idea in a subsequent paper.

A perspective on network operating systems*

by STEPHEN R. KIMBLETON and RICHARD L. MANDELL
USC/Information Sciences Institute
Marina del Rey, California

ABSTRACT

The viability of packet switched computer communication has been demonstrated. The potential for more effective computing through resource sharing and load leveling is evident. Realization of this potential requires expanded user support to reduce or eliminate much of the need for users to learn the command languages of the hosts being accessed and of the communications subnetwork. Such a capability can be provided by a mediating agent providing ease of access to resources and control of resource access—a role traditionally ascribed to an operating system in the context of an individual computer system. This mediating agent, hereafter termed a Network Operating System (NOS), requires careful exploration to determine its appropriate interaction with the operating systems of the hosts within the network. This paper discusses the functions required of a Network Operating System and identifies major differences between the role of the Network Operating System and an individual host operating system. As such, it is intended to provide a basic perspective on the field of Network Operating Systems.

INTRODUCTION

Early computing experience quickly demonstrated the undesirability of requiring the user to directly interact with and control raw physical resources. As a result, operating systems were introduced which provided two primary functions: (i) provision of ease of access to computing resources, and (ii) control of the allocation of resources across multiple competing requests. Thus, the operating system may be regarded as an *agent* interposed between the user and the system resources.

Heterogeneous networks, such as ARPANET,[1-4] potentially permit both sharing of dissimilar resources and balancing of workload across a collection of similar resources such as the Operating System Class (OSC) consisting of the collection of TENEX operating systems within ARPANET. Presently, the viability of packet switched computer communications technology as used in ARPANET may be regarded as proved. However, the user wishing to make full use of the resource sharing potential of a heterogeneous network is currently faced with a requirement for learning the command languages of each separate system being accessed and, additionally, the command language required to support network communication. For the casual (non systems programmer) network user, this constitutes an immense startup cost which must be incurred prior to any reasonable use of network resources. The natural result is a minimization of the tendency to utilize potentially more effective remote resources.

Upon reflection, the obvious conclusion is that another entity, hereafter termed a mediator or *Network Operating System (NOS)*, is required to interface with the collection of host operating systems. In recognition of the urgent necessity for such a capability, an increasing number of papers are undergoing gestation and are scheduled to appear. The objective of this paper is to provide a global overview of the subject; to indicate some of the major components required for an NOS; to discuss the results of an NOS study[5] and to provide context for the remainder of the papers in this session.

It should be noted that the discussion of NOS in this paper is predicated upon an assumption that the existing host operating systems must remain essentially intact. In the alternative case in which one is free to design the operating systems for both the computer and the communications capabilities, substantial simplifications can result as the discussion in References 6 and 7 demonstrate.

To provide a perspective for reading subsequent sections, the remainder of this section identifies major differences between an NOS and an OS, establishes some of the major NOS objectives, and identifies requirements implicit in NOS design. The second section then discusses the major classes of primitives required for NOS implementation. Based upon this discussion, the two subsequent sections discuss issues and implica-

tions of the primitives required for data migration and network job execution. The fifth section examines the relationship of this work to existing capabilities and the sixth section closes with some summary remarks.

NOS-OS similarities and differences

From the viewpoint of an individual user, the basic atoms of both a network and an individual computer system are job steps and data. However, several major differences exist including: control of individual host resources; encapsulation; heterogeneity; geographical separation; and differing organizational constraints.

An individual operating system provides direct access to and control of individual host resources. In contrast, a Network Operating System provides a mediator which, to avoid substantial modifications to host operating systems, interfaces with the collection of operating systems to effect the requested functions. This has the advantage of eliminating the need for writing device drivers and many system utilities. The disadvantage is the need for explicit interfacing with a collection of distinct operating systems which may not provide comparable collections of capabilities.

A Network Operating System, in contrast with an individual operating system which has total control of system resources through effective encapsulation of the user, only mediates the interaction of the user with the operating system. Thus, the individual network user provided with access to a given system is assumed to have effectively the same potential spectrum of available capabilities as a local user. Moreover, since the user is not encapsulated, and the NOS is designed to support general purpose computing, it will usually be necessary to have some knowledge of local systems for interpretation of diagnostics and miscellaneous system responses created by program or programming errors. However, remote procedure calls, invocation of debugged programs, and many data operations could proceed without such knowledge.

For some applications, encapsulation may prove mandatory. Thus, the National Software Works provides such a capability in the context of providing a software production capability. This requires interrupt capturing, developing appropriate diagnostic translators and, for comparable items of software executing on distinct systems, development of standardized translators (grammars). This knowledge of the program to be executed is a prerequisite for its encapsulation. Encapsulation clearly provides significantly greater control of both user and host and, conceptually, is closer to heterogeneous multiprocessing. In view of the NSW demonstration of the feasibility of encapsulation, determination of its desirability is effectively a cost benefit exercise.

Host heterogeneity raises issues for both job processing and data movement. Job processing effectiveness is expedited through provision of a common command language.[8-10] However, as discussed above, determination of the proper amount of uniformity to provide in diagnostic and control messages may be regarded as an open issue. The data implication of host heterogeneity is reflected in the need for data selection, translation and transformation as discussed later.

The intent within a Network Operating System is to provide a collection of capabilities which enables an individual user to access remote resources (programs, data or systems) just as if the user were local to all these resources. Formally, this objective, although feasible, still requires caution on the part of the user in view of the time delays induced through accessing remote resources. This issue has been discussed in the context of providing a network based programming environment[11] and the care required seems similar to that required by the advent of virtual systems. That is, assuming that virtual memory was identical to real memory it could, for programs with poor locality, result in both poor utilization of system resources and high delay in program execution. It seems likely that improper utilization of network resources via an NOS will be reflected in the same manner.

Differing organizations have different viewpoints regarding sharing, accounting, and control of resource utilization. In a local environment these differences quickly become known and, through negotiation, become acceptable. In contrast, in a networking environment, the identity of the real user would usually be unknown and more formalized and rationalized procedures must be used. The precise implications of these organizational differences in style seem to be an open issue whose resolution is likely to be slow. However, the implications of poor accounting algorithms are already becoming manifest.[12-14]

NOS objectives and requirements

Five primary issues must be considered in developing a network operating system:

- provision of a uniform user viewpoint of resources
- modular expansibility
- control of host network interaction
- allocation of global network resources to network computing requirements, and
- implementation mode

The first objective was discussed above. The second is required to permit hosts to provide varying levels of NOS support as dictated by need. The third is required to assure adequate protection of host interests in a networking environment. The fourth is required to support efficient network based computing in general, and is mandatory for Mission Oriented Networks[5] in which a "collection" of computers must work cooperatively to achieve the organizational information processing function. The fifth consideration is required to ensure that the stated objectives do, indeed, prove economically feasible.

The developer of an operating system is effectively free to start from scratch. In contrast, the developer of a Network Operating System must interface with the existing software technology. Moreover, to be truly useful, the developer must also accept the fact that different sites are likely to have differing aspirations regarding network utilization and, as a result, will be likely to support different levels of sophistication in their NOS. It follows that a realistic NOS must be modularly expansible; the evident corollary is that it must support interaction with users not wishing to participate in the NOS as would be the case in ARPANET for users wishing to rely upon the existing protocols.

In almost any scientific or engineering endeavor, the first objective is to show that something can be done. The second is to show that it can be done well and the third is control. Control, in an NOS context, requires control of the host network interaction to prevent network demands from unfairly impacting local users. In addition, control in the context of a Mission Oriented Network[4] is also required to balance resource requirements against resource requests.

The mediator viewpoint described supports basic implementation and refinement of an NOS. The required element of control, however, imposes a host requirement significantly different from that currently existing since the network user is a relatively more unknown issue. As a result, the resource requirements of such a user are less predictable and the need for online, near real time control is increased. This, in turn, requires automated data gathering, archiving, and analysis. In addition, it requires the existence of a centralized network management capability to provide a common access point for users, individual installations and the network to obtain status and availability information. Such a capability would also permit balancing resource requirements against resources.

Host operating systems are complex, packet switched subnetworks are complex, and it is reasonable to assume that a completed network operating system will be complex. This necessitates careful consideration of its implementation mode. Two major alternatives exist: implementation within the host or implementation via augmentation of the host with a separate computer interposed between the host and the packet switch (IMP). In our opinion, the dramatic decline in hardware costs coupled with the increasing expense of sophisticated systems programmers argues strongly for the augmentation approach. Utilization of such an approach permits centralized design, implementation and support of the Network Operating Systems. Thus, only the host interfaces need be separately tailored. It should be noted that this support processor differs in scope from that usually subsumed under the title Front End Processor,[8] which is primarily concerned with offloading common portions of the software required to support ARPANET protocols. However, both have in common the need for case by case implementation of host interfaces.

NOS PRIMITIVE CATEGORIES

The global objectives of a Network Operating System require development of primitives in four categories:

- user communication,
- data migration,
- network job execution, and
- control.

User communication

User communication primitives are required since, in a geographically dispersed environment, the communication alternatives would require utilization of telephone, telegraph, etc. However, in view of the need to transmit programs, data, documentation, and user guidance (counseling), provision of a suitable mechanism within the computer communications network is clearly required. It should be noted that some of the more sophisticated individual host operating systems also provide such a capability.[15] Currently, rather general capabilities for user communication are available within the ARPANET for the TENEX subcollection of hosts.

In passing, it is worth noting that although rather general capabilities already exist, substantially more sophisticated capabilities can be considered. Two major branches can be distinguished: message processing and teleconferencing.

Message processing provides five basic categories of services:[16-18] creation, coordination, forwarding, alerting, and event processing. Through their provision, the ability of a large organization to respond in a timely manner to the dynamics of the environment is substantially facilitated. Creation and coordination permit generation and refinement of a proposed message by the collection of relevant originators. Forwarding encompasses the transmission process. Alerting supports early notification of the appropriate spectrum of recipients as determined from the addressee list or via content analysis. Finally, event processing can permit automatic invocation of computer operations appropriate to the message content (e.g., inventory reorders upon notification of outages in intermediate warehouses).

As observed in Reference 4, "Teleconferencing encompasses both multiparty voice/visual communication and a more formalized collection of capabilities related to hardcopy message communication.[19-23] A particular form of teleconferencing, computer-based conferencing, provides a natural support basis for communication among geographically dispersed computer users. This latter form of communication is also advantageous when it is appropriate to maintain permanent conference records, e.g., command and control. The general capabilities provided include archiving, indexing, searching, and updating of conferences. Through their utilization, communication between users is substantially enhanced."

Data migration

Data migration is the basic capability provided within a network for access to remote data. Current ARPANET provided capabilities primarily support transmission of sequential text files or block transmission of binary files. However, as discussed in the following section, efficient network utilization requires substantially more sophisticated capabilities. The spectrum of capabilities required for data migration is discussed later.

Network job execution

Network job execution differs from job execution in an individual computer system in the possibilities for: concurrent execution of parallel job steps; migration of a given job step to alternative sites; synchronization of job step execution across hosts; and the need for control of these capabilities. Moreover, in a heterogeneous network, job execution will generally require access to remote data. These and other issues are discussed in the next section.

Control

Control in a computer communications network can be considered at three levels:

- subnetwork control,
- host control, and
- network (host plus subnetwork) control.

Current subnetwork control capabilities are primarily limited to topology and link capacity modification. As a result, the control actions which can be invoked are rather static and the time constant for their invocation is on the order of months.

In the future, such static approaches to control promise to be unacceptable due to the emergent need for handling multimodal traffic including:[3,27]

- interactive traffic
- high throughput traffic such as file transfer,
- real time traffic such as digital transmission of speech, and
- guaranteed bandwidth traffic.

Since the available capacity directly interconnecting any two packet switches is relatively static, assurance of an equitable allocation of capacity among these traffic types as well as provision of guarantees that limited amounts of traffic of each type will get through requires careful investigation. An immediate requirement for such an investigation is online, near real time monitoring of traffic conditions and a likely corollary is an ability to effect control actions in near real time. The importance of research in this area is only beginning to be perceived with the transition of packet switching communication capabilities from the status of a research instrument to the status of a utility.

In a Value Added Network, by definition,[4] individual hosts as well as the subnetwork are organizationally independent. As a result, there is little need to coordinate and control the effects of job and data assignments. In contrast, in a Mission Oriented Network, a collection of hosts as well as, perhaps, the subnetwork are expected to work together cooperatively to achieve the organizational information processing function. This, in turn, is likely to require significant host control capabilities in order to ensure effective workload processing in the face of dynamically varying job and data assignments.

At the present time, work on centralized host network control capabilities is only beginning.[24] Their absence reflects the need for control strategies concerned with basic issues of: scheduling, major software capabilities and the basic hardware architecture of a system. In a single site computing environment, control strategies tended to be a byproduct of control tactics used for fine tuning the system.[25] Such tactics were primarily implemented by systems programmers having detailed knowledge of the system, its workload, anticipated needs, and the informal pecking order of customer priorities and were oriented toward a fine tuning of the system in a manner appropriate to such knowledge. It follows that tactics are relatively unsuited to centralized implementation while, as discussed in Reference 24, the opportunities for a centralized implementation of control strategies seem reasonable. A clear requirement for an effective control strategy is a careful, guaranteed delivery of system resources. An innovative approach to this subject is described in Reference 26.

Network (host plus subnetwork) control is clearly destined to be a subject of extreme importance in the context of Mission Oriented Networks. Existence of network control capabilities permits development and control of geographically dispersed data bases, tradeoffs between computing and communication, and assurance that remote users receive service comparable to that experienced by local users.

DATA MIGRATION

Data migration, as discussed in the Introduction, provides the basic capability required to permit a process executing in one computer to access data contained in another computer. Current data migration capabilities require that such access be accomplished via transmission of the file to the site at which the data is to be processed. Although this approach is, perhaps, reasonable in the context of an individual computer system, it seems unlikely to be acceptable in a data processing environment in which, typically, the owner of a file is unwilling to permit users to copy the file. In addition, for reasons of security and privacy, the owner may also be unwilling to let an accessing user access the entire file and may instead wish to restrict access to limited portions of the file.

Development of a general data migration capability requires three basic capabilities:

- data selection,
- data translation, and
- data transformation.

Data selection provides the basic capability (daemon) for remote accessing of data at the subfile level. As such, it should be envisioned as a transaction processor co-located with the data which, upon issuance of an appropriate request by a remote process, accesses a description of the file (specified in some appropriate data description language), and reads the requested record(s) in order to transmit them to the requesting process. At a conceptual level, it follows that the accessing process could therefore treat remote data just as it treats local data. At a practical level this observation needs to be tempered by the knowledge that network accesses will, in general, consume significantly more time than local data accesses and, as a result, access delays must be factored in to determine the relative desirability of utilizing a data selection capability versus transmission of the entire file. From an implementation viewpoint, it is of interest to observe that the basic data selection capabilities required relate closely to those required to support data translation.[28] Moreover, these capabilities also seem required to implement an effective locking capability in a networking environment.[29]

It is well recognized that hosts in a heterogeneous network use different bit patterns for encoding information. Data translation is the basic capability which permits hosts to communicate with each other in spite of these differences. It follows that a data translation capability is central to any effective capability to communicate among heterogeneous computers.

Data, particularly in a data processing environment, is usually stored as a collection of structured records. Effective transmission of data therefore requires augmentation of data translation to encompass preservation of record structure. The prerequisite capability for such preservation is an ability to describe the record structure and this, in turn, requires Data Description Languages.

Data description languages can be structured into Logical Data Description Languages (LDDLs) concerned with describing the logical structure of the data and with characterizing fields, and Physical Data Description Languages (PDDLs) which serve as the mechanism for describing how the data is physically laid out on the storage media.

LDDLs are relatively straightforward and can be pursued at various levels of abstraction as discussed in References 30, 31 and 32. PDDLs[33,34] are also logically straightforward but, from a user viewpoint, tedious. However, in a non-networking environment, PDDLs are clearly required to permit one system to read data written by another system. In contrast, in a networking environment, it seems feasible to eliminate the need for PDDLs and rely upon the system access routines to access the requested data and via a utility program, translate it into an appropriate "normal" form for transmission to the requesting site where it is again retranslated from the "normal" form into an appropriate local form. An exploratory discussion of this approach is contained in the paper: *An Approach To Data Migration in Computer Networks.*[28] It follows that data translation in a networking environment seems substantially simpler than translation in a non-networking environment.

Data transformation provides the basic capability for restructuring the logical form of data into a form more appropriate to the needs of the user or, alternatively, one which the owner of the data is willing to have transmitted. (For example, the owner may be unwilling to permit certain fields such as salary information to be transmitted.)

Data transformation requires, in general, three basic capabilities:

- arithmetic operations,
- logical operations,
- string operations.

Moreover, to be useful in a generalized data base environment, data transformation should permit operation on multiple input streams to produce multiple output streams.

Currently, some work is being done on the general topic of data transformation.[28,35,36] Moreover, a general single input stream single output stream data transformation capability was implemented within ARPANET in the context of the Data Reconfiguration Service. This system, in view of the primitive nature of the user interface and the highly procedural nature of the transformations could more properly be regarded as an experiment demonstrating the viability of the concept and, in this perspective should be viewed as a success. However, to be useful as a general purpose tool, substantially more sophisticated interface capabilities are required. Moreover, it would be generally desirable to permit both distributed and centralized implementations of this capability.

In summary, the basic needs required to support a data migration capability are reasonably clear and can be structured in a fairly coherent manner. Moreover, many of the required capabilities exist in various rudimentary forms at the present time.

NETWORK JOB EXECUTION

We define a network job to consist of a lattice (tied tree) of job steps which, as illustrated in Figure 1, may each be executed on a distinct and possibly dissimilar host. The characteristics of a network job are determined by those of the individual job steps.

In the simplest case, a job step may be a "batch" step which, once initiated, requires no further interaction with the NOS until termination. Support of the execution requirements of such a step is relatively straightforward.

In general, job steps executing in a networking environment may be anticipated to have more sophisticated support requirements including:

- user interaction,
- remote procedure calls, and
- synchronization with remote processes.

(It should be noted that execution of a network job is often viewed as an interprocess communication issue and thus a process rather than a job viewpoint is adopted. This viewpoint is correct for an implementor; however, from the viewpoint of the user the issue is really whether a remote job can be executed as is evident from the discussion of the Call-Return mechanism in Reference 11 as the basic primitive provided to a user.)

Support of user interaction with a network job step may prove relatively difficult in some operating systems since it tends to conflict with the desire for encapsulation of the job step which is useful in carefully controlling the interaction of the job step with the local host support capabilities such as the file system.

Provision of a capability to support remote procedure calls in a manner analogous to that in which local procedure calls are supported is clearly desirable. One approach to the development of such a capability is described in the paper *A High-Level Framework For Network-Based Resource Sharing.*[11] In this paper it is observed that this capability is particularly desirable to provide an alternative means to the more general issue of protocol implementation within a computer network.

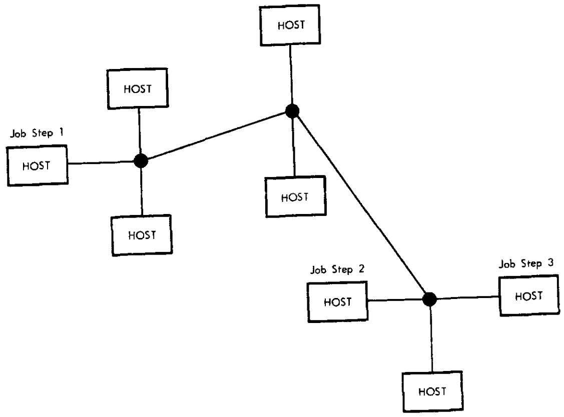

Figure 1—Job step assignment in a distributed network

Support of remote procedure calls carries, by analogy with the characteristics of local procedure calls, the implication that the calling process will terminate execution pending satisfaction of the call. In general, this need not be the case and, in view of the relatively large delays likely to occur in calls to remote systems (on the order of a few hundred milliseconds minimum due to subnetwork delays), more sophisticated capabilities are desirable to permit concurrent execution of local and remote processes. Thus, synchronization capabilities are required.

Network job execution requirements

Execution of a network job requires four major capabilities:

- job step assignment and control,
- step execution monitoring,
- JCL Generation, and
- Interprocess Communication Support.

Job step assignment and control is required for assigning job steps to processors: arranging for job step initiation upon satisfaction of all appropriate precedence and priority constraints; migration of files as required to permit job step initiation; and communication with the user. Assignment of job steps clearly requires a capability to detect any existing (step) parallelism. Moreover, such assignment may be made at the direction of the user, at the request of the host (to reduce peak workload), or at the suggestion of some centralized network management capability to balance global resource requests against resource availability.

Step execution monitoring is required to interface the scheduling of network originated jobs with local jobs. In particular, it provides step initiation; monitors step execution to provide restart and, potentially, recovery capabilities; and notifies the job step assignment routines of the termination of one step to permit initiation of successor steps. To support the needs of a job step to communicate with remote data, the appropriate data paths with data selectors stored in remote hosts must also be arranged.

Network JCL

A job control language provides four generic capabilities:

- identifying the precedence and priority conditions required for job step execution,
- making files within a user's directory known to

the step which usually has its own expectations regarding the naming of the files,

- inserting files generated by a program into the appropriate directory, and
- controlling the assignment of files to devices and, for a given file, controlling the layout of the file on the device.

Powerful job control languages, such as are commonly available with the larger data processing systems provide great power in effecting these functions and, as a result, are noted for the complexity of the statements required to achieve relatively simple (compile-load-go) objectives. In contrast, the JCL's provided with many of the scientifically oriented computer systems are quite simple and reflect a more limited spectrum of potential user needs. An intermediate point in this spectrum is provided by the capability which some of the more sophisticated JCL's provide of using "canned" procedures to achieve relatively straight-forward objectives. In this context, it seems likely that interactive approaches to JCL generation can be established which expedite generation of the appropriate JCL for the broad majority of user requirements. Users interested in maximum flexibility will probably still have to fend for themselves with the appropriate JCL. That is, user utilization of remote systems can be rendered no simpler than local usage if access to the full spectrum of system capabilities is to be provided.

Network IPC

Interprocess communication is required both as a technical prerequisite to building a network operating system and as a capability to be provided to users of the system to enable them to take full advantage of the opportunities (remote procedure calls, parallel execution, synchronized execution) afforded by the network. User IPC primitives are required for data transmission and process synchronization and control. Data primitives were discussed earlier. Synchronization and control primitives required to call procedures or processes, transfer data, and synchronize resource utilization can be divided into four major types:

- signal/wait-signal,
- wait/no-wait,
- transfer-control/retain-control, and
- preserve-state/reset-state.

The first primitive is required to permit a process to signal another process or procedure advertising its intentions; wait-signal is then required in order to permit a process to enter the wait state until receipt of an appropriate signal. The second primitive determines if parallel execution of both caller and called processes (entities) is to be supported The third primitive supports coroutines—in which both the calling and the called process have equal status—and the fourth capability is also required to support coroutine calls since the return location depends on the call location.

IPC capabilities can be provided in varying levels of sophistication reflecting: quality of the user interface, error recovery capabilities, and permissible complexity in the parameter string passed to the called procedure or process. Careful investigations of the total environment desirable to support effective and efficient IPC have been undertaken. Effectiveness issues are discussed in Reference 11, while issues of efficiency are discussed in Reference 37. Moreover, alternative message based implementation strategies to the connection oriented ARPANET approach to inter-process communication are described in Reference 38.

EXISTING RELATED CAPABILITIES

An overview of Network Operating Systems would not be complete without a discussion of currently existing capabilities. Currently, three such major capabilities can be distinguished:

- ARPANET Protocols,
- RSEXEC, and
- National Software Works.

ARPANET protocols

ARPANET protocols, as illustrated in Figure 2, can be structured in a hierarchical manner. The first level of user oriented protocols encompasses the three major function oriented protocols: TELNET, File Transfer Protocol (FTP), and Data Reconfiguration Service (DRS). The capabilities provided by these protocols have been discussed in the preceding sections and the salient factor from the viewpoint of an NOS is the observation that the protocol only standardizes the communication path between a user process (with which

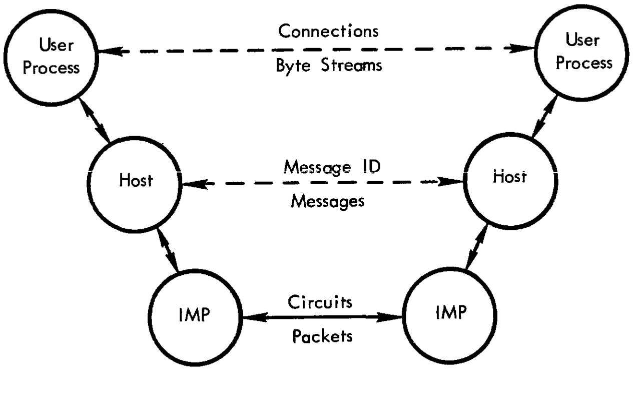

Figure 2—ARPANET protocol organization.[43,44] Solid lines denote real communication; dashed lines denote virtual communication

the user interacts) and a server process (which effects the necessary actions). Thus, these protocols at a minimum fail to provide program callability and require some degree of reprogramming for its achievement.

To provide more directly applicable user capabilities, ARPANET protocols also contain several applications oriented protocols such as Graphics[39] and the Network Voice Protocol[40] which are oriented toward provision of a specific collection of functional capabilities. As an alternative approach, one may wish to consider implementation of a more general user programming environment such as is proposed in the paper: *A High-Level Framework for Network-Based Resource Sharing.*[11]

RSEXEC

The Resource Sharing Executive (RSEXEC)[41] provides a network file system for the TENEX subcollection of hosts within the ARPANET. As such, it provides Network Wide Directories and, in addition, has supported system modifications which enable automatic file migration for dynamically generated file calls to non-local files. The standard set of inter-file manipulation commands are also provided. However, in view of the homogeneous nature of the hosts, issues of data translation did not require consideration and the issues of data selection, data transformation, and network job execution (excluding network IPC) were not specifically attacked.

National software works

The National Software Works (NSW)[42] is concerned with providing a program production capability distributed across a collection of hosts. It thereby potentially permits utilization of more sophisticated, relatively non-portable tools than would be possible if all tools were forced to execute at a single host.

Achievement of the NSW objectives requires careful consideration of many of the issues which are relevant in the design of a Network Operating System. However, in view of its more limited objective, substantially more sophisticated capabilities can be provided. In particular, in supporting tool access within the NSW framework, it proves feasible to render the host operating system apparently invisible to the user through effective encapsulation of the user and all interactions with the tool. Thus, the mediation role provided by an NOS is augmented to encompass encapsulation. In view of the magnitude of the NSW project we defer a more detailed discussion of NSW capabilities and refer the reader to Reference 5.

CONCLUDING REMARKS

In summary, we feel we have established the major objectives and goals underlying development of a general purpose Network Operating System. Although space limitations preclude a general discussion of their feasibility and manner of attainment, the interested reader may consult a study directed to this end.[5] As discussed therein, we feel it is reasonable to conclude that the objectives established are technically feasible; their utility is clearly manifest; and substantial portions of the required technological capabilities currently exist.

A high-level framework for network-based resource sharing*

by JAMES E. WHITE
Stanford Research Institute
Menlo Park, California

ABSTRACT

This paper proposes a high-level, application-independent framework for the construction of distributed systems within a resource sharing computer network. The framework generalizes design techniques in use within the ARPA Computer Network. It eliminates the need for application-specific communication protocols and support software, thus easing the task of the applications programmer and so encouraging the sharing of resources. The framework consists of a network-wide protocol for invoking arbitrary named functions in a remote process, and machine-dependent system software that interfaces one applications program to another via the protocol. The protocol provides mechanisms for supplying arguments to remote functions and for retrieving their results; it also defines a small number of standard data types from which all arguments and results must be modeled. The paper further proposes that remote functions be thought of as remotely callable subroutines or procedures. This model would enable the framework to more gracefully extend the local programming environment to embrace modules on other machines.

THE GOAL, RESOURCE SHARING

The principal goal of all resource-sharing computer networks, including the now international ARPA Network (the ARPANET), is to usefully interconnect geographically distributed hardware, software, and human resources.[1] Achieving this goal requires the design and implementation of various levels of support software within each constituent computer, and the specification of network-wide "protocols" (that is, conventions regarding the format and the relative timing of network messages) governing their interaction. This paper outlines an alternative to the approach that ARPANET system builders have been taking since work in this area began in 1970, and suggests a strategy for modeling distributed systems within any large computer network.

The first section of this paper describes the prevailing ARPANET protocol strategy, which involves specifying a family of application-dependent protocols with a network-wide inter-process communication facility as their common foundation. In the second section, the application-independent command/response discipline that characterizes this protocol family is identified and its isolation as a separate protocol proposed. Such isolation would reduce the work of the applications programmer by allowing the software that implements the protocol to be factored out of each applications program and supplied as a single, installation-maintained module. The final section of this paper proposes an extensible model for this class of network interaction that in itself would even further encourage the use of network resources.

THE CURRENT SOFTWARE APPROACH TO RESOURCE SHARING

Function-oriented protocols

The current ARPANET software approach to facilitating resource sharing has been detailed elsewhere in the literature.[2,3,4] Briefly, it involves defining a Host-Host Protocol by which the operating systems of the various "host" computers cooperate to support a network-wide inter-process communication (IPC) facility, and then various function-oriented protocols by which processes deliver and receive specific services via IPC. Each function-oriented protocol regulates the dialog between a resident "server process" providing the service, and a "user process" seeking the service on behalf of a user (the terms "user" and "user process" will be used consistently throughout this paper to distinguish the human user from the computer process acting on his behalf).

The current Host-Host Protocol has been in service since 1970. Since its initial design and implementation, a variety of deficiencies have been recognized and several alternative protocols suggested.[5,6] Although improvements at this level would surely have a positive effect upon Network resource sharing, the present paper simply assumes the existence of some form of

* The work reported here was supported by the Advanced Research Projects Agency of the Department of Defense, and by the Rome Air Development Center of the Air Force.

IPC and focuses attention upon higher level protocol design issues.

Each of the function-oriented protocols mentioned in this paper constitutes the official ARPANET protocol for its respective application domain and is therefore implemented at nearly all of the 75 host installations that now comprise the Network. It is primarily upon this widely implemented protocol family (and the philosophy it represents) that the present paper focuses. Needless to say, other important resource-sharing tools have also been constructed within the ARPANET. The Resource-Sharing Executive (RSEXEC), designed and implemented by Bolt, Beranek and Newman, Inc.,[7] provides an excellent example of such work.

Experience with and limitations of hands-on resource sharing

The oldest and still by far the most heavily used function-oriented protocol is the Telecommunications Network protocol (TELNET),[8] which effectively attaches a terminal on one computer to an interactive time-sharing system on another, and allows a user to interact with the remote system via the terminal as if he were one of its local users.

As depicted in Figure 1, TELNET specifies the means by which a user process monitoring the user's terminal is interconnected, via an IPC communication channel, with a server process with access to the target time-sharing system. TELNET also legislates a standard character set in which the user's commands and the system's responses are to be represented in transmission between machines. The syntax and semantics of these interchanges, however, vary from one system to another and are unregulated by the protocol; the user and server processes simply shuttle characters between the human user and the target system.

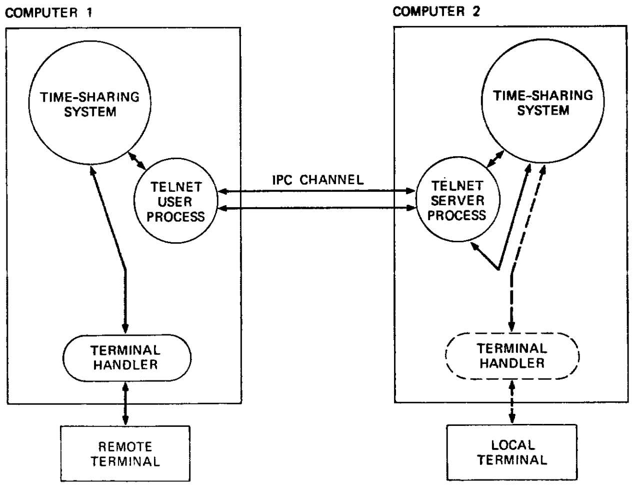

Figure 1—Interfacing a remote terminal to a local time-sharing system via the TELNET Protocol

Although the hands-on use of remote resources that TELNET makes possible is a natural and highly visible form of resource sharing, several limitations severely reduce its long-term utility:

(1) It forces upon the user all of the trappings of the resource's own system.

To exploit a remote resource, the user must leave the familiar working environment provided by his local system and enter an alien one with its own peculiar system structure (login, logout, and subsystem entry and exit procedures) and command language discipline (command recognition and completion conventions, editing characters, and so on). Hands-on resource sharing thus fails to provide the user with the kind of organized and consistent workshop he requires to work effectively.[9]

(2) It provides no basis for bootstrapping new composite resources from existing ones.

Because the network access discipline imposed by each resource is a human-engineered command language, rather than a machine-oriented communication protocol, it is virtually impossible for one resource to programatically draw upon the services of others. Doing so would require that the program deal successfully with complicated echoing and feedback characteristics; unstructured, even unsolicited system responses; and so forth. Hands-on resource sharing thus does nothing to provide an environment in which existing resources can be used as building blocks to construct new, more powerful ones.

These inherent limitations of hands-on resource sharing are removed by a protocol that simplifies and standardizes the dialog between user and server processes. Given such a protocol, the various remote resources upon which a user might wish to draw can indeed be made to appear as a single, coherent workshop by interposing between him and them a command language interpreter that transforms his commands into the appropriate protocol utterances.[10,11] The construction of composite resources also becomes feasible, since each resource is accessible by means of a machine-oriented protocol and can thus be readily employed by other processes within the network.

Standardizing the inter-machine dialog in specific application areas

After the TELNET protocol had been designed and widely implemented within the ARPANET, work began on a family of function-oriented protocols designed for use by programs, rather than human users. Each such protocol standardizes the inter-machine dialog in a particular application area. While TELNET dictates only the manner in which user and server processes are interconnected via the IPC facility, and the character set in which the two processes communicate once connected, each member of this family specifies in addition the syntax and semantics of the commands and responses that comprise their dialog.

Protocols within this family necessarily differ in substance, each specifying its own application-specific command set. The File Transfer Protocol (FTP),[12] for example, specifies commands for manipulating files, and the Remote Job Entry Protocol (RJE)[13] specifies commands for manipulating batch jobs. Protocols throughout the family are, however, similar in form, each successive family member having simply inherited the physical features of its predecessors. Thus FTP and RJE enforce the same conventions for formulating commands and responses.

This common command/response discipline requires that commands and responses have the following respective formats:

```
command-name    <SP> parameter <CRLF>
response-number <SP> text      <CRLF>
```

Each command invoked by the user process is identified by NAME and is allowed a single PARAMETER. Each response generated by the server process contains a three-digit decimal response NUMBER (to be interpreted by the user process) and explanatory TEXT (for presentation, if necessary, to the user). Response numbers are assigned in such a way that, for example, positive and negative acknowledgments can be easily distinguished by the user process.

FTP contains, among others, the following commands (each listed with one of its possible responses) for retrieving, appending to, replacing, and deleting files, respectively, within the server process file system:

Command	Response
RETR <SP> filename <CRLF>	250 <SP> Beginning transfer. <CRLF>
APPE <SP> filename <CRLF>	400 <SP> Not implemented. <CRLF>
STOR <SP> filename <CRLF>	453 <SP> Directory overflow. <CRLF>
DELE <SP> filename <CRLF>	450 <SP> File not found. <CRLF>

The first three commands serve only to initiate the transfer of a file from one machine to another. The transfer itself occurs on a separate IPC channel and is governed by what amounts to a separate protocol.

Since the general command format admits but a single parameter, multiparameter operations must be implemented as sequences of commands. Thus two commands are required to rename a file:

Command	Response
RNFR <SP> oldname <CRLF>	200 <SP> Next parameter. <CRLF>
RNTO <SP> newname <CRLF>	253 <SP> File renamed. <CRLF>

A COMMAND/RESPONSE PROTOCOL, THE BASIS FOR AN ALTERNATIVE APPROACH

The importance of factoring out the command/response discipline

That FTP, RJE, and the other protocols within this family share a common command/response discipline is a fact not formally recognized within the protocol literature, and each new protocol document describes it in detail, as if for the first time. Nowhere are these conventions codified in isolation from the various contexts in which they find use, being viewed as a necessary but relatively unimportant facet of each function-oriented protocol. "This common command/response discipline has thus gone unrecognized as the important, application-independent protocol that it is."

This oversight has had two important negative effects upon the growth of resource sharing within the ARPANET:

(1) It has allowed the command/response discipline to remain crude.

As already noted, operations that require more than a single parameter are consistently implemented as two or more separate commands, each of which requires a response and thus incurs the overhead of a full round-trip network delay. Furthermore, there are no standards for encoding parameter types other than character strings, nor is there provision for returning results in a command response.

(2) It has placed upon the applications programmer the burden of implementing the network "run-time environment (RTE)" that enables him to access remote processes at the desired, functional level.

Before he can address remote processes in terms like the following:

execute function DELE with argument TEXTFILE on machine X

the applications programmer must first construct (as he invariably does in every program he writes) a module that provides the desired program interface while implementing the agreed upon command/response discipline. This run-time environment contains the code required to properly format outgoing commands, to interface with the IPC facility, and to parse incoming responses. Because the system provides only the IPC facility as a foundation, the applications programmer is deterred from using remote resources by the amount of specialized knowledge and software that must first be acquired.

If, on the other hand, the command/response discipline were formalized as a separate protocol, its use in subsequent function-oriented protocols could rightly be anticipated by the systems programmer, and a single run-time environment constructed for use throughout an installation (in the worst case, one implementation per programming language per machine might be required). This module could then be placed in a library and, as depicted in Figure 2, link loaded with (or otherwise made available to) each new applications program, thereby greatly simplifying its use of remote resources.

Furthermore, since enhancements to it would pay dividends to every applications program employing its services, the run-time environment would gradually be augmented to provide additional new services to the programmer.

The thesis of the present paper is that one of the keys to facilitating network resource sharing lies in (1) isolating as a separate protocol the command/response discipline common to a large class of applications protocols; (2) making this new, application-independent protocol flexible and efficient; and (3) constructing at each installation a RTE that employs it to give the applications programmer easy and high-level access to remote resources.

Specifications for the command/response protocol

Having argued the value of a command/response protocol (hereafter termed the Protocol) as the foundation for a large class of applications protocols, there remains the task of suggesting the form that the Protocol might take. There are eight requirements. First, it must reproduce the capabilities of the discipline it replaces:

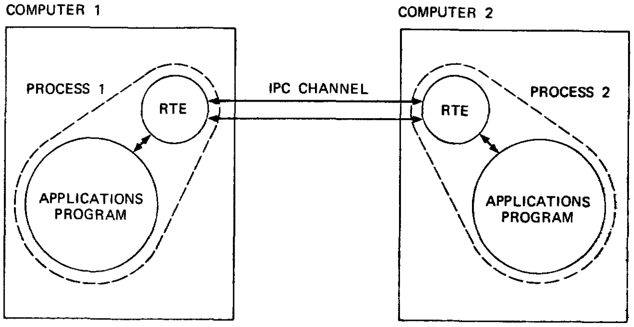

Figure 2—Interfacing distant applications programs via their run-time environments

(1) Permit invocation of arbitrary, named commands (or functions) implemented by the remote process.

(2) Permit command outcomes to be reported in a way that aids both the program invoking the command and the user under whose control it may be executing.

Second, the Protocol should remove the known deficiencies of its predecessor, that is:

(3) Allow an arbitrary number of parameters to be supplied as arguments to a single command.

(4) Provide representations for a variety of parameter types, including but not limited to character strings.

(5) Permit commands to return parameters as results as well as accept them as arguments.

And, finally, the Protocol should provide whatever additional capabilities are required by the more complex distributed systems whose creation the Protocol seeks to encourage. Although others may later be identified, the three capabilities below are recognized now to be important:

(6) Permit the server process to invoke commands in the user process, that is, eliminate entirely the often inappropriate user/server distinction, and allow each process to invoke commands in the other.

In the workshop environment alluded to earlier, for example, the user process is the command language interpreter and the server process is any of the software tools available to the user. While most commands are issued by the interpreter and addressed to the tool, occasionally the tool must invoke commands in the interpreter or in another tool. A graphical text editor, for example, must invoke commands within the interpreter to update the user's display screen after an editing operation.

(7) Permit a process to accept two or more commands for concurrent execution.

The text editor may wish to permit the user to initiate a long formatting operation with one command and yet continue to issue additional, shorter commands before there is a response to the first.

(8) Allow the process issuing a command to suppress the response the command would otherwise elicit.

This feature would permit network traffic to be reduced in those cases in which the process invoking the command deems a response unnecessary. Commands that always succeed but never return results are obvious candidates for this kind of treatment.

A formulation of the protocol that meets these specifications

The eight requirements listed above are met by a protocol in which the following two messages are defined:

message-type=COMMAND [tid] command-name arguments

message-type=RESPONSE tid outcome results

Here and in subsequent protocol descriptions, elements enclosed in square brackets are optional.

The first message invokes the command whose NAME is specified using the ARGUMENTS provided. The second is issued in eventual response to the first and returns the OUTCOME and RESULTS of the completed command. Whenever OUTCOME indicates that a command has failed, the command's RESULTS are required to be an error number and diagnostic message, the former to help the invoking program determine what to do next, the latter for possible presentation to the user. The protocol thus provides a framework for reporting errors, while leaving to the applications program the tasks of assigning error numbers and composing the text of error messages.

There are several elements of the Protocol that are absent from the existing command/response discipline:

(1) RESULTS, in fulfillment of Requirement 5.

(2) A MESSAGE TYPE that distinguishes commands from responses, arising from Requirement 6.

In the existing discipline, this distinction is implicit, since user and server processes receive only responses and commands, respectively.

(3) An optional transaction identifier TID by which a command and its response are associated, arising from Requirements 7 and 8.

The presence of a transaction identifier in a command implies the necessity of a response echoing the identifier; and no two concurrently outstanding commands may bear the same identifier.

Requirements 3 and 4—the ability to transmit an arbitrary number of parameters of various types with each command or response—are most economically and effectively met by defining a small set of primitive "data types" (for example, booleans, integers, character strings) from which concrete parameters can be modeled, and a "transmission format" in which such parameters can be encoded. Appendix A suggests a set of data types suitable for a large class of applications; Appendix B defines some possible transmission formats.

The protocol description given above is, of course, purely symbolic. Appendix C explores one possible encoding of the Protocol in detail.

Summarizing the arguments advanced so far

The author trusts that little of what has been presented thus far will be considered controversial by the reader. The following principal arguments have been made:

(1) The more effective forms of resource sharing depend upon remote resources being usefully accessible to other programs, not just to human users.

(2) Application-dependent protocols providing such access using the current approach leave to the applications programmer the task of constructing the additional layer of software (above the IPC facility provided by the system) required to make remote resources accessible at the functional level, thus discouraging their use.

(3) A single, resource-independent protocol providing flexible and efficient access at the functional level to arbitrary remote resources can be devised.

(4) This protocol would make possible the construction at each installation of an application-independent, network run-time environment making remote resources accessible at the functional level and thus encouraging their use by the applications programmer.

A protocol as simple as that suggested here has great potential for stimulating the sharing of resources within a computer network. First, it would reduce the cost of adapting existing resources for network use by eliminating the need for the design, documentation, and implementation of specialized delivery protocols. Second, it would encourage the use of remote resources by eliminating the need for application-specific interface software. And finally, it would encourage the construction of new resources built expressly for remote access, because of the ease with which they could be offered and used within the network software marketplace.

A HIGH-LEVEL MODEL OF THE NETWORK ENVIRONMENT

The importance of the model imposed by the protocol

The Protocol proposed above imposes upon the applications programmer a particular model of the network environment. In a heterogeneous computer network, nearly every protocol intended for general implementation has this effect, since it idealizes a class of operations that have concrete but slightly different equivalents in each system. Thus the ARPANET's TELNET Protocol alluded to earlier, for example, specifies a Network Virtual Terminal that attempts to provide a best fit to the many real terminals in use around the Network.

As now formulated, the Protocol models a remote resource as an interactive program with a simple, rigidly specified command language. This model follows naturally from the fact that the function-oriented protocols from which the Protocol was extracted were necessitated by the complexity and diversity of user-oriented command languages. The Protocol may thus legitimately be viewed as a vehicle for providing, as an adjunct to the sophisticated command languages already available to users, a family of simple command languages that can readily be employed by programs.

While the command/response model is a natural one, others are possible. A remote resource might also be modeled as a process that services and replies to requests it receives from other computer processes. This request/reply model would emphasize the fact that the Protocol is a vehicle for inter-process communication and that no human user is directly involved.

Substituting the request/reply model for the command/response model requires only cosmetic changes to the Protocol:

message-type=REQUEST [tid] op-code
arguments

message-type=REPLY tid outcome
results

In the formulation above, the terms "REQUEST", "REPLY", and "op-code" have simply been substituted for "COMMAND", "RESPONSE", and "command-name", respectively.

The choice of model need affect neither the content of the Protocol nor the behavior of the processes whose dialog it governs. Use of the word "command" in the command/response model, for example, is not meant to imply that the remote process can be coerced into action. Whatever model is adopted, a process has complete freedom to reject an incoming remote request that it is incapable of or unwilling to fulfill.

But even though it has no substantive effect upon the Protocol, the selection of a model—command/response, request/reply, and so on—is an important task because it determines the way in which both applications and systems programmers perceive the network environment. If the network environment is made to appear foreign to him, the applications programmer may be discouraged from using it. The choice of model also constrains the kind and range of protocol extensions that are likely to occur to the systems programmer; one model may suggest a rich set of useful extensions, another lead nowhere (or worse still, in the wrong direction).

In this final section of the paper, the author suggests a network model (hereafter termed the Model) that he believes will both encourage the use of remote resources by the applications programmer and suggest to the systems programmer a wide variety of useful Protocol extensions. Unlike the substance of the Protocol, however, the Model has already proven quite controversial within the ARPANET community.

Modeling resources as collections of procedures

Ideally, the goal of both the Protocol and its accompanying RTE is to make remote resources as easy to use as local ones. Since local resources usually take the form of resident and/or library subroutines, the possibility of modeling remote commands as "procedures" immediately suggests itself. The Model is further confirmed by the similarity that exists between local procedures and the remote commands to which the Protocol provides access. Both carry out arbitrarily complex, named operations on behalf of the requesting program (the caller); are governed by arguments supplied by the caller; and return to it results that reflect the outcome of the operation. The procedure call model thus acknowledges that, in a network environment, programs must sometimes call subroutines in machines other than their own.

Like the request/reply model already described, the procedure call model requires only cosmetic changes to the Protocol:

message-type=CALL [tid] procedure-name
arguments

message-type=RETURN tid outcome
results

In this third formulation, the terms "CALL", "RETURN", and "procedure-name" have been substituted for "COMMAND", "RESPONSE", and "command-name", respectively. And in this form, the Protocol might aptly be designated a "procedure call protocol (PCP)".

"The procedure call model would elevate the task of creating applications protocols to that of defining procedures and their calling sequences. It would also provide the foundation for a true distributed programming system (DPS) that encourages and facilitates the work of the applications programmer by gracefully extending the local programming environment, via the RTE, to embrace modules on other machines." This integration of local and network programming environments can even be carried as far as modifying compilers to provide minor variants of their normal procedure-calling constructs for addressing remote procedures (for which calls to the appropriate RTE primitives would be dropped out).

Finally, the Model is one that can be naturally extended in a variety of ways (for example, coroutine linkages and signals) to further enhance the distributed programming environment.

Clarifying the procedure call model

Although in many ways it accurately portrays the class of network interactions with which this paper deals, the Model suggested above may in other respects tend to mislead the applications programmer. The Model must therefore be clarified:

(1) Local procedure calls are cheap; remote procedure calls are not.

Local procedure calls are often effected by means of a single machine instruction and are therefore relatively inexpensive. Remote procedure calls, on the other hand, would be effected by means of a primitive provided by the local RTE and require an exchange of messages via IPC.

Because of this cost differential, the applications programmer must exercise discretion in his use of remote resources, even though the mechanics of their use will have been greatly simplified by the RTE. Like virtual memory, the procedure call model offers great convenience, and therefore power, in exchange for reasonable alertness to the possibilities of abuse.

(2) Conventional programs usually have a single locus of control; distributed programs need not.

Conventional programs are usually implemented as a single process with exactly one locus of control. A procedure call, therefore, traditionally implies a transfer of control from caller to callee. Distributed systems, on the other hand, are implemented as two or more processes, each of which is capable of independent execution. In this new environment, a remote procedure call need not suspend the caller, which is capable of continuing execution in parallel with the called procedure.

The RTE can therefore be expected to provide, for convenience, two modes of remote procedure invocation: a blocking mode that suspends the caller until the procedure returns; and a non-blocking mode that releases the caller as soon as the CALL message has been sent or queued. Most conventional operating systems already provide such a mode choice for I/O operations. For non-blocking calls, the RTE must also, of course, either arrange to asynchronously notify the program when the call is complete, or provide an additional primitive by which the applications program can periodically test for that condition.

Finally, the applications programmer must recognize that by no means all useful forms of network communication are effectively modeled as procedure calls. The lower level IPC facility that remains directly accessible to him must therefore be employed in those applications for which the procedure call model is inappropriate and RTE-provided primitives simply will not do.

SOME EXPECTATIONS

Both the Procedure Call Protocol and its associated Run-Time Environment have great potential for facilitating the work of the network programmer; only a small percentage of that potential has been discussed in the present paper. Upon the foundation provided by PCP can be erected higher level application-independent protocol layers that further enhance the distributed programming environment by providing even more powerful capabilities (see Appendix D).

As the importance of the RTE becomes fully evident, additional tasks will gradually be assigned to it, including perhaps those of:

(1) Converting parameters between the format employed internally by the applications program, and that imposed by the Protocol.
(2) Automatically selecting the most appropriate inter-process transmission format on the basis of the two machines' word sizes.
(3) Automatically substituting for network IPC a more efficient form of communication when both processes reside on the same machine.

The RTE will eventually offer the programmer a wide variety of application-independent, network-programming conveniences, and so, by means of the Protocol, become an increasingly powerful distributed-system-building tool.

ACKNOWLEDGMENTS

Many individuals within both SRI's Augmentation Research Center (ARC) and the larger ARPANET community have contributed their time and ideas to the development of the Protocol and Model described in this paper. The contributions of the following individuals are expressly acknowledged: Dick Watson, Jon Postel, Charles Irby, Ken Victor, Dave Maynard, and Larry Garlick of ARC; and Bob Thomas and Rick Schantz of Bolt, Beranek and Newman, Inc.

ARC has been working toward a high-level framework for network-based distributed systems for a number of years now.[14] The particular Protocol and Model described here result from research begun by ARC in July of 1974. This research included developing the Model; designing and documenting the Protocol required to support it;[15] and designing, documenting, and implementing a prototype run-time environment for a particular machine,[16,17] specifically a PDP-10 running the Tenex operating system developed by Bolt, Beranek and Newman, Inc.[18] Three design iterations were carried out during a 12-month period, and the resulting specification implemented for Tenex. The Tenex RTE provides a superset of the capabilities presented in the body of this paper and Appendices A through C as well as those alluded to in Appendix D.

APPENDIX A—SUGGESTED DATA TYPES

The Protocol requires that every parameter or "data object" be represented by one of several primitive data types defined by the Model. The set of data types below is sufficient to conveniently model a large class of data objects, but since the need for additional data types (for example, floating-point numbers) will surely arise, the set must remain open-ended. Throughout the descriptions below, N is confined to the range [0, 2**15-1]:

LIST: A list is an ordered sequence of N data objects called "elements". A LIST may contain other LISTs as elements, and can therefore be employed to construct arbitrarily complex composite data objects.

CHARSTR: A character string is an ordered sequence of N ASCII characters, and conveniently models a variety of textual entities, from short user names to whole paragraphs of text.

BITSTR: A bit string is an ordered sequence of N bits and, therefore, provides a means for representing arbitrary binary data (for example, the contents of a word of memory).

INTEGER: An integer is a fixed-point number in the range [-2**31, 2**31-1], and conveniently models various kinds of numerical data, including time intervals, distances, and so on.

INDEX: An index is an integer in the range [1, 2**15-1]. As its name and value range suggest, an INDEX can be used to address a particular bit or character within a string, or element within a list. INDEXes have other uses as well, including the modeling of handles or identifiers for open files, created processes, and the like. Also, because of their restricted range, INDEXes are more compact in transmission than INTEGERs (see Appendix B).

BOOLEAN: A boolean represents a single bit of information, and has either the value true or false.

EMPTY: An empty is a valueless place holder within a LIST or parameter list.

APPENDIX B—SUGGESTED TRANSMISSION FORMATS

Parameters must be encoded in a standard transmission format before they can be sent from one process to another via the Protocol. An effective strategy is to define several formats and select the most appropriate one at run-time, adding to the Protocol a mechanism for format negotiation. Format negotiation would be another responsibility of the RTE and could thus be made completely invisible to the applications program.

Suggested below are two transmission formats. The first is a 36-bit binary format for use between 36-bit machines, the second an 8-bit binary, "universal" format for use between dissimilar machines. Data objects are fully typed in each format to enable the RTE to automatically decode and internalize incoming parameters should it be desired to provide this service to the applications program.

PCPB36, For Use Between 36-Bit Machines

Bits 0-13 Unused (zero)
Bits 14-17 Data type

EMPTY	=1	INTEGER	=4	LIST	=7
BOOLEAN	=2	BITSTR	=5		
INDEX	=3	CHARSTR	=6		

Bits 18-20 Unused (zero)
Bits 21-35 Value or length N

EMPTY	unused (zero)
BOOLEAN	14 zero-bits + 1-bit value (TRUE=1/FALSE=0)
INDEX	unsigned value
INTEGER	unused (zero)
BITSTR	unsigned bit count N
CHARSTR	unsigned character count N
LIST	unsigned element count N

Bits 36- Value

EMPTY	unused (nonexistent)
BOOLEAN	unused (nonexistent)
INDEX	unused (nonexistent)
INTEGER	two's complement full-word value
BITSTR	bit string + zero padding to word boundary
CHARSTR	ASCII string + zero padding to word boundary
LIST	element data objects

PCPB8, For Use Between Dissimilar Machines

Byte 0 Data type

EMPTY	=1	INTEGER	=4	LIST	=7
BOOLEAN	=2	BITSTR	=5		
INDEX	=3	CHARSTR	=6		

Bytes 1- Value

EMPTY	unused (nonexistent)
BOOLEAN	7 zero-bits + 1-bit value (TRUE=1/FALSE=0)
INDEX	2-byte unsigned value
INTEGER	4-byte two's complement value
BITSTR	2-byte unsigned bit count N + bit string + zero padding to byte boundary
CHARSTR	2-byte unsigned character count N + ASCII string
LIST	2-byte element count N + element data objects

APPENDIX C—A DETAILED ENCODING OF THE PROCEDURE CALL PROTOCOL

Although the data types and transmission formats detailed in the previous appendixes serve primarily as vehicles for representing the arguments and results of remote procedures, they can just as readily and effectively be employed to represent the commands and responses by which those parameters are transmitted.

Taking this approach, one might model each of the two Protocol messages as a PCP data object, specifically a LIST whose first element is an INDEX message type. The following concise statement of the Protocol then results:

```
LIST (CALL,       tid,      procedure,  arguments)
      INDEX=1   INDEX/
                EMPTY     CHARSTR     LIST
LIST (RETURN,     tid,      outcome,    results)
      INDEX=2   INDEX     BOOLEAN     LIST
```

The RESULTS of an unsuccessful procedure would be represented as follows:

```
LIST (error,    diagnostic)
      INDEX     CHARSTR
```

APPENDIX D—A LOOK AT SOME POSSIBLE EXTENSIONS TO THE MODEL

The result of the distributed-system-building strategy proposed in the body of this paper and the preceding appendices is depicted in Figure 3. At the core of each process is the inter-process communication facility provided by the operating system, which effects the transmission of arbitrary binary data between distant processes. Surrounding this core are conventions regarding first the format in which a few, primitive types of data objects are encoded in binary for IPC, and then the formats of several composite data objects (that is, messages) whose transmission either invokes or acknowledges the previous invocation of a remote procedure. Immediately above lies an open-ended protocol layer in which an arbitrary number of enhancements to the distributed programming environment can be implemented. Encapsulating these various protocol layers is the installation-provided run-time environment, which delivers DPS services to the applications program according to machine- and possibly programming-language-dependent conventions.

The Protocol proposed in the present paper recognizes only the most fundamental aspects of remote procedure calling. It permits the caller to identify the procedure to be called, supply the necessary arguments, determine the outcome of the procedure, and recover its results. In a second paper,[19] the author proposes some extensions to this simple procedure call model, and attempts to identify other common forms of inter-process interaction whose standardization would

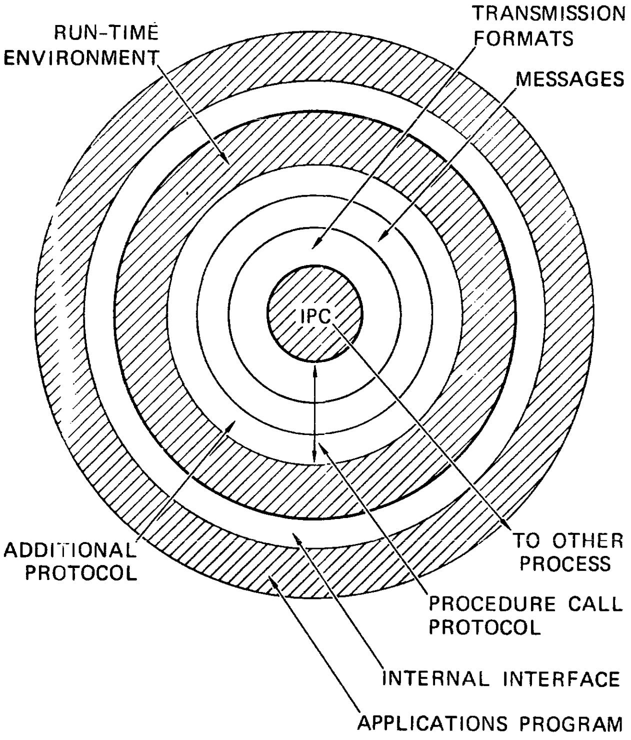

Figure 3—Software and protocol layers comprising a process within the distributed programming system

enhance the distributed programming environment. Included among the topics discussed are:

(1) Coroutine linkages and other forms of communication between the caller and callee.
(2) Propagation of notices and requests up the thread of control that results from nested procedure calls.
(3) Standard mechanisms for remotely reading or writing system-global data objects within another program.
(4) Access controls for collections of related procedures.
(5) A standard means for creating and initializing processes, that is, for establishing contact with and logging into a remote machine, identifying the program to be executed, and so forth. This facility would permit arbitrarily complex process hierarchies to be created.
(6) A mechanism for introducing processes to one another, that is, for superimposing more general communication paths upon the process hierarchy.

These and other extensions can all find a place in the open-ended protocol layer of Figure 3. The particular extensions explored in Reference 19 are offered not as dogma but rather as a means of suggesting the possibilities and stimulating further research.

Factors in interprocess communication protocol efficiency for computer networks*

by CARL A. SUNSHINE
The Rand Corporation
Santa Monica, California

ABSTRACT

This paper considers the efficiency of interprocess communication protocols for distributed processing environments such as computer networks. Previous research has emphasized system performance at lower levels, within the communication medium itself, while this work examines requirements and performance of protocols for communication between processes in the Host computers attached to the communication system. Efficiency primarily concerns throughput and delay achievable for communication between remote processes. Various aspects of protocol operation are analyzed, and protocol policies concerning retransmission, flow control, buffering, acknowledgment, and packet size emerge as the most important factors in determining efficiency. Several graphs showing quantitative performance results for representative situations are included.

INTRODUCTION

The tremendous growth of computer communications in recent years has provided new problems as well as new opportunities in distributed processing. In particular, computer networks such as the ARPANET[7,23] demand new techniques for providing reliable and efficient communication between processes running in different Host computers connected to the network. Typical network transmission characteristics include variable delay, limited bandwidth, and occasional loss, damage, duplication, or out-of-order delivery of messages.[1–3] These transmission characteristics demand specially robust *protocols*, or algorithms and message formats for data exchange between remote processes, compared to mechanisms appropriate in a centralized system with common memory.

Protocols for such environments are usually based on transmission of packets containing data, control information such as sequence numbers, and a checksum for error detection. Correctly received packets are positively acknowledged by the destination. If no acknowledgment is received at the source within a given time-out period, packets are retransmitted. The reliability of such Positive Acknowledgment, Retransmission (PAR) protocols in the face of network transmission characteristics mentioned above has received increasing attention.[3] This paper discusses major factors determining the *efficiency* of protocols for communication between remote processes over a packet switching network (PSN). Research on interprocess communication level protocols has just begun[4,5] while related work on performance analysis of protocols used within a PSN is more abundant.[6–11]

The two performance measures of primary interest are mean *delay* and mean *throughput* attainable. Throughput may be defined as the transmission rate of useful data between processes, excluding any control information or retransmissions required by the protocol. Delay is the time from starting to transmit a packet at the sender to successful arrival of the entire packet at the receiver in the case of one-way delay, or until arrival of an acknowledgment at the sender in the case of roundtrip delay. (Note that any waiting time between packet creation and start of transmission is not included in this delay definition.) Other efficiency performance measures of interest include *retransmission rate* (the proportion of packets which are retransmissions), *line efficiency* (the ratio of useful traffic to total traffic), and *buffer requirements.*

Numerous factors such as buffer allocation, receiver processing rate, flow control, error rates, error recovery techniques, header overhead, and network transmission delay and bandwidth help determine protocol performance. Some of these factors depend directly on communication network design and operation and represent essentially uncontrollable characteristics from the point of view of an interprocess communication protocol. Other factors depend on the behavior of processes communicating via the protocol.

* This work was supported by the Defense Advanced Research Projects Agency under ARPA Order No. 2494, Contract No. MDA903-76C-0093 with Stanford University. The views and conclusions contained in this document are those of the author and do not necessarily represent the policies of the Defense Advanced Research Projects Agency of the United States Government.

This paper focuses on a third class of factors which are subject to control by the protocol itself. To provide efficient communication within the constraints of given network characteristics and user process behavior, a protocol can attempt to optimize several internal parameters such as retransmission interval, flow control strategy, buffering, acknowledgment scheme, and packet size. In the following sections, the impact of each of these parameters on protocol efficiency is explored. For this purpose, some simple mathematical models based on probability and queuing theory prove helpful. This paper discusses some of the results derived from these models, while Reference 5 presents a more complete treatment of the subject including full derivations of the results presented here.

RETRANSMISSION

As noted above, the primary purpose of retransmission is to overcome loss or damage of data packets (or acknowledgments) by the communication network. The protocol parameter controlling retransmission is the *retransmission interval,* R. If no acknowledgment for a transmitted packet is received within time R, the packet will be retransmitted.

The choice of R can have significant effects on both throughput and delay. A small R minimizes mean delay since lost packets are retransmitted promptly. If there is significant variation in network transmission delay for a packet, then quick retransmission may reduce mean delay even when no packets are lost or damaged. Larger R, on the other hand, tends to maximize throughput since no bandwidth is "wasted" on unnecessary retransmissions. Assuming packets need not be delivered in order, there is no penalty for waiting until loss of a packet is certain before retransmitting it, since other packets can continue to be delivered.

To quantify these general observations, the following simple model proves useful. Let the network transmission delay be represented by a probability density function f(t) to allow for variation in delay. Both propagation time through the network (Tprop) and transmission time into the network (for a packet of length P and Host-to-network bandwidth of B, this is P/B) are included in f(t). f(t) typically has a high peak around the "normal" delay, and a small but long tail representing the possibility of occasional long delays (see Figure 1). If the probability of lost or damaged packets is LS, then f(t) includes an impulse at t=infinity with value LS (the probability that a packet never arrives).

f(t) and its associated cumulative distribution F(t) now represent the behavior of a packet of length P transmitted through the network. Assuming packets are retransmitted at intervals R, and that f(t) is identical for each (re)transmission of a packet (independence of successive transmissions),[12,13] the cumulative delay distribution until the first *successful* receipt of a packet, G(t), may be derived from F(t) and R.

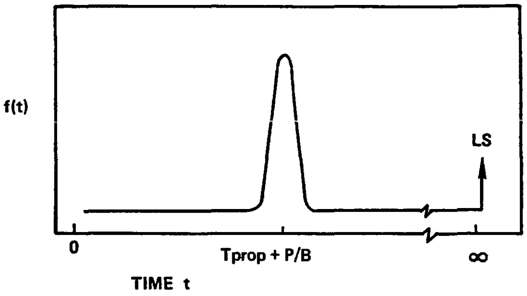

Figure 1—Network transmission delay density function f(t) including packet loss probability LS

$$\begin{aligned} G(t) &= \text{Prob}\{\text{at least one successful delivery by time } t\} \\ &= 1-\text{Prob}\{\text{no success by time } t\} \\ &= 1-\prod_{i=0}^{n-1}[1-F(t-i\cdot R)] \qquad n=\lceil t/R \rceil \end{aligned}$$

If f(t) represents roundtrip delay (time from transmitting a packet until an acknowledgment is received), then G(t) provides sufficient information to calculate the mean delay DL until the first successful acknowledged transmission, and the mean number of transmissions N. Since each successful transmission requires on the average N actual transmissions, throughput attainable will be proportional to a throughput factor TPretrans equal to the inverse of N.

To demonstrate this analysis, let f(t) be the Erlangian family of distributions:

$$f(t)=(k\cdot u)\cdot\frac{(k\cdot u\cdot t)^{k-1}}{(k-1)!}\cdot e^{-k\cdot u\cdot t}$$

With an appropriate choice of the shape parameter k (e.g., k=16), this distribution provides an adequate model of typical network transmission delays[12] (see Figure 2). Applying the above analysis to the Erlang-

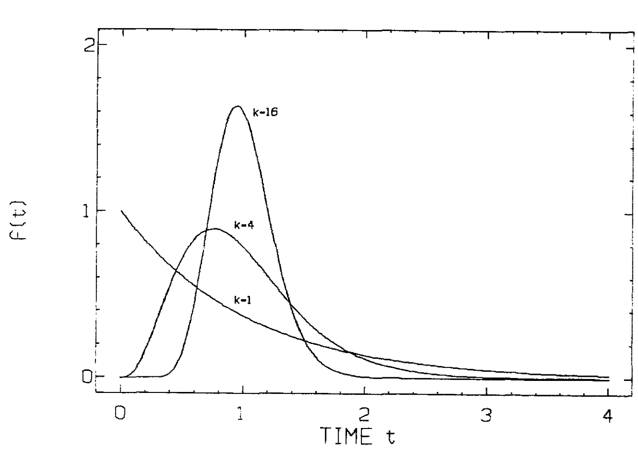

Figure 2—Erlangian probability density function, f(t), with mean=1 and shape parameter k=1,4, 16

ian f(t) with k=16 gives Figure 3, a plot of throughput versus delay for varying retransmission interval R and several packet loss probabilities LS (the results for exponential f(t) are shown dotted for comparison). The definite "knee" in the curves for nonzero LS indicate an optimal value of R. For larger R, delay is increased with little savings in throughput. For smaller, R, throughput is reduced (due to excessive retransmission) at little improvement in delay. This optimal value of R occurs at the time in the f(t) curve by which "most" transmissions would have succeeded (if no packets were lost or damaged). The optimal R is more clearly defined for f(t) with sharp peaks (more constant delay) and for higher packet loss probabilities.

To extend this analysis to protocols which perform sequencing, the assumption of independent identically distributed roundtrip delays for successive transmissions must be modified. In particular, loss of a packet or its acknowledgment causes acknowledgment of all subsequent packets to be delayed until the earlier error is corrected, even though other packets are successfully received. In this case, negative acknowledgments may improve performance by forcing prompt retransmission of the damaged packet, and suppressing retransmission of other outstanding packets (c.f. next section). Although negative acknowledgments help reduce performance losses, higher delay and lower throughput must be expected with a sequencing protocol if packets arrive significantly out of order.

FLOW CONTROL

Roundtrip delay is typically an order of magnitude greater than Host-to-network packet transmission time over a packet switching network. In this environment, a simple protocol that waits for acknowledgment of each packet before transmitting the next packet will be idle a large fraction of the time. Therefore, to achieve higher throughput, the sender must be allowed to transmit multiple packets before receiving any acknowledgments. Since each outstanding packet requires buffering and other communication resources, the amount of advance transmission required to achieve maximum throughput becomes an important efficiency question.

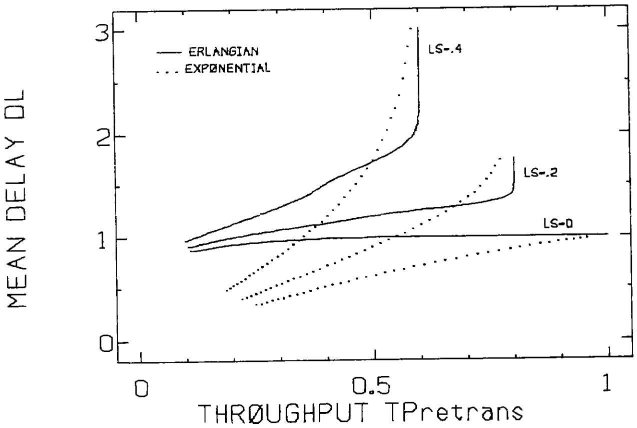

Figure 3—Mean delay DL vs. throughput factor TPretrans for Erlangian network transmission delay with mean=1 and k=16

On the other hand, it is also necessary to limit the flow of information from source process to destination process. The communication network itself must guard against internal congestion by imposing "congestion control" constraints on traffic sources.[2,14] More relevant to this study, each sender's transmission rate should be matched to the receiver's acceptance rate to minimize protocol resources required to support the given traffic. Achieving this matching is the primary purpose of a protocol's *flow control* mechanisms.

Most flow control strategies can be described in terms of a limited *window size* of Nwin packets (and/or bits) that may be transmitted but not yet acknowledged.[1,15-18] When this limit is reached, the sender must stop transmitting new packets (although retransmissions of pending packets may proceed) until more transmission "credits" are returned by the receiver (often associated with acknowledgments).

This situation can be modeled as a dual-server closed queuing system with the transmitter as one server, and the network and receiver as the other. (This second server is an "infinite" server since packets can proceed in parallel through the network.) Service time at the transmitter (Tlocal) is the Host-to-network transmission time for a packet (P/B), while service time 2 (Tnet) which includes propagation of the packet through the network, receiver processing, and return of an acknowledgment, is the roundtrip delay less service time 1. Define RHO as the ratio of service time 1 to service time 2. The window size Nwin defines the number of customers (packets) in the system (see Figure 4).

The utilization of server 1 (UT) is the fraction of time that the transmitter is active (allowed to transmit) with a given window size, and hence provides a good indication of throughput attainable. Figure 5 shows this utilization as a function of window size for several values of RHO and assuming exponentially distributed service times (high variance). Realistic values of RHO in a typical PSN are typically about 0.1 since roundtrip delays are an order of magnitude larger than Host-to-network transmission times. Throughput rises linearly with window size (note the logarithmic scale for window size) up to the half-way point, and then somewhat more slowly. For constant service times (no variance), throughput would rise linearly with window size all the way to its maximum value, while service time distributions (roundtrip delays) with intermediate variance would behave between these limits.

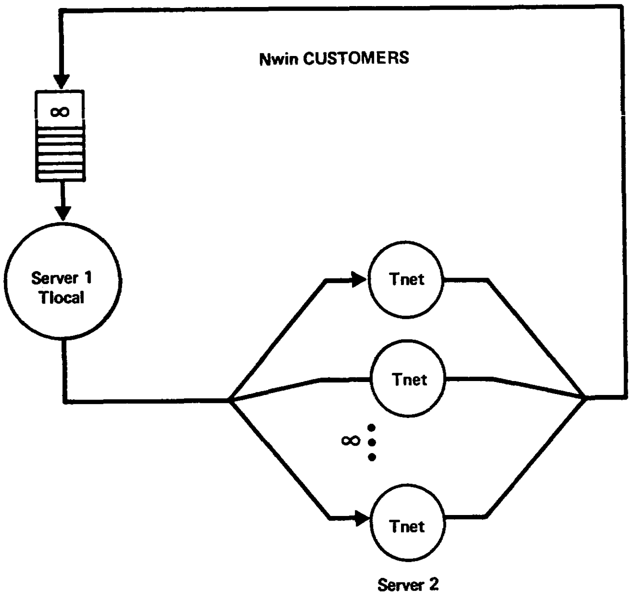

Figure 4—Queuing model of flow control

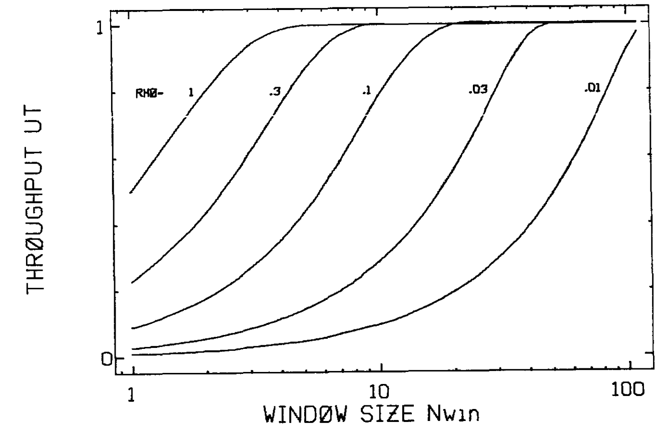

Figure 5—Throughput factor UT vs. flow control window size Nwin for various RHO-Tlocal/Tnet (the ratio of packet transmission time to roundtrip delay through the network)

This model provides information for both flow control concerns expressed above. To achieve *maximum* throughput, a window size approximately equal to the roundtrip delay divided by the Host-to-network transmission time for a packet is optimal (a larger window does not increase throughput much). This confirms the intuitive approach of "keeping the pipe full" between sender and receiver. To *limit* throughput to a desired fraction of the bandwidth available, the same fraction of this optimal window size should be used.

As long as packet loss and damage probabilities remain low, the above analysis shows how throughput may be *flow control limited* by a small window size. In networks where transmission errors are more likely, throughput may become *retransmission limited* because retransmissions of pending packets have priority over new transmissions. In general, achievable throughput will be the minimum due to either flow control or retransmission constraints.

A third similar constraint may be imposed by the *source* further restricting the window size for a connection (below what the receiver might allow) in order to share its communication resources fairly among all connections. For example, the ARPANET TIP[19] limits each terminal (up to 300 baud) to a window of 6-12 characters in order to share its relatively scarce buffer space among all users. In the next section, the effects of destination buffer space limits or protocol performance will be explored.

DESTINATION BUFFERING AND ACKNOWLEDGMENT STRATEGIES

Buffering of received packets at the destination is necessary to smooth uneven production and consumption rates (hold packets until they can be processed) and to hold out-of-order arrivals for proper sequencing (if the protocol provides a sequencing function). Inadequate space for either purpose means that successfully received packets may have to be discarded if no space is available to hold them, increasing retransmission rate and delay.

In an attempt to avoid these problems, "conservative" acknowledgment strategies delay returning permission to send new data (c.f. last section) until buffer space to receive it has actually been made available by "consuming" arrived packets or furnishing additional space. In this case, no arriving packets need be discarded, but roundtrip delay for flow control credits is increased because processing time is included, and hence throughput may be reduced as shown in the last section.

Under favorable conditions, new flow control credits can be returned immediately on successful receipt of a packet, reducing the roundtrip time. As long as packet arrivals and receiver processing proceed smoothly (at regular intervals), no packets will be discarded. A larger window size than the buffer space available may be used to achieve higher throughput with reduced buffering requirements. Storage space along the network transmission path actually provides the rest of the space in the window.

Another simple queuing model provides insight into the performance of this optimistic strategy. The receiver is represented by a single server with mean service (processing) rate u, and size-limited queue of Nbuf packet buffers. Packets arrive at a mean rate A determined by retransmission and flow control constraints discussed earlier, and the ratio of arrival rate to processing rate is RHO = A/u. Assuming exponential distributions, well-known queuing results[20] give the probability that an arriving packet will find all the buffers full, and have to be discarded.

$$\text{Pfull}(\text{Nbuf},\text{RHO}) = (1-\text{RHO}) \cdot \frac{\text{RHO}^{\text{Nbuf}}}{1-\text{RHO}^{\text{Nbuf}+1}}$$

Three general cases may be distinguished.

For RHO>>1, (arrival rate>>processing rate), nearly all arriving packets will be discarded regardless of the size of Nbuf. In this case, throughput is clearly *receiver rate limited,* and the window size should be reduced to limit the sender's transmission rate to the receiver's processing rate.

For RHO<<1, very few packets will be discarded even if Nbuf is small. A fast receiver requires very little buffering, and buffer pooling among multiple connections may be advantageous.

For RHO = 1, (matched sending and receiving rates), the number of buffers required depends heavily on the "smoothness" of source and destination activity. Very regular activity allows a minimum of buffering. Unfortunately, irregular packet arrival and processing rates are more typical in computer networks, particularly in multiprogramming systems where process activity occurs in bursts. If process scheduling intervals in multiprogramming systems are large compared to roundtrip delays, then large window sizes and buffer allocations may be necessary to achieve high throughput.

PACKET SIZE

In transmitting large amounts of information between processes, a communication protocol must determine the amount of data to transmit in each packet. The primary result of varying packet size is to vary transmission delay through the network, f(t). Transmission delay in a store-and-forward network has a large component proportional to packet length because the transmission time on each hop between switching nodes is equal to packet length divided by bandwidth[7] (although some networks either fragment or combine submitted packets before internal transmission).

Assuming this proportionality holds, shorter packets mean lower per packet delay, with ensuing effects on protocol performance as described in earlier sections. Unfortunately, overhead for short packets increases since each packet carries a fixed amount of header and control information, and more acknowledgments and general processing for the same amount of data will be necessary.[4] Hence, maximum throughput attainable decreases while line efficiency (and total cost in bits transmitted) increases for shorter packets. Longer packets reduce overhead and allow higher throughput at the cost of increased delay. Packet switching networks typically impose an upper bound on the size of packets submitted for transmission in order to manage their internal resources and to ensure prompt access to other customers.[2]

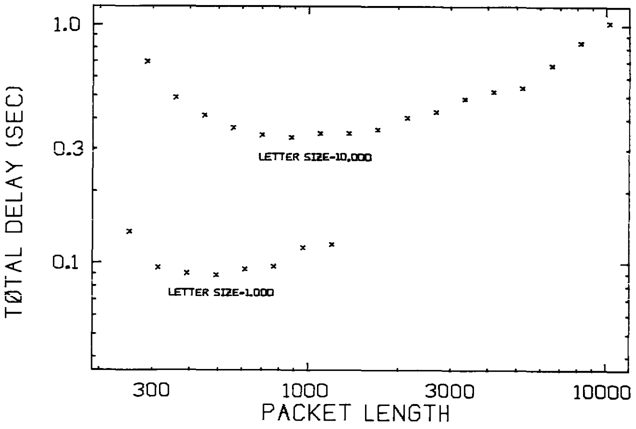

Figure 6—Total delay vs. packet length for two block (letter) sizes

Network bandwidth=50 kb/sec
Number of hops=5
Header length=200 bits
Packet less probability=0

To illustrate some of these trade-offs, Figure 6 shows the total time to transmit a large block of information using different packet sizes, assuming typical PSN characteristics (but no packet loss) and transmission delay proportional to packet length. Using the smallest packets, throughput is so low that total delay is high. For very large packets, the increasing delay per packet also leads to high total delay. The "optimal" value for this application results from an intermediate packet size.

Other applications may have other priorities for cost, throughput, and delay performance.[9] Transaction or interactive applications may select short packets to achieve low delay at somewhat higher cost and reduced throughout. Minimum cost or maximum throughput users willing to tolerate larger average delays may use long packets. "Real-time" traffic requiring moderate delay and good throughput for moderate block lengths may use intermediate packet sizes. As network bandwidth increases and error rates drop, the impact of packet length on protocol performance should lessen.

CONCLUSIONS

Distributed processing environments such as computer networks demand new techniques for providing reliable and efficient communication between remote processes. Good performance of communication protocols developed for this purpose depends heavily on tuning protocol parameters to complement network transmission characteristics. This paper has discussed the impact on communication efficiency of major protocol policies concerning retransmission, flow control, buffer allocation, acknowledgment, and packet size.

More complete resnlts and more detailed development of the models underlying these results are contained in another paper by the author.[5] Experiments are currently under way to verify the predictions of these models using the newly developed Transmission Control Program[17,21,22] as an interprocess communication protocol.

Performance of file directory systems for data bases in star and distributed networks*

by WESLEY W. CHU
University of California, Los Angeles
Los Angeles, California

ABSTRACT

Three classes of file directories for distributed data bases are studied: The centralized directory system, the local directory system, and the distributed directory system. The parameters considered are communication cost, storage cost, code translation cost, query rate, update rate, directory size, and directory response time. This study reports the cost performance tradeoffs of these three classes of directory systems in star and distributed networks and provides a guide in the design of file directory systems when operating in these network environments.

INTRODUCTION

In the automation of large information systems, a major portion of the planning is concerned with methods of storing, updating, retrieving, and distributing large quantities of information in an information processing system. Examples of such efforts are found in business, medicine, library and management information systems. These systems, which may consist of several geographically separate divisions, need to process information files in common and thus form a network information processing system known as a distributed data base. One of the significant advantages of this network environment is the resource sharing capability. Problems that arise in the design of distributed data bases include file allocation policy,[1,2,3] avoidance of file deadlock,[4] file directory design, file partitioning policy, file reliability, privacy, and security issues, and interfacing considerations. This paper concerns itself with the allocation of directories in a distributed data base.

A directory is a listing of files available to the users of the network. Such a directory will enable a user at any node to determine where in a network a specific sharable file exists. One can consider such a directory to be similar to a card catalog of a public library. These sharable files are referred to as public files. Users at each node may offer to list their files in this directory of public files for sharing purposes. A user may interrogate this list to determine its contents or to obtain information on where a specific sharable file exists. The list of non-shared files is assumed to be stored at the computer that is known to its users and, therefore, is not considered here. Further, we assume that each computer has its own local directory which consists of all the public files stored in that computer. To locate a file that is not in the local computer, the user must consult the file directory.

There are several ways to design the file directory: centralized file directory, local file directory and distributed file directory. Based on the computer network topology, operating cost (communication cost, storage cost, and code translation cost), directory query rate and directory update rate, we use mathematical models to study the operating cost and response time of these directory systems as a function of directory query rate, directory update rate, and the ratio of storage cost to communication cost. Two numerical examples are given (one with a star network topology, the other with a distributed network topology) to illustrate the applications of the models. The results provide us with insights on how to optimally plan for a file directory for a distributed data base.

THE MODEL

In this section, several mathematical models are introduced to study the performance of file directory systems for operating in the star network and distributed network topologies. Let us first consider the centralized file directory system.

Centralized file directory system

Single master directory

In the centralized file directory system, a master directory is located at one of the computers. When a

* This research was supported by the U.S. Office of Naval Research, Contract No. N00014-75-C-0650.

user requires a file that is not stored at his local directory, he consults the master directory to find out the location or content of that file. The centralized directory must be updated when there is a change in the storage location or contents of a file, or a creation of a new version of the file. Directory updating in such a system is relatively easy. However, there are communication costs incurred for each transaction. The operating cost for such a system per unit time is

$$C_c=\underbrace{\sum_{\substack{i=1\\i\neq d}}^{n} C_{id}{}^t s_{id} l_i \sum_{j=1}^{m_i} q_{ij}(2+p_{ij})}_{\text{communication cost}}+\underbrace{\sum_{\substack{i=1\\i\neq d}}^{n}\sum_{j=1}^{m_i}[T_i q_{ij}(2+P_{ij})]}_{\text{translation cost}}+\underbrace{C_d{}^s F}_{\text{storage cost}} \tag{1}$$

Where: m_i = total number of files in the ith computer

n = total number of computers in the network

d = location of the master directory

$C_{id}{}^t$ = transmission cost per character and per unit distance from the ith computer to the master directory

s_{id} = distance between the ith computer to the master directory.

l_i = average record length in characters for each transaction at the ith computer, $i=1, 2, \ldots, n$

q_{ij} = directory query rate by the jth file at the ith computer per unit time. $j=1, 2, \ldots, m$.

P_{ij} = normalized directory update rate (the ratio of directory update rate to directory query rate) of the jth file generated by the ith computer. $0\leq P_{ij}\leq 1$.

T_i = code translation cost per transaction by the ith computer at the master directory.

$C_d{}^s$ = storage cost per character per unit time at the master directory

F = size of the master file directory in characters.

The first term in Equation (1) represents the transmission cost for querying and updating the file directory, the second term represents the code translation cost (due to non-uniform information representations) for transactions (querying and updating) performed by all the computers at the directory, and the last term is the cost for storing the master file directory.

To simplify the notation in Equation (1), we let $q_i=\sum_{j=1}^{m_i} q_{ij}$. The q_i is the total number of queries generated per unit time by the ith computer for the directory. Further, we assume that all the files at the ith computer have the same directory update; that is, $P_{ij}=P_i$ for all j. Equation (1) then reduces to

$$C_c=\sum_{\substack{i=1\\i\neq d}}^{n} C_{id}{}^t s_{id} l_i q_i (2+p_i)+\sum_{\substack{i=1\\i\neq d}}^{n} T_i q_i (2+P_i)+C_d{}^s F \tag{2}$$

Extended centralized directory

In a centralized file directory, once the user finds the location or description of a file, he can append this information onto his local directory. Should the user use this file again, the directory information for this file can be obtained from his local directory, thereby reducing the communication cost as well as time for querying the master directory. However, when the information of that file at the master directory is updated, we also require updating of the information of that file in the local directories. Therefore, for notification of future updates in the master directory, the list of local directories that have appended file information is recorded in the master directory. The operating cost of such a system is:

$$C_{EC}=\sum_{\substack{i=1\\i\neq d}}^{n} C_{id}{}^t s_{id} l_i q_i p_i+\sum_{\substack{i=1\\i\neq d}}^{n} q_i p_i T_i + C_d{}^s(F+F_e)$$
$$+\sum_{\substack{i=1\\i\neq d}}^{n}\alpha_i C_i{}^s F+\sum_{\substack{i\neq k\\i=1}}^{n}\sum_{\substack{k\neq d\\k=1}}^{n} q_i p_i \beta_{ki}(C_{dk}{}^t s_{dk} l_k + T_{dk}) \tag{3}$$

where α_i = fraction of the master directory being appended at the local directory of the ith computer, $0\leq\alpha_i\leq 1$ $i=1, 2, \ldots, n$.

β_{ki} = probability that a file at the kth computer has a transaction at the ith computer, $0\leq\beta_{ki}\leq 1$, $i=1, 2, \ldots, n$ and $k=1, 2, \ldots, n$.

T_{dk} = translation cost for the master directory to perform a transaction with the kth computer.

F_e = the size of the list of all the files stored at the master directory that requires notification for directory updates (in characters).

We assume that compared with the overall operating cost, the first cost of locating a file in the master directory is negligible. The first term in Equation (3) is the transmission cost for updating the master directory, the second term is the code translation cost for updating the master directory, the third term is the cost for storing the directory and the list of the transaction records for notification of future file directory updates, the fourth term is the cost for storing the extended file directories at all the local directories, and the last term is the communication cost and translation cost for the master directory to update the relevant appended local directories.

Multiple master directories

When the computers in a network are clustered in groups, it is often cost effective to provide a master directory at each of these clusters. The savings in communication cost for a multiple master directory system could far outweigh the cost of storing and updating the file directories. We can partition the n computers in the system into r clusters ($r \leq n$) such that

$$\sum_{j=1}^{r} n_j = n$$

where n_j is the number of computers in the jth cluster. During normal operation, the computers in the jth cluster will query the jth directory which is a member of the jth cluster. One way to partition the n computers into r groups is to base on the network topology such that the partitioned clusters yield minimum communication costs. Another way is to base the clusters on directory query rate and directory update rate to achieve minimum response time. The operating cost for such a system is:

$$C_M = \sum_{k=1}^{r} \left\{ \sum_{\substack{\{i\}\epsilon d_k \\ d_k \neq i}} C_{id_k}{}^t s_{id_k} l_i q_i (2+p_i) + \sum_{\substack{\{i\}\epsilon d_k \\ i \neq d_k}} T_i q_i (2+p_i) \right\}$$
$$+ \sum_{k=1}^{r} C_{d_k}{}^s F \quad \sum_{g=1}^{r} \sum_{\substack{k=1 \\ k\neq g}}^{r} \sum_{\{i\}\epsilon d_k} (C_{d_k d_g}{}^t \cdot s_{d_k d_g} \cdot l_i + T_{d_k d_g}) p_i q_i \qquad (4)$$

where r = number of master directories in the system

d_k = the kth master directory, $k = 1, 2, \ldots, r$.

$\{i\}\epsilon d_k$ = the set of computers that uses the kth master directory

$C_{d_k}{}^s$ = storage cost per character per unit time of the kth master directory

$C_{id_k}{}^t$ = transmission cost per character per unit distance from the ith computer to the kth master directory, $i = 1, 2, \ldots, n$ and $k = 1, 2, \ldots, r$.

The last term of (4) is the communication cost and translation cost for updating the rest of the multiple directories in the system. For the single master directory case ($r=1$), Equation (4) reduces to (2).

Local file directory system

In the local directory case, there is no master directory in the system. When a requested file is not stored in the user's local directory, the user queries all the other local directories in the system until the requested file has been located. Such a directory system requires high communication cost and translation cost, as well as search time for locating the file. For a system of n computers, it requires an average of (n-1)/2 directory queries to locate a file. Assuming the directory can only be updated by its owner, updating is done at its local directory which does not require communications cost. The operating cost for such a system is

$$C_L = \tfrac{1}{2}\left[\underbrace{2 \sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} C_{ik}{}^t s_{ik} l_i \sum_{j=1}^{m_i} q_{ij}}_{\text{Communication Cost}} + \underbrace{2 \sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} T_{ik} \sum_{j=1}^{m_i} q_{ij}}_{\text{Translation Cost}} \right] \qquad (5)$$

where T_{ik} is the code translation cost per transaction for the ith computer at the kth computer. The first term of Equation (5) is the expected communication costs for querying to and replying from all the local directories for those files that are not stored in the local computer, and the second term is the expected code translation costs for transactions with all the local directories in the system. The factor 1/2 is for taking the average operating cost. Since there is no master directory in such a system, there is no storage cost in Equation (5).

For simplicity in notation, we let $q_i = \sum_{j=1}^{m_i} q_{ij}$. Eq. (5) becomes

$$C_L = \sum_{i=1}^{n} \sum_{\substack{k=1 \\ k\neq 1}}^{n} [C_i{}^t s_{ik} l_i + T_{ik}]\, q_i \qquad (6)$$

Let us consider the case where each of the computers contains a routing table which routes the directory query directly to the other computers rather than returning the negative query reply to the sender. As a result, the expected total communication cost can be greatly reduced, particularly if the routing sequence takes into consideration the probability of finding the file in the directory. The total operating cost reduces to

$$C_L' = \gamma \sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} [C_{i_k}{}^t s_{ik} l_i q_i + T_{ik} q_i] + \sum_{i=1}^{n} C_{ik}{}^t s_{ik} l_i q_i \qquad (7)$$

where $0 < \gamma < 0.5$. The value of γ depends on the network topology and the policy used in the routing table. The last term of Eq. (7) is the communication cost for replying to the queries.

Distributed file directory system

In the distributed directory case, each computer in the system has a master directory. The advantage of this system is its fast response time. The disadvantage of this system is the cost of storing master file directories at each computer as well as the communication cost for updating all these directories. The operating cost per unit time of such a system is

$$C_D = \underbrace{\sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} C_{ik}{}^t s_{ik} l_i \sum_{j=1}^{m_i} q_{ij} p_{ij}}_{\text{Communication Cost}}$$
$$+ \underbrace{\sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} T_{ik} \sum_{j=1}^{m_i} q_{ij} p_{ij}}_{\text{Translation Cost}} + \underbrace{\sum_{i=1}^{n} C_i{}^s F}_{\text{Storage Cost}} \qquad (8)$$

The first term of Equation (8) is the communication cost for updating all the distributed master directories in the system, the second term is the translation cost associated with the updating of all the distributed directories, and the last term is the cost for storing all the master directories. If we assume that the directory update rates of all the files at the ith computer are identical, then $P_{ij}=P_i$. Again for simplicity in notation, we let $q_i=\sum_{j=1}^{m_i} q_{ij}$. Then (8) reduces to

$$C_D=\sum_{\substack{i=1\\ i\neq k}}^{n}\sum_{k=1}^{n}(C_{ik}{}^t s_{ik} l_i+T_{ik})\,p_i q_i+\sum_{i=1}^{n}C_i{}^s F \qquad (9)$$

OPERATING COST TRADEOFFS OF DIRECTORY SYSTEMS

The intersection of two operating cost curves $C_x(P)$ and $C_y(P)$ (Figures 1 and 2) represent the cost tradeoff point (in terms of update rate) for directory systems x and y. If we assume that all the computers in the system have identical directory update rates, then the operating cost is a linear function of the normalized update rate P. Thus $C_x(P)$ and $C_y(P)$ can be expressed as:

$$C_x(P)=a_xP+b_x$$

$$\text{and}\quad C_y(P)=a_yP+b_y$$

where a_x and a_y are incremental costs for directory updates and b_x and b_y are fixed directory operating costs. The intersection point of $C_x(p)$ and $C_y(P)$, $P(x,y)$, satisfies

$$P(x,y)=\frac{b_y-b_x}{a_x-a_y} \qquad (10)$$

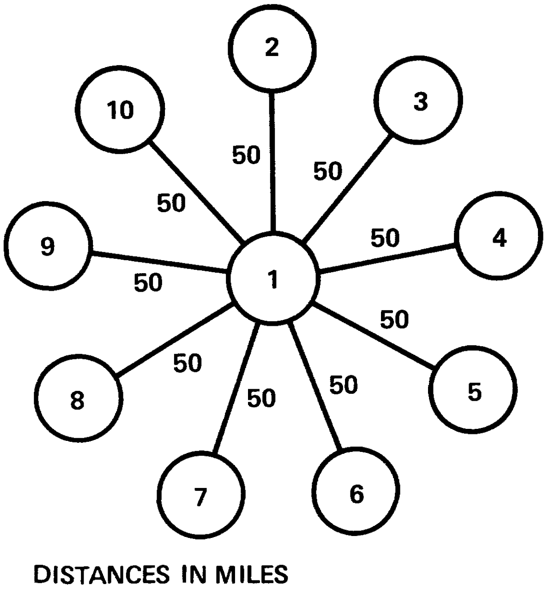

Figure 1—Performance of directory systems for a star network $C^t/C^s=10$ month/mile—(a) A star network

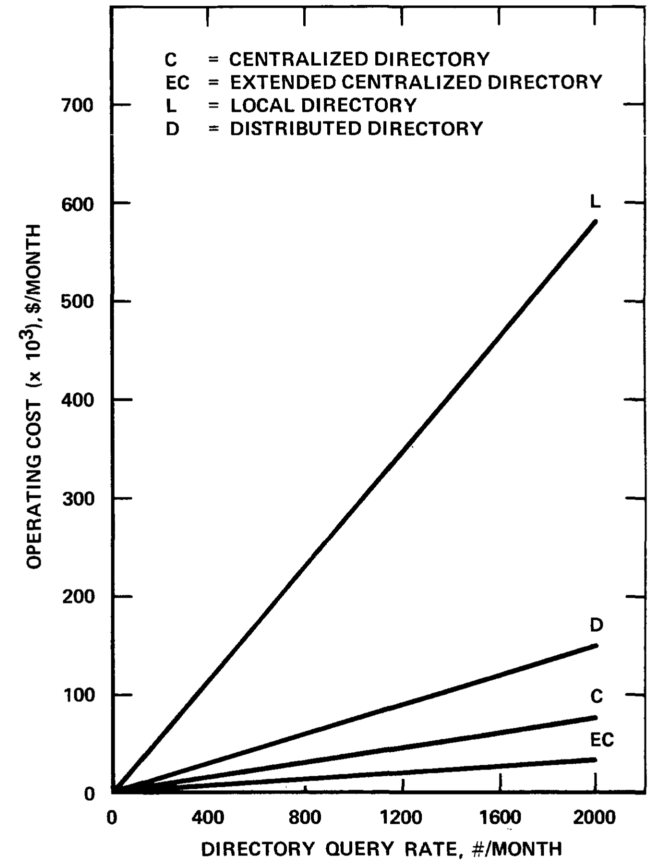


(b) Directory operating cost vs. directory query rate

Let us now consider the intersection of the cost curves for the centralized and extended centralized directory systems. From Equation (2), we have

$$a_c=\sum_{\substack{i=1\\ i\neq d}}^{n}C_{id}{}^t s_{id} l_i q_i+\sum_{\substack{i=1\\ i\neq d}}^{n}T_i q_i$$

$$b_c=\sum_{\substack{i=1\\ i\neq d}}^{n}2C_{id}{}^t s_{id} l_i q_i+\sum_{\substack{i=1\\ i\neq d}}^{n}2T_i q_i+C_d{}^s F$$

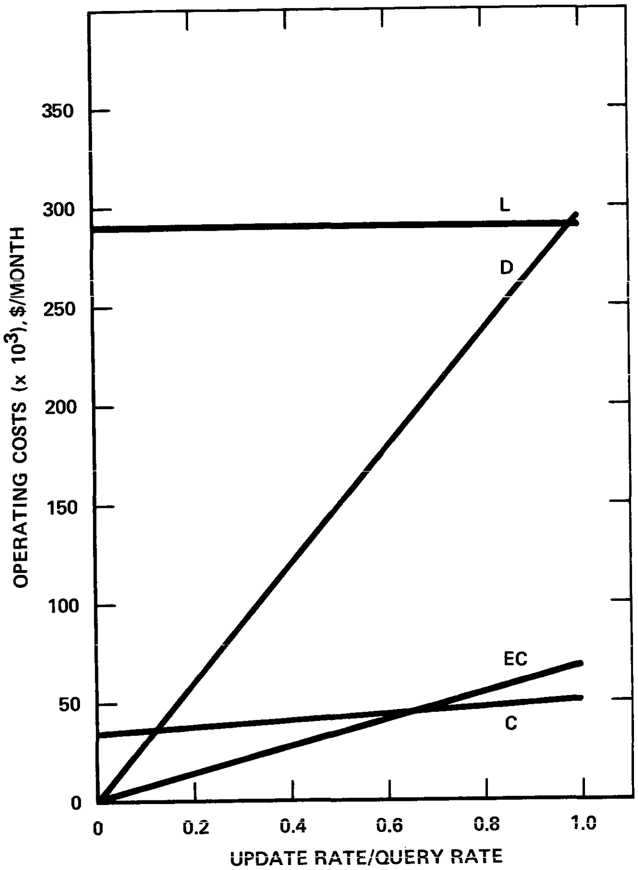
From (3), we have

$$a_{EC}=\sum_{\substack{i=1\\ i\neq d}}^{n}C_{id}{}^t s_{id} l_i q_i+\sum_{\substack{i=1\\ i\neq d}}^{n}q_i T_i+\sum_{\substack{i\neq k\\ i=1}}^{n}\sum_{\substack{k\neq d\\ k=1}}^{n}q_i\beta_{ki}(C_{dk}{}^t s_{dk} l_k+T_{dk})$$

$$b_{EC}=C_d{}^s(F+F_e)+\sum_{\substack{i=1\\ i\neq d}}^{n}\alpha_i C_i{}^s F$$

Substituting a_c, a_{EC}, b_c, and b_{EC} into (10) and simplifying, we have

$$P(c,EC)=\frac{C_d{}^s F_e-\sum_{\substack{i=1\\ i\neq d}}^{n}\alpha_i C_i{}^s F+\sum_{\substack{i=1\\ i\neq d}}^{n}2T_i q_i+\sum_{\substack{i=1\\ i\neq d}}^{n}2C_{id}{}^t s_{id} l_i q_i}{\sum_{\substack{i\neq k\\ i=1}}^{n}\sum_{k\neq d}^{n}q_i\beta_{ki}(C_{dk}{}^t s_{dk} l_k+T_{dk})} \qquad (11)$$



(c) Directory operating cost vs. normalized directory update rate. Query rate=1000/month

In order to simplify equation (11), we assume that (1) the communication cost is much higher than the storage cost so that the storage cost becomes negligible, (2) all the computers in the system are using the same software code, thus translation cost is not required; that is, $T_i=0$, and (3) $\beta_{ki}=\beta$, $l_i=l$, and $q_i=q$ for all i, then (11) reduces to

$$P(c,EC) \doteq \frac{2}{(n-1)\cdot\beta} \qquad (12)$$

For example, if $n=10$ and $\beta=1/3$, then $P(c,EC)=2/3=0.667$. Thus for a network with ten computers operated in the above stated environment, when the directory update rate of each computer is less than 67 percent of its query rate, the extended centralized directory system yields a lower operating cost than that of the centralized directory system.

We shall now consider the directory operating cost tradeoff between the centralized directory system and the distributed directory system. From (9), we have

$$a_D=\sum_{i=1}^{n}\sum_{\substack{k=1\\ i\neq k}}^{n}(C_{ik}{}^t s_{ik} l_i+T_{ik})\,q_i$$

$$b_D=\sum_{i=1}^{n} C_i{}^s F$$

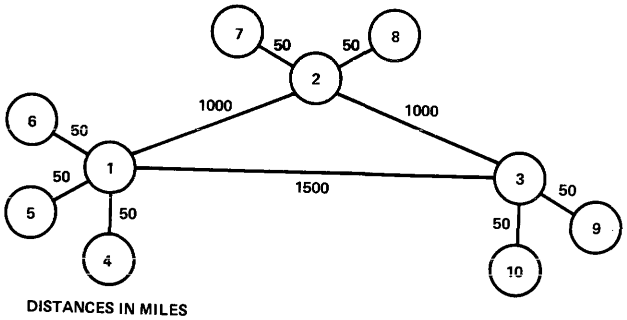


Figure 2—Performance of directory system for a distributed network. $C^t/C^s=10$ month/mile—(a) A distributed network

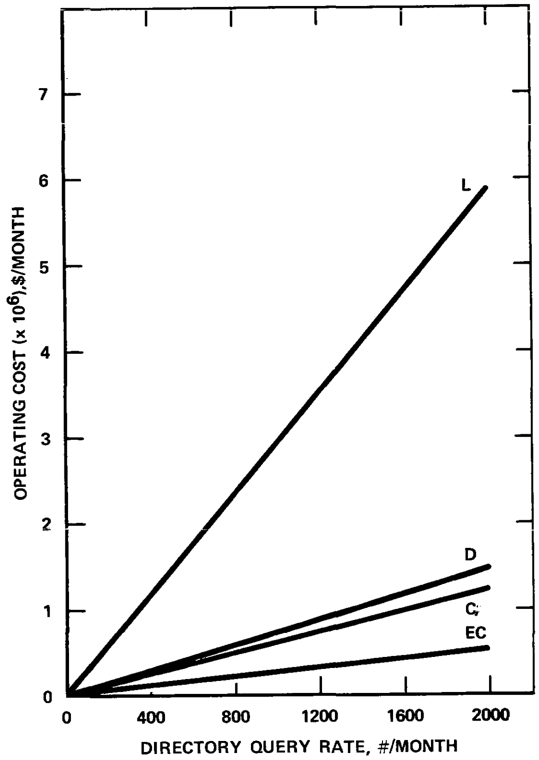
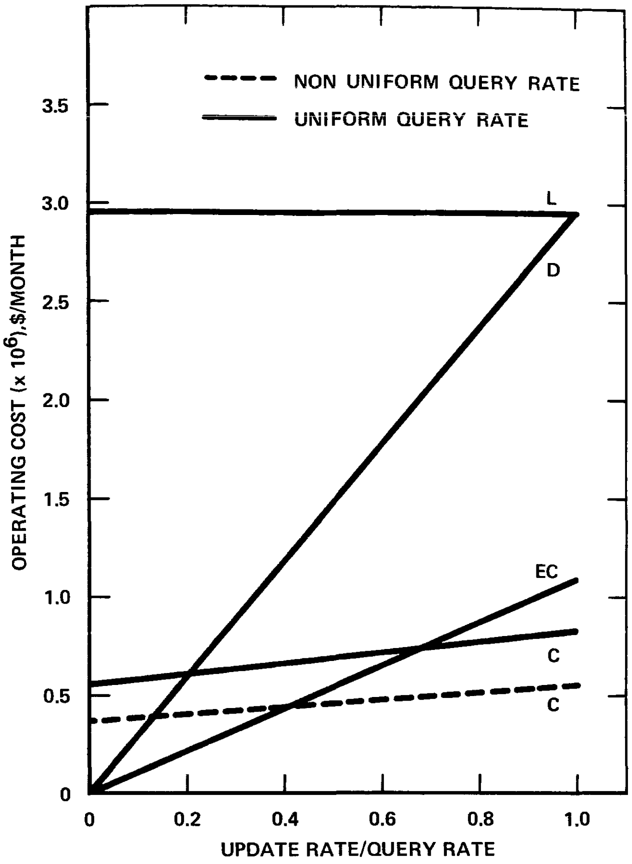
Substituting a_c, a_D, b_c, and b_D into (10), we have

$$P(c,D)=\frac{-\sum\limits_{\substack{i=1\\ i\neq d}}^{n} C_i{}^s F+\sum\limits_{\substack{i=1\\ i\neq d}}^{n} 2C_{id}{}^t s_{id} l_i q_i+\sum\limits_{\substack{i=1\\ i\neq d}}^{n} 2T_i q_i}{\sum\limits_{\substack{i=1\\ i\neq k}}^{n}\sum\limits_{\substack{k=1\\ i\neq d}}^{n}(C_{ik}{}^t s_{ik} l_i+T_{ik})\,q_i} \qquad (13)$$

Compared with the communication cost, the storage cost again can be assumed to be negligible. Further we



(b) Directory operating cost vs. directory query rate. Normalized directory update rate=0.25



(c) Effect of query rate on operating cost. Master directory at computer 1. Uniform query rate query case: $q_i=1000$ queries/month, $i=1, 2, \ldots, 10$; Non-uniform Query Case: $q_i=1500$ queries/month $i=1, 2, \ldots, 5$ and $q_i=500$ queries/month, $j=6, 7, \ldots, 10$

assume that $l_i=1$, $q_i=q$, for $i=1,2, \ldots, n$; $C_{ik}{}^t s_{ik} \doteq C_{id}{}^t s_{id}$ and $T_i=T_{ik}=0$. Then (13) reduces to

$$P(c,D) \doteq \frac{2}{(n-1)} \tag{14}$$

For a network with ten computers operated in the above stated environment, from (14) we know that $P(C,D) \doteq 0.22$ which implies that when the directory update rate is less than 22 percent of its query rate, the distributed file directory yields a lower operating cost than the centralized file directory.

We shall now consider the intersection of the local file directory cost curve $C_L(P)$ with the distributed file directory cost curve $C_D(P)$. From (6), we have

$$a_L = 0$$

$$b_L = \sum_{i=1}^{n} \sum_{\substack{k=1 \\ i \neq k}}^{n} [C_{ik}{}^t s_{ik} l_i q_i + T_{ik} q_i]$$

Substituting a_L, a_D, b_L and b_D into (10), we have

$$P(L,D) = \frac{-\sum_{i=1}^{n} C_i{}^s F + \sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} (C_{ik}{}^t s_{ik} l_i + T_{ik}) q_i}{\sum_{i=1}^{n} \sum_{\substack{k=1 \\ i\neq k}}^{n} (C_{ik}{}^t s_{ik} l_i + T_{ik}) q_i} \tag{15}$$

When $C_{ik}{}^t \gg C_i{}^s$, $P(L,D) \to 1$. This implies that when the communication cost is high as compared to the storage cost and when the directory update rate is less than the directory query rate, the distributed file directory system yields a lower operating cost than that of the local file directory system.

Comparing the approximate results obtained from Equations (12), (14), and (15) with those from direct computation as shown in Figure 3, we note that they agree quite well at high communication cost. Therefore (12), (14), and (15) may be used to estimate the approximate operating cost tradeoffs for high communication cost cases.

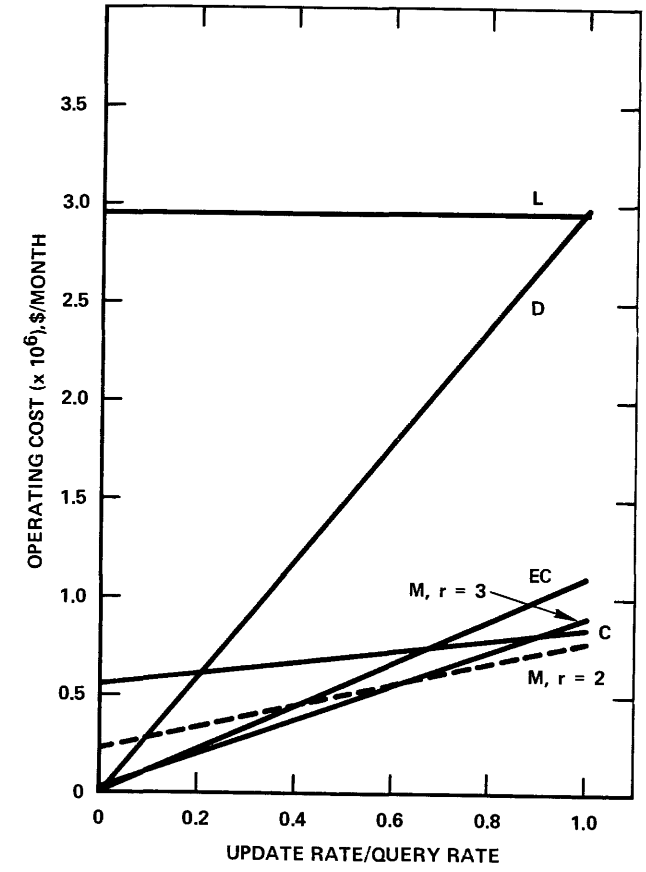


Figure 3—Performance of multiple directory systems for the distributed network. $C^t/C^s=10$ month/mile, and query rate$=$1000 queries/month. For $r=2$, master directories at computers 1 and 2; For $r=3$, master directories at computers 1, 2, and 3

DIRECTORY QUERY RESPONSE TIME

In this section, we shall consider the query response time for various directory systems. The expected response time for the i^{th} computer to query its directory is defined as from initiation of a query at the i^{th} computer to the directory until the start of its reception. The expected response time consists of the waiting time at the input queue of the directory for processing the query $t_1(i)$, the waiting time at the output queue of the directory for transmission $t_2(i)$, the time to transmit the query to and its reply from the directory $t_3(i)$, and the directory processing time $t_4(i)$. The processing time consists of code translation, searching, and accessing. It depends on the file structure of the directory as well as the access time of the storage device and could be different from one system to another and should be known to the users. Here, therefore, we only consider the delay incurred at the input queue and output queue(s) of the directory, and the time to transmit the query on the communication channel. Let us denote the sum of these components as $t_{i,d}$, known as the directory query response time from the i^{th} computer to the directory; thus

$$t_{i.d}=t_1(i)+t_2(i)+t_3(i) \tag{16}$$

Clearly, the real query response time incurred by the users, $t^r_{i.d}$, is equal to the sum of $t_{i.d}$ and $t_4(i)$.

The arrivals at the input queue of the directory are the queries and updates generated by all the computers. The arrivals at the output queue(s) of the directory are the query replies generated at the directory. We shall assume these query arrivals can be approximated by a Poisson Process. The time between interrupts by the computer to process directory queries is $1/\mu_1$. Since the communication line transmits at a constant rate of R characters/second, the time to transmit (send or reply) a query of l character is $1/\mu_2=l/R$. Under these conditions, the waiting time can be computed from known queuing theory results. The average waiting time for a single server queuing system with Poisson arrivals and constant service time,[5] M/D/1, is

$$W=\frac{1}{\mu}\cdot\frac{\lambda}{2(\mu-\lambda)}$$

where

$1/\mu$ = time to service a query in seconds
λ = average number of queries arrived/second

Assuming that queries and their replies generated at the directory input and output queues can be approximated as a Poisson process, then the query response time equals

$$t_{i,d}=t_1(i)+t_2(i)+t_3(i)=\frac{\lambda_1}{2\mu_1(\mu_1-\lambda_1)}+\frac{\lambda_2}{2\mu_2(\mu_2-\lambda_2)}+2/\mu_2 \tag{18}$$

Let us first consider the centralized directory system. The total number of queries arriving at the directory, λ_d, consists of directory queries and their updates from all the computers in the system. Thus $\lambda_1=\lambda_d=\sum_{i=1}^{n}q_i(1+p_i)$. Since the directory does not have to reply to update traffic, and since each destination has its own output queue, the arrival rate at the output queue for the i^{th} computer is equal to $\lambda_2=\lambda_{di}=q_i$. By substituting λ_1 and λ_2 into (18), we have

$$t_{i,d}=\frac{\sum_{i=1}^{n}q_i(1+p_i)}{2\mu_1\left[\mu_1-\sum_{i=1}^{n}q_i(1+p_i)\right]}+\frac{lq_i}{2R[R/l-{}_iq]}+\frac{2l}{R} \tag{19}$$

For the computer that stores the master directory, $t_2(d)=t_3(d)=0$. The expected query response time $t_{d.d}=t_1(d)$.

Let us now consider the extended centralized directory system. For those files that have not yet been queried at the directory by the i^{th} computer, the response time is similar to (19) except that the directory query rate is much smaller and the directory output queue for the i^{th} computer should also include the update traffic (generated by all the computers) for the i^{th} computer. For those files whose directory information has already been appended to the local directory at the i^{th} computer, there is no need for the i^{th} computer to consult the master directory about these files. Thus the query response time reduces to $t_{i,d}=t_1(i)$.

For multiple master directory systems, since the directory queries are shared by the multiple master directories, the waiting time for processing the directory queries at each master directory is much lower than the single master directory system. Therefore, the response time for the multiple master directory is lower than that of the single master directory system. The query arrival rate at the k^{th} master directory d_k is $\lambda_1=\lambda_{d_k}=\sum_{\{i\}\epsilon d_k}q_i+\sum_{i=1}^{n}p_iq_i$ and the query reply rate at the output queue for the i^{th} computer is $\lambda_2=q_i$. Thus the response time for the i^{th} computer to the k^{th} master directory can be computed from (19) by replacing the $\sum_i q_i(1+p_i)$ in the first term of (19) by $\sum_{\{i\}\epsilon d_k}q_i+\sum_{i=1}^{n}p_iq_i$. When directory queries are generated by those computers that store the master directories, these query replies do not require transmission. Thus the response time equals $t_1(d)$.

For the local directory system whose replies are returned directly to the sender (i.e., without routing), the i^{th} computer may locate the information of the file before reaching the k^{th} local directory. Therefore on the average only half of the queries generated at the i^{th} computer will reach the k^{th} computer. Thus the query arrival rate at the input queue of the k^{th} local directory is $\lambda_1=\frac{1}{2}\sum_{i=1}^{n}q_i$, where q_i = directory query rate generated by the i^{th} computer. Assuming there is an output queue for each destination at the k^{th} computer, then the arrival rate at the output designated for the i^{th} computer is $\lambda_2 = q_i$. Substituting λ_1 and λ_2 into (18), we have

$$t_{i,k} = \frac{\sum_{i=1}^{n} q_i}{4\mu_1\left(\mu_1 - \frac{1}{2}\sum_{i=1}^{n} q_i\right)} + \frac{lq_i}{2R[R/l - q_i]} + \frac{2l}{R} \tag{20}$$

Because the local directory system uses routing, queries are passed around from one directory to another rather than sent directly to the sender. With a carefully designed routing strategy, the input traffic rate λ could be greatly reduced. Further the third term of (20) reduces to half of its value. Therefore, the query response time for the system with routing could be much smaller than that without routing.

Assuming all the files in the data base are equally likely to be stored in any local directory system, the time to locate a file by the i^{th} computer is

$$t_i = \frac{1}{2}\sum_{k=1}^{n} t_{i,k} \tag{21}$$

and the real expected directory response time for the i^{th} computer is

$$t_i^r = \frac{1}{2}\sum_{k=1}^{n} [t_{ik} + t_4(k)]$$

For the distributed directory system, each computer has a master directory. Public file information can be obtained from the file directory at the user's computer. Thus, $t_2(i) = t_3(i) = 0$. The query arrival rate at the directory input queue is $\lambda_1 = q_i\left(1 + \sum_{k=1}^{n} p_k\right)$. The expected directory query response time reduces to

$$t_{i,i} = t_1(i) = q_i\left(1 + \sum_{k=1}^{n} p_k\right) \Big/ \left\{2\mu_1\left[\mu_1 - q_i\left(1 + \sum_{k=1}^{n} p_k\right)\right]\right\} \tag{22}$$

NUMERICAL COMPUTATIONS

From the models we developed in the last section, we know that the operating cost of the directory system depends on many parameters such as network topology, transmission cost, storage cost, translation cost, directory query rate, directory update rate, and directory size. Although the models are formulated in general terms and can be applied to different parameter values, in order to draw some meaningful conclusions as well as limit the number of study cases, we shall select two types of network topologies: a star network which has the property that the distances from the center node to all the computers are equal, and a distributed network of computers that forms clusters, the distances among these clusters being unequal. In our example we assume that all the computers in the system have the same storage cost, code translation cost, and directory update rate; the size of the master file directory is directly proportional to the number of computers in the system; all communication channels have full duplex capabilities and the same communication cost. First, we study the star network as shown in Figure 1a. We computed the monthly operating cost as a function of file directory query rate and directory update rate for various directory systems. Numerical results are shown in Figures 1b and 1c. The parameters used in this example are: $C^t/C^s = 10$ month/mile, $T/C^s = 2000$ byte month/transaction, $C^s = 7.0 \times 10^{-5}$ \$/byte month, $F = 6 \times 10^5$ bytes, $F_1 = 3 \times 10^3$ bytes, $l = 50$ bytes, $\alpha = 0.1$, $\beta = 1/3$, and $q = q_i = 1000$ queries/month. The directory update rate is expressed in terms of the normalized directory update rate which is the ratio of directory update rate to directory query rate.

In the same manner, we study the distributed network which consists of ten computers that forms into three clusters as shown in Figure 2(a). Using the same parameter values as for the star network, we compute the monthly operating cost as a function of directory query rate and normalized directory update rate. The results are given in Figures 2(b) and 2(c).

So far we have assumed that each computer has the same directory query rate. We shall now relax this assumption and let the query rate at each computer be different. In order to compare with the uniform query rate case, we let the total number of directory queries generated from all the computers remain the same but vary the query rates among the computers. For example, we let computers 1, 2, 3, 4, and 5 have a rate of 1500 queries/month and others 500 queries/month. The results reveal that the operating cost of the centralized directory system with the above stated query rate is lower than that of the case that 1000 queries/month generated from each computer (Figure 2(c)). On the other hand, if we interchange the directory query rate of computers 1 to 5 with computers 6 to 10, then the operating cost of the centralized directory system with the above non-uniform query rate is higher than that of the uniform query rate case.

Next, we study the operating cost characteristics of the multiple master directories system. According to the distance among computers, we partitioned the ten computers into three groups in which each computer belongs to one of the three master directories. We evaluate the monthly operating costs as a function of directory update rate from Equation (5) and compare them with those of the extended centralized directory system, the local file directory system, and the distributed directory system as shown in Figure 3.

Figure 4 shows the operating cost trade-offs for file directory systems as a function of the ratio of communication cost to storage cost. The results are obtained from the intersection of the operating cost curves un-

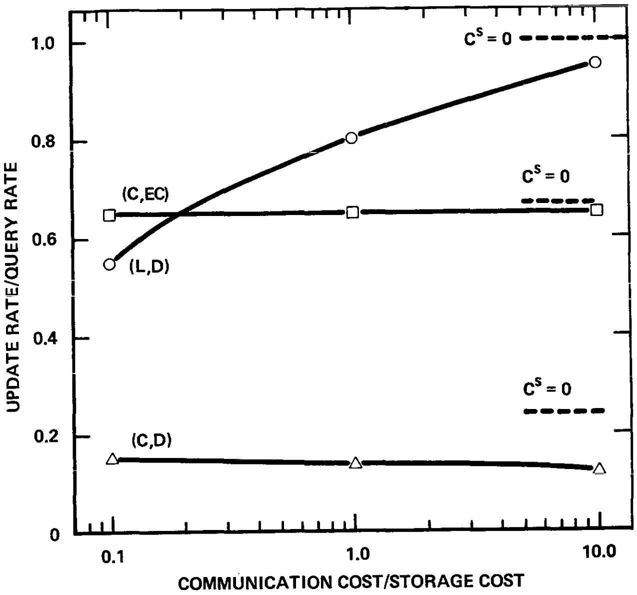

Figure 4—Cost trade-offs for various directory systems. (x,y) = cost trade-offs for directory systems x and y—(a) Star network

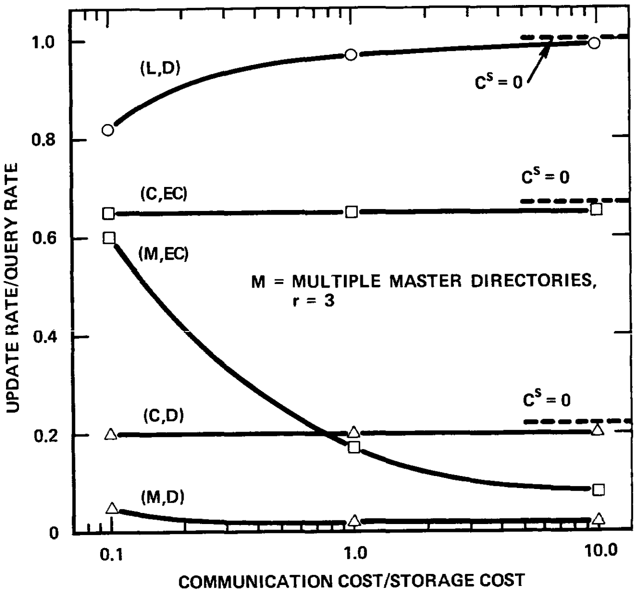
der various communication cost to storage cost ratios.

Finally, we study the query response time for the three classes of directories. The time between interrupts to process the directory is assumed to be equal to the time required to transmit the query; that is, $1/\mu_1 = 1/\mu_2 = 1/R$, where R is the transmission rate of the communication channel. Numerical results of the delay occurring at the directory input queues, directory query response time, and the traffic intensities with $R = 960$ char/sec are portrayed in Figure 5.



(b) Distributed network

DISCUSSION OF RESULTS

From the numerical examples studied in the last section we notice that the operating cost of the file directory depends greatly on the directory query rate and the directory update rate. Because of the large amount of data communication and translation associated with the directory updates in the distributed directory system, the rate of increase in operating cost with respect to directory update rate for the distributed directory system is higher than that of the centralized directory system. In the local directory system, we only need to update the local directory that generates the update and no transmission is required. Therefore, the operating cost is independent of the directory update rate. For a given network topology the operating costs of the local directory systems are higher than the centralized directory systems.

Assuming that the transmission cost is higher than the storage cost, our study reveals that when the directory update rate is low (e.g., less than 10% of the query rate), the distributed directory system yields lower operating costs than the centralized directory system. As directory update rate increases, the oper-

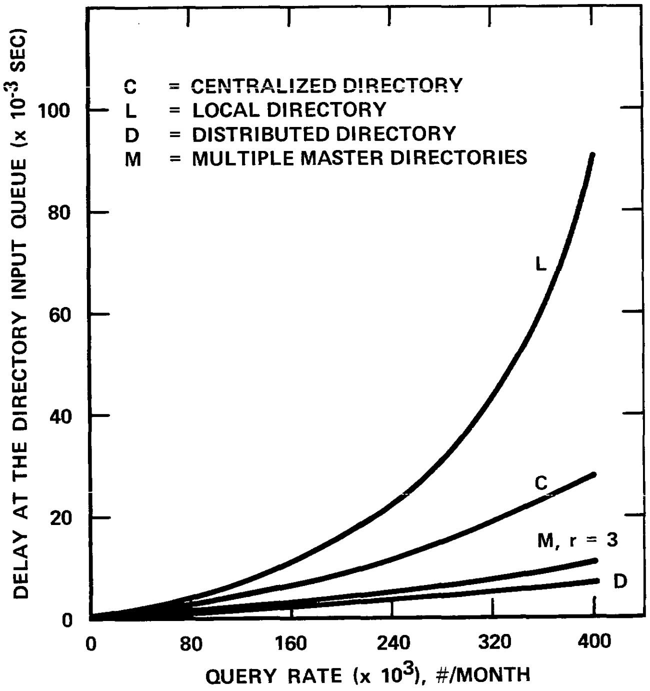


Figure 5—Expected queuing delay time for various directory systems—(a) Expected delay at the directory input queue vs. directory query rate. Normalized directory update rate=0.5

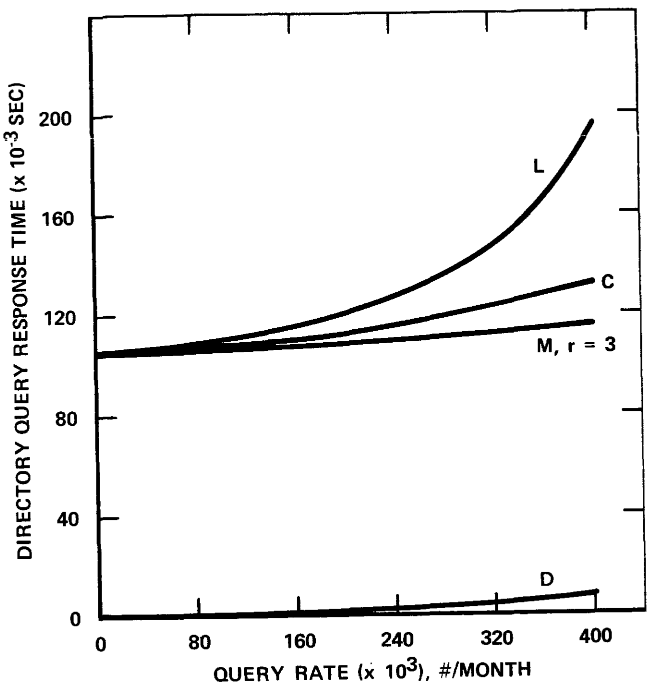
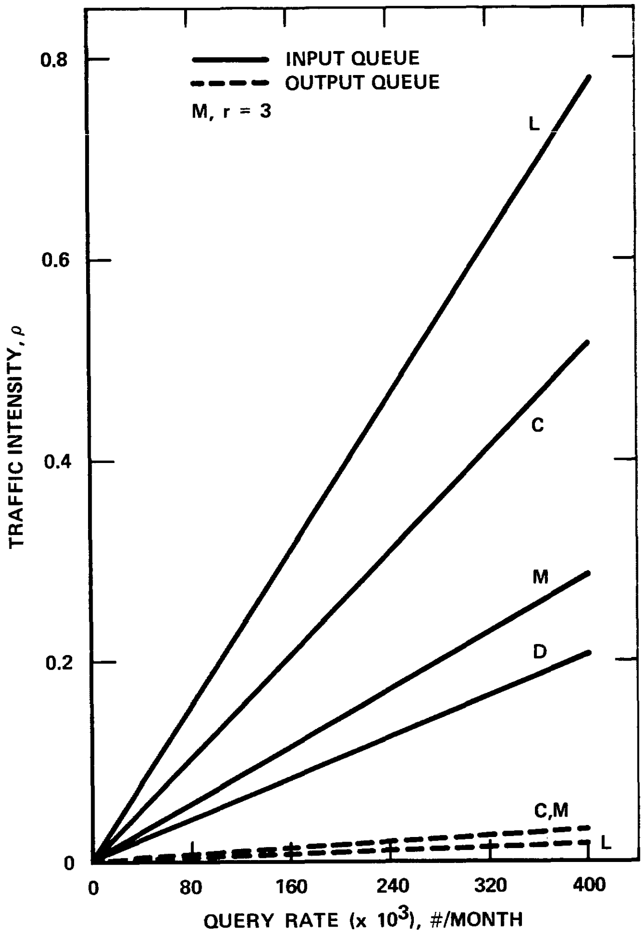


(b) Expected directory query response time vs. directory query rate. Normalized directory update rate=0.5

ating cost of the centralized directory system yields lower operating costs than the distributed directory system.

Comparing the two types of centralized directory systems, the extended centralized directory yields lower operating costs than the centralized directory at low directory updating (less than 50% of the query rate), and the performance reverses at high directory update rates. This is because of the excessive data communications required in the extended centralized directory system to update all the extended local directories. The exact cross-over point of the operating cost curves for these two types of directory systems depends on network topology and such parameters as storage cost, transmission costs, translation costs, etc. As the directory update rate increases, the performance characteristics of the extended centralized directory system become similar to that of the distributed directory system.

We also studied the influence of the distribution of the directory query traffic on the operating cost. In order to provide a common base for comparison, we kept the total number of queries generated by the computers to be a constant, and varied the query traffic among the computers. We found that the traffic distribution does not have an effect on the directory operating cost when all the computers are equal distances from each other, and does have an effect on the operating cost when the distances among the computers are different.



(c) Traffic intensity vs. directory query rate. Normalized directory update rate=0.5

When a network of computers forms in clusters (Figure 2(a)) and when their directory update rates are low, our studied example reveals that installing a master directory at each cluster requires less communication cost and therefore yields better performance than the extended centralized directory system as shown in Figure 3.

Figure 5(a) displays the queuing delay occurring at the input of the directory. The queuing delay increases as the query rate increases. Except in the local directory case, the queuing delay increases as the directory update rate increases. This is because the update messages are considered as input traffic to the directory. Since the input traffic to the multiple master directory system is shared among the master directories, it yields lower queuing delay than the centralized directory system. In the distributed directory system, the input traffic consists only of queries generated from its initiator and the directory updates generated from the rest of the computers in the system. Therefore such systems have the lowest delay at the directory input queue. Figure 5(b) displays the query response time for different types of directory systems. For the range of query rates that we have studied, the time spent in transmission to and from the directories constitutes a large portion of the delay. Since the distributed directory system does not require such transmission, it yields the lowest query response time. In the extended centralized directory system, the directory output traffic also has to include directory update traffic; therefore, the query response time of the extended centralized directory system has similar characteristics but slightly higher than those of the distributed directory system. Figure 5(c) displays the traffic intensity of the directory input queue and the directory output queue as a function of query rate. The traffic intensity provides an indication of the level of traffic at input queue and output queue(s) at the directory.

CONCLUSION

Based on the computer network topology, communication cost, storage cost, code translation cost, directory query rate, and directory update rate, we studied the cost-performance tradeoffs of the three classes of directory systems. Assuming that the transmission cost is much higher than the storage cost, our study reveals that for low directory update rates (less than 10% of the query rate), the distributed file directory yields a lower operating cost than the centralized directory system. When the update rate is greater than about 15% of the query rate, the centralized directory yields a lower operating cost than the distributed file directory system and also the local directory system. The extended centralized file directory system yields a lower operating cost than the centralized directory systems at low directory update rate (for example, less than 50% of the query rate). For a system which has a very low directory update, for example, less than 5-10% of query rate, the extended centralized directory system should be used. When a network topology forms in clusters and when directory updating is greater than 5-10% of the query rate, multiple directories systems with a master directory at each cluster yield a lower operating cost and directory response time than the extended centralized file directory system.

In the local directory system, because of the large amount of communication costs associated with searching a file when it is not stored in the user's local file directory, the operating cost is much higher than that of the centralized directory system. However, when the directory update rate is very high (greater than 50% of the query rate) and when communication cost is lower than the storage cost, the local directory system yields a lower operating cost than the distributed directory system. Since the local directory system requires a large amount of communications as well as search time for locating a file, efficient routing strategy could greatly reduce the operating cost and query response time in such systems.

We have also studied the cost tradeoffs when the storage cost is equal to or greater than the communication cost. Our study reveals that the cost curves are similar to the cases where the communication cost is higher than the storage cost except the intersection points of these cost curves differ as shown in Figure 4.

Since the distributed directory system and the extended centralized directory system (assuming that the requested file resides in the appended local directory at the user's computer) do not require communication for querying the directory, they yield lower file query response time than those of the centralized directory system and the localized directory system. When using the multiple master directories, the queries generated by the users are shared by the master directories in the system. Therefore, the directory query response time for the multiple directory system is lower than that of the single master directory system.

For a given network topology and operating environment, we can use the models developed in this paper to study the operating cost tradeoffs and directory response time for various directory systems. Such investigation provides us with a guide in designing directory systems for distributed data bases.

ACKNOWLEDGMENTS

The author wishes to thank E. E. Nahouraii of IBM for his stimulating discussion in the formulation of the model and David Lee and Shaila V. Kinariwala of UCLA for their assistance in performing the computation.

ABSTRACT

The growth of computer networks has proven both the need for and the success of resource sharing technology. A new resource sharing technique, utilizing broadcast channels, has been under development as a Packet Radio system and will shortly undergo testing. In this paper, we consider that Packet Radio system, and examine the measurement tasks necessary to support such important measurement goals as the validation of mathematical models, the evaluation of system protocols and the detection of design flaws. We describe the data necessary to measure the many aspects of network behavior, the tools needed to gather this data and the means of collecting it at a central location; all in a fashion consistent with the system protocols and hardware constraints, and with minimal impact on the system operation itself.

INTRODUCTION

This paper is primarily concerned with the unique measurement aspects of Packet Radio Systems as regards network evaluation, and considers the design of a set of measurement facilities, the development of data gathering techniques within the framework of the system design and the use of these measurements to evaluate the system performance and its operational algorithms.

The need for sharing of computer resources by organizing these resources into computer networks has been long recognized[1] and the feasibility of constructing such networks has been demonstrated by many successfully operating network systems. Perhaps the most prominent example is the ARPANET,[2] which utilizes the technique of packet-switching, appropriate for bursty computer network traffic, thus achieving better sharing of the communication resources.

The ARPANET emerged in 1969 as the first major packet-switching network experiment; since the essence of an experiment is measurement, and in line with Hamming's observation that "it is difficult to have a science without measurement", considerable care was taken from the beginning in the design and development effort to include the tools necessary and appropriate to satisfy the many measurement goals. As a result of well designed experiments on the ARPANET using these tools, valuable insight has been gained regarding the network usage and behavior.[3]

The Packet Radio System is another yet different example of a computer resource sharing network.[4] It is being developed by the Advanced Research Projects Agency in order to demonstrate the applicability of the packet radio concept in organizing computer resources into a computer communications network. It is this packet radio network which is of concern to us in this paper. The network is currently in its design phase,* and, as was the case with the ARPANET, care is being taken to include the ability to measure network behavior. UCLA is in charge of this measurement effort.

This concern for measurement is due to several factors. Firstly, these measurements provide a means to evaluate the performance of the operational protocols employed and the identification of their key parameters. Moreover, this realistic observation of the system behavior will assist in the validation and improvement of existing analytical models devised to study some of these operational schemes, such as the access modes and routing strategies.[5,6] Secondly, these measurements will allow for the detection of system inefficiencies and the identification of design flaws such as the inadvertent creation of a deadlock condition.[7] Thirdly, measurement facilities and data, when used to improve network design, are a valuable feedback process in which design deficiencies are detected and subsequently corrected. Wire networks differ from radio networks mainly in the omni-directional broadcast nature of the communication and consequently the protocols employed; therefore, it calls for new approaches in the design and implementation of the measurement facilities and their use.

* This work was supported by the Advanced Research Projects Agency of the Department of Defense (DAHC-15-73-C-0368).

* A preliminary demonstration of the system is under way. A prototype network is being set up in the Palo Alto, California, area.

In the following section, we present an overview of the packet radio system concepts and a brief description of the currently specified operational procedures.

In a later section, we describe the network measurement facilities which consist of the measurement tools and the techniques for data collection. In the last section, we identify and discuss in some detail the desirable measurement functions to satisfy the need for validation and performance evaluation outlined above.

THE PACKET RADIO SYSTEM

Several papers have already appeared in the literature which describe the packet radio concept and discuss many of the issues involved in the system design.[4-6,8-10] In this section, we briefly describe these system components and operational procedures necessary to understand the measurement considerations presented below.

There are three basic functional components of a packet radio system:

(i) packet radio terminals—these are the sources and destinations of traffic on the packet radio network.

(ii) packet radio stations—these function as S/F switches for local traffic and as interfaces between the broadcast system and other computers or networks. Also, they perform directory, monitoring and control functions for the overall system, and they play a central role in that all traffic passes through the station, i.e., we have a centralized network.

(iii) packet radio repeaters—their function is to extend the effective range of terminals and stations by acting as Store-and-Forward relays.

The repeater, which has been developed by Collins Radio and is called a packet radio unit (PRU), consists of a radio transceiver and a microprocessor. The function of the PRU is to receive and transmit packets according to dynamic routing and control algorithms specified by the station. For simplicity and uniformity of design, the PRU is used as the front-end of terminal devices and of stations, interfacing them with the radio net. In Figure 1 we show an oversimplified picture of the PRU identifying its various sections: the radio transceiver, the store-and-forward software, the control process, and the measurement process.

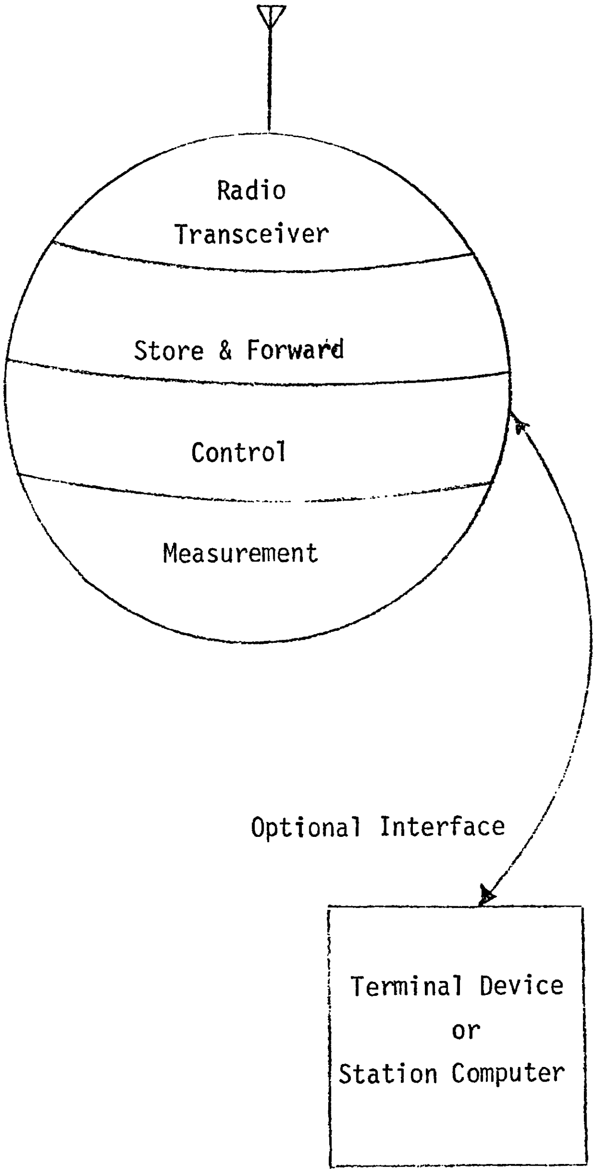

Figure 1—The packet radio unit

In this initial system, the terminals, stations and repeaters are linked together by a single broadcast channel using omni-directional antennas. The repeaters do not determine routes. All the routing computations are performed by the station. A hierarchical routing algorithm is used which makes the routing in the broadcast network resemble routing in a point-to-point network by forming a hierarchical tree structure. This structure is constructed by having the station assign to each repeater a label which defines its position in the tree. A packet is routed along the path determined by the tree, requiring the packet header to contain a string of appropriate repeater ID's, or labels. Thus, neighboring repeaters hearing the broadcasted packet but not on the determined path will reject the packet rather than relay it. However, this algorithm is flexible in that it allows the repeater to seek an alternate route for a packet when a path seems to be blocked. Moreover, the station with its monitoring procedures can dynamically restructure the tree by relabeling any of the repeaters in response to component failures or traffic congestion.

In order to achieve reliable packet transport, acknowledgment procedures are required. There are two types of acknowledgments; the end-to-end acknowledgments (FTE) between end devices, and hop-by-hop acknowledgments (HBH) between repeaters.[6] Except for the last hop on a packet's route, HBH acknowledgments are passive in that the relaying of a packet over a hop constitutes an acknowledgment of the transmission over the previous hop; this "echo acknowledgment" is due to the omni-directional broadcast property. At the last hop, an *active* HBH acknowledgment must be generated.

MEASUREMENT FACILITIES

Several factors exist in the packet radio system which do not allow for a simple transfer of ARPANET-like measurement facilities to a packet radio network. Although the latter utilizes the same technique of packet-switching, the packet radio concept is unique in the constraints it places on all system operations and the measurement effort in particular.

The radio broadcast nature of transmissions is such that the transmission of measurement data not only introduces overhead over its own path, but causes transmission interference at neighboring repeaters within hearing distances and creates additional overhead on those PRU's activities. Moreover, the desire to keep the components small and portable, as well as the limited speed of the IMP's CPU within the PRUs, place significant constraints on the measurement facilities and their usage. The available storage is extremely limited and the overhead placed on the PRU's CPU is of utmost importance in evaluating the feasibility of a measurement tool and of the collection of data in support of a measurement function. As the operational protocols of the net are different from wire nets, the measurement functions devised to support the evaluation of their performance are unique. Thus, the measurement effort consisted of identifying the measurement functions (as described in the following section) and devising the measurement facilities required to support those functions under the constraints that the system imposes. The development of the tools was an iterative design process seeking a balance between supporting the measurement functions and satisfying the system constraints, as well as making sure that the network communication protocols allow the implementation and proper functioning of those tools.

In this section, we describe the various types of statistics desired in the Packet Radio Net,* the traffic sources required in measurement experiments and the techniques available for measurement data collection. We shall postpone until the next section the detailed list of the quantities that will be measured by each of the types of statistics (tools).

Cumulative statistics (Cumstats)

As its name suggests these consist of data regarding a variety of events, accumulated over a given period of time, and provided in the form of sums, frequencies and histograms. We shall distinguish between those data collected at the PRUs (PRU based Cumstats) and those collected at the end devices (the end-to-end Cumstats). The PRU based Cumstats provide information about the *local* environment and behavior such as traffic load, channel access, routing performance, and repeater activity. Conversely, end-to-end statistics collected at network sources and sinks, that is stations and terminal devices, will reflect more global network behavior such as user delays and network throughput.

Trace statistics

The trace capability allows one to literally follow a packet through the network, and to trace the route which it takes and the delays which it encounters at each hop. In the ARPANET, selected IMPs gather data on packets to be traced (which may include any packet) and send this data to the collection point as a new packet. In the packet radio network, however, the collection of trace data at the repeaters is prohibited by the limited size of storage in the PRU. To overcome this problem, we have introduced a new type of packet called the Pickup Packet.* These packets are generated with an empty text field by traffic generators at end devices. As these packets flow normally in the network according to the transport protocols, selected repeaters will gather the trace statistics and will store them within the text field of the pickup packets themselves.

Snapshot statistics

Snapshots give an instantaneous peek at a PRU, showing its state at that moment with regard to buffer assignment and queue lengths. (In the ARPANET, which is a decentralized network in which each node contains routing algorithms and data, snapshots also include routing related information; in the Packet Radio Network, such information is available at the station). Changes to appropriate station tables will be time stamped and collected as the station's snapshot function.

Artificial traffic generators

Traffic sources

The creation of streams of packets between given points in the net, with given durations, intervals,

* These types of statistics, as well as traffic generators, which have been widely used in ARPANET measurement experiments, will differ significantly from those of the Packet Radio Network in regards to the specific quantities gathered and the means of collecting them at a central location.

* The notion of the pickup packet was first suggested by H. Opderbeck.

packet lengths, and packet types (Information and Pickup Packets) is clearly a requirement of any experimental system. While it might be desirable to provide each PRU with the capability of creating such traffic, this additional burden on the PRU software can be avoided if there exists a reasonable number of terminals with processors attached which, along with the station, will be programmed to provide the traffic-source functions indicated above.

Specifically, traffic-source features which the terminals (and Station) should provide are: (1) Information Packets—the user specifies the packet length, frequency, destination and duration of one or more streams of Information Packets. (The text content may be arbitrary.) (2) Pickup Packets—the user specifies the packet length, frequency, destination and duration of one or more streams of Pickup Packets.

In the initial system, there will be a limited number of system elements, making it desirable to simulate in a terminal a multi-terminal environment. That is, the traffic generated at a single terminal will emulate the traffic that would be generated by several separate sources. A great deal of complexity is introduced in the design of these devices because of the hardware and software capabilities required to support this function. Feasibility and techniques of achieving this is under investigation.

Station measurement process

Since the station is the central node and provides central control for the operation of the entire network it therefore plays a central role in the execution of measurement functions. It is through the station that the initiation and termination of measurement experiments is controlled. In particular, the station enables and disables the Cumstat and Pickup packets functions at the PRU's, and assigns to the various elements the intervals for Cumstat collections, and to the artificial traffic generator, their corresponding parameters. Moreover, it is to the station that all measurement data is ultimately destined; upon arrival at the station, the data is time-stamped and stored in a single measurement file for off-line reduction and analysis. In addition, all changes to the station's internal tables (routing, connectivity, PRU operational parameters, etc.) will be reflected by an entry into the measurement file, thus allowing the correlation of measurement results to the actual network configuration. A (measurement) process at the station will perform all of the above functions.

Measurement data collection

As mentioned earlier, pickup packets are generated at stations and terminals. Those packets generated at a terminal are destined to (and collected at) the station; those generated by the station will be returned by their destinations to the station as regular packets for collection into the measurement file.

Let us now discuss the techniques for centrally collecting cumulative statistics. The data, generated at the PRU's or terminal devices, must be transmitted to the station using the PR Net itself. One way of achieving this is to form at the PRU, at the end of each Cumstat interval, a measurement packet called the Cumstat packet, which is time-stamped and transmitted to the station. The second method consists of having the station send at regular intervals to appropriate PRU's an executable control packet* called an Examine packet which collects time stamped Cumstat data and which returns back to the station.

For purposes of analysis, it is desirable for the Cumstat data received at the station to correspond to equal length time intervals at the generating device. This can be achieved in the automatic method if reliable ETE transmission exists, i.e., if ETE acknowledgment capabilities are provided in all terminal devices and PRU's, preventing the loss of a Cumstat packet from a device on its way to the station. In the absence of the ETE capability in the PRU's, one may decrease the Cumstat intervals (thus increasing the frequency of transmitting Cumstat data), thereby decreasing the gaps between correctly received Cumstat packets. With the Examine method, variable length Cumstat intervals will occur since Examine packets, sent at regular intervals from the station, are subject to (i) the network random delays en route to the destination PRU, and (ii) the possibility of loss in either direction.

The choice of a collection method will have to take into consideration the overhead that it imposes on the PRUs and on the network.

MEASUREMENT FUNCTIONS

We have described in the previous section the measurement facilities that are desirable in a PRNET to support the measurement functions. In this section we shall identify and discuss these functions in some detail, determine the required data items and describe the role of these measurement facilities in supplying the data. These include: channel access, operational protocols, repeater performance, traffic characteristics, and the network's global performance.

Channel access

One of the main features that distinguish the Packet Radio Network from point-to-point networks is that

* An executable control packet is a packet that originates at the station and is destined to a PRU. It contains code to be executed by the destination PRU. In particular, the Examine packet contains the necessary code to load the contents of specified memory locations into the text of the packet for shipment back to the station.

devices transmit packets over a broadcast channel by using a random access scheme. These random access schemes are characterized by the sharing of a single channel in a multi-access fashion, thus allowing for packet interference to occur. Considerable progress has been made in analyzing these access modes, which include pure and slotted ALOHA and the more recently developed techniques of Carrier Sense Multiple Access (CSMA).[5,11-13] In the initial experimental system pure ALOHA, 1-persistent CSMA and non-persistent CSMA will be available. Our measurement aims are to validate the analytical models of the three access modes and to evaluate their performance in realistic environments.

In evaluating terminal access in a single hop system (a model commonly used in analysis), we consider an environment consisting of a single station and a population of terminals within range and in line-of-sight of the station. In order to determine the relationships between the network throughput (rate of successfully received packets at the station) and channel traffic (rate of packet transmissions over the channel), as well as the relationships between the network throughput and packet delays, the following quantities will be measured:

(a) the number of transmissions a packet incurs before success

(b) the one-hop packet delay: time elapsed since the packet is ready for transmission until it is acknowledged, i.e., until its acknowledgment packet is received from the station

(c) network throughput: average number of packets received at the station per unit time

Items (a) and (b) are obtained in the form of histograms by the Cumstat tools at the PRU and the end device respectively. Item (b) may also be obtained individually for each Pickup packet by having the originating device store in it its time of generation and its transmission times, and in the succeeding Pickup packet, store the time its acknowledgment arrived. Item (c) is obtained at the station from end-to-end cumulative statistics.

The task of measuring performance of terminal access techniques in multi-repeater environments differs from the previous one in that repeater-to-repeater traffic is present contending on the same channel. The environment consists of a number of repeaters and stations and a population of terminals, not necessarily all within range and in line-of-sight. The same quantities as listed above, measured over the terminal-to-repeater hop, will be collected using the same tools.

Operational protocols

Acknowledgment protocols

Echo acknowledgment suffers from packet interference. The delay until the echo acknowledgment is received at the transmitter is random. Thus, the packet may incur some additional transmissions beyond the first successful one creating additional overhead on the channel and in the PRUs. This number of additional transmissions is a measure of the inefficiency of echo acknowledgments; so too will be the number of packets discarded at the transmitter because of lack of reception of the echo acknowledgment. That is, the transmitter reached the maximum number of retransmissions of a packet before the echo acknowledgment was received; although the packet may have been successful, the transmitter declares itself unsuccessful in establishing communication!

Thus, we shall measure the efficiency of the Echo Acknowledgment protocol by measuring the number of additional transmissions beyond success incurred by a packet. To compute this number, a PRU must have two pieces of information; it must know how many times the packet has been transmitted, and it must also know which of those retransmissions was the one that reached the next repeater successfully. This information will be contained in two fields in each packet header, which we refer to here as fields A and B. Field B is used by the PRU to store the current transmission number of the packet. When the packet is successfully heard by the intended receiver, the contents of field B are saved by being stored into field A; when the Echo acknowledgment is successfully heard by the sending PRU, field A of the echo acknowledgment is compared with the current number of transmissions of the packet, i.e., the contents of field B in the sender's copy of the packet. If these two numbers differ, then the magnitude of that difference represents the number of times that the packet was retransmitted after it had already been successfully received at the next hop. This data is collected as part of the cumulative statistics of the sending PRU.

Routing protocols

Earlier we introduced the hierarchical routing scheme in use, which is based on a tree structure with the station as its root. The initial tree structure is created dynamically by the Initialization Procedure in which the station uses PRU connectivity information to create a tree that minimizes the number of hops between each repeater and the station. Thus the routing strategy initially performs shortest path (minimum hop) routing from repeaters to station and from station to repeaters. However, when the first choice shortest path cannot be used, the packet departs from this path and uses a shortest path from its new location. This will occur when a repeater has transmitted a packet over a hop the maximum number of times allowed without receiving an HBH acknowledgment; the repeater then alters the packet's header (to what is called the "ALL" label) so that any repeater within hearing distance and able to relay the packet in its intended direction will do so. This packet is then said to be alternately routed. It is retransmitted with its "ALL" header until either an HBH acknowledgment is received or the maximum number of retransmissions is once again reached, at which time the packet is discarded.

The analysis of a routing algorithm, particularly in a broadcast, and thus mobile, network, is a complex task, in that routing is topology- and load-dependent, and involves, with varying degrees of subtlety, all of the system's protocols. Thus, routing considerations are really a synthesis of most elements of the system design, and as such, the measurement of the algorithm involves at times the study of the interaction of the many system protocols.

Given the patterns of input load on the network, the *distribution of traffic flow* in the net is an indication of the behavior and efficiency of the routing and initialization algorithms. One may detect the concentration of traffic on specific routes creating congestion while alternate routes are not assigned; thus smaller delay routes may have been ignored in favor of the shorter routes provided by the initialization procedure.

To obtain the distribution of traffic flow, the following quantities are to be measured.

(a) the total number of packets received and transmitted at each repeater (obtained in the PRU Cumstats)

(b) the fraction of time the transceiver is busy (obtained by snapshot statistics, or in the PRU Cumstat by regular sampling of the transceiver's state)

Also, the point-to-point nature of this routing algorithm, restricting a packet at a given hop to a single repeater as its immediate destination, does not take advantage of the broadcast nature of the channel, in which several neighbors may actually hear the transmission and be capable of relaying the packet. Thus the following quantity is relevant:

(c) the number of packets correctly received and discarded because they are destined to other components in the net (obtained in the PRU Cumstat).

Moreover, to measure the potential of each neighboring repeater (say, repeater "n") as an immediate destination, it is essential to know the probability of success P(n) repeater n has to correctly receive a broadcast packet. This we do by maintaining in each PRU a table counting the number of successfully received packets from each immediate neighbor. The ratio of the number of packets correctly received from a given neighbor, to the number of packets transmitted by that neighbor, is a measure of P(n).

Another important feature of a routing algorithm is its adaptability to network changes: input traffic load, connectivity and component failure and repair. In evaluating the dynamics of such an algorithm, three factors must be examined: the time required to detect the network change, the time required to respond, and the quality of the response. The data items at each PRU necessary for these studies, which include some of those mentioned earlier, are:

(a) tables counting the number of packets correctly received from immediate neighbors

(b) number of packets alternately routed

(c) number of packets discarded, suggesting route congestion or component failure

(d) percent of time repeater is busy transmitting and receiving

These are obtained as cumulative statistics in the PRU.

In addition, the Pickup packet is a valuable tool in routing studies in that it contains the actual and complete route taken by the packet (pinpointing alternate routing), as well as time stamps to compute the queueing and transmission delays incurred at each repeater.

Repeater's performance

The evaluation of the performance of a repeater is most important in the analysis of network behavior; it allows us to break down key network measures (such as packet delay and throughput) into their elementary components and to examine the effects on these measures of the repeater activity and design (including buffer management, queueing discipline, and packet processing priorities).

The quantities relevant to packet delays are:

(a) The processing time of a packet flowing through a repeater; this is counted in Pickup Packets as the time lapse between the packet's arrival and the time it is placed on the transmission queue. This processing includes various checks such as checksum, packet type, routing labels, etc.

(b) the packet queueing delay at a repeater; this is also counted in Pickup Packets as the time elapsed from when the packet is placed on the transmission queue until it is considered for transmission (i.e., until it is at the head of the line, in a first-come-first-served discipline).

(c) the packet's service time; this is also counted in Pickup packets as the time elapsed from when the packet is at the head of the queue until its echo-acknowledgement is correctly received. Note that the actual service time (time until the packet is correctly received at the next repeater) is smaller than the one measured here due to the echo acknowledgment protocol used in this system. Note also that the service times of consecutive packets are correlated.

The quantities related to a repeater's communications activity are:

(d) percent of time the PRU transceiver is busy transmitting and receiving; this can be obtained in the PRU

Cumstat by regular sampling of the transceiver's state.
(e) the total number of transmitted packets at each repeater relative to the number of successfully transmitted packets. The latter number is obtained for each neighboring repeater by examining its table count which gives the number of packets correctly received from immediate neighbors.
(f) the percent of traffic received with checksum error (obtained in the PRU Cumstats).
(g) the percent of traffic received correctly but not intended for this repeater (obtained in the PRU Cumstat).

The quantities relevant to buffer management and occupancy are:

(h) the percent of time packet buffers are in a given state (free, queued for packet transmission, reserved for packet receive). This can be obtained in the PRU Cumstat by a regular sampling of the buffer states.
(i) the frequency of buffer overflow as a function of the load, and this is obtained also in the Cumstats by counting the number of packets discarded due to lack of buffer space.

Traffic characteristics

In determining the traffic characteristics, one should distinguish between *external traffic* (the input traffic generated by network users and traffic sources) and *internal traffic* (traffic relayed and generated at repeaters). The measurement functions determining the external traffic characteristics are not necessary when the entire traffic is artificially generated. They include:

(a) the geographical distribution of the input load (obtained in the end device Cumstats)
(b) characteristics of the terminal input processes (obtained in the form of histograms of packet intergeneration time from the end device Cumstats)
(c) the amount of traffic generated at repeaters for special purposes such as: control, measurement, etc. (i.e., overhead traffic) (obtained in the PRU Cumstats)

The characterization of internal traffic is crucial in the creation and validation of assumptions made in repeater models aimed at an analytic prediction of the performance of multi-repeater packet radio networks. To characterize this internal traffic, we may measure the following quantities at each repeater:

(a) interarrival time (defined as the time between the arrivals of two successive packets that have been correctly received and are destined to that repeater).
(b) interdeparture time (defined as the time elapsed between the acknowledgment of two consecutively transmitted packets).

Histograms of these quantities can be created from the information contained in the Pickup Packets.

Network's global performance

The ultimate goal of all system considerations is to create a network of high capacity providing minimal user (end-to-end) delay. We examine the success in achieving this goal by measuring the end-to-end delay and the network throughput (counted as the number of packets received at their respective destinations), under various patterns of input load, as well as the frequency of lost and duplicated packets.

It is important to note that these quantities are fundamentally affected by all the operational protocols. They allow us to obtain the main performance curves of throughput and delay.

The role of measurements in flow control

The station has the responsibility for centralized control over the entire network. To carry out this responsibility, the station requires various indications of network activity and performance. Some of this information will be acquired from incoming traffic, but much of this information must be specifically obtained by having monitoring procedures collect, from the various devices, a subset of the measurement items that have been seen presented throughout the paper.

CONCLUSION

In this paper, we have presented some of the results of our activities in the measurement aspect of the ARPA Packet Radio Project. We described the Packet Radio Network measurement facilities, consisting of the measurement tools and the techniques for data collection. We also identified and discussed the measurement functions required to gain insight into the behavior of this broadcast network. In so doing, we determined the data items required to support these functions and the means for their collection. This information is summarized in Table I.

In the design of these measurement facilities, a constant concern is to keep the overhead they create at the components and on the broadcast channel at a low level. An important activity will be to evaluate the cost of each element of the facilities in the prototype network, and to assess their impact on the network operation so as to design and conduct experiments in a manner that will minimize the bias introduced.

ACKNOWLEDGMENTS

We would like to acknowledge the Packet Radio Working Group and particularly Ralph Jones, David Retz, Ron Kunzelman and Don Nielson from Stanford Research Institute and Dick Sunlin from Collins Radio Corporation for the fruitful discussions that have taken place with them.

TABLE I—Summary of Measurement Items

Pickup Packets (at each PRU, the following data items are collected in the Pickup packet):

- time of arrival of the packet at the PRU
- time the Pickup packet was first placed on the transmit queue
- time of each transmission
- time HBH ack arrived (stored in next Pickup packet)
- the current PRU ID

PRU based Cumulative Statistics

- # of packets received in error
- # of packets received but not intended for this PRU
- histogram of # of transmissions per successful packet
- # of unsuccessful packets (dropped because of lack of ack)
- # of packets discarded because of lack of buffer space
- # of alternately routed ("ALL") packets received
- table counting number of correctly received packets from immediate neighbors
- # of transmissions beyond success
- # of packets incurring transmissions beyond success
- table sampling frequency of buffer states (and transceiver states)

End-Device Cumulative Statistics

- histogram of round-trip times
- # of packets transmitted
- # of duplicate packets detected
- # of packets discarded by the sender because of lack of ETE ack
- histogram of # of transmissions per successful (ETE) packet
- histogram of packet intergeneration time

Note: certain Cumstat items will distinguish between inbound (to the station) and outbound (from the station) traffic.

Monitoring and access control of the London node of ARPANET

by ADRIAN V. STOKES, DAVID L. BATES* and PETER T. KIRSTEIN
University College London
London, England

ABSTRACT

At University College London, we have developed a novel way of monitoring a network node using a separate processor and have applied this technique to the London node of ARPANET. A monitoring program on a PDP-9 records usage of the London-TIP via the dial-up ports and these data are sent to the Rutherford Laboratory IBM 360/195 for detailed analysis. In this paper, we describe the method we have developed and present some of the results we have so far obtained.

INTRODUCTION

The ARPA computer network[1] has been operational for over six years. During this time, there have been extensive measurements on the performance of the communications subnetwork, particularly by the Network Measurement Center at the University of California[2,3] and Bolt, Beranek and Newman.[4] There have been extensive measurements of usage of specific hosts, for example by the National Bureau of Standards. There have also been certain measurements of the network usage made for certain large applications to justify the cost of running the network. There have not, however, been any consistent measurements of network usage via one site. There are several reasons for this omission. Partly it is due to there being no mechanism by which US users of ARPANET could be forced to keep statistics of their usage, and partly it is due to there being no automatic accounting system for the use of the network.

An attempt was made in late 1974 to introduce an automatic accounting system into the subnetwork. The mechanism was that each communication computer would connect to a specific Access Control Host before it permitted a connection to be opened to any other Host. Further connections were permitted only if the correct user/password combination was given; after each session over a virtual circuit, the accounting Host was informed of the length of the connection and the number of packets transferred (unless the Access Control computer was not available, in which case the statistics were stored for later transmission). This mechanism was abandoned after a few weeks for several reasons; amongst these were the difficulty of maintaining the password file on the Access Control Host and the sluggishness of the response of the access control mechanism.

At about the same time we, at the University College London (UCL) node of ARPANET, became interested in providing access control and accounting. There were two reasons for this. Many bodies wished to analyze the extent and value of usage of the ARPANET link via the UCL node; they also wished to be able to control the access—particularly via the Public Switched Telephone Network (PSTN). Because we were a node like any other, it was not possible to put any special code into the Honeywell 316 Terminal Interface Message Processor[5] which acts as the communication processor to the UCL site. Instead, any such code had to be provided outside the subnetwork. However, since all the use of the UCL node is purely experimental, we were entitled to enforce any extra login procedures we wished onto our users. We have been looking at three different types of measurement:

(a) Characteristics of usage of Hosts via the UCL node
(b) Characteristics of the data traffic for several specific applications
(c) Overheads incurred in the different levels of protocol

This paper is concerned only with the first of the above; the others will be discussed in later papers. Only sample measurements will be presented here; fuller measurements will be discussed at the Conference and are really more appropriate to a Technical Report.[6] In order to provide meaningful statistics, we also have had to provide access controls; this subject is also considered here.

At UCL is sited a TIP; two PDP-9 computers are connected to the TIP, one of which acts as a gateway between various computer networks, in particular, between ARPA and the Rutherford Laboratory (RL) star network based on an IBM 360/195.[7] The second PDP-9 is used both as a development machine and for monitoring and access control of the ARPANET; it also provides a simple form of access to the National Library of Medicine (NLM) Medline system. It is

* D. L. Bates is now at CERN, Geneva, Switzerland.

the measurements made using this machine which are the subject of this paper.

OVERVIEW OF THE SYSTEM

The TIP has 8 slow (300/300 bps) and 1 faster (1200/75 bps) dial-up ports as well as three leased lines. The PDP-9 used for this work (known as PDP-9B) is connected to the TIP as a Host. It has 32K words of core (18 bit), a 256K disk and various other peripherals.

DESCRIPTION OF THE QUES PROGRAM

The program which performs the actual monitoring and access control is called QUES. This is one segment of a network system which runs on the PDP-9. When the system is initialized and has established communication with the TIP, QUES sets up a control connection to a specific port on the TIP; via this connection, QUES attempts to connect to other TIP ports (which are specified by entries in a disk file which may be modified easily). Each port may be in one of three states. The first is WILD, in which case there is no user connected; in this state, QUES may (and indeed does) make the connection. When a user dials in, this connection is broken and, on noting this, QUES remakes it and interrogates the user by asking for surname, TIP password and number of required Host (a typical scenario is shown in Figure 1). To save time, a user may give all three replies in response to the first question.

If the replies are satisfactory, QUES then breaks the connection and waits 20 seconds before attempting to remake it. If the replies are unsatisfactory, the user is allowed a second attempt then, if still incorrect, he is disconnected. It would have been possible for us to have better access control by making the connection for the user. This would require, however, a considerably heavier cpu load and to reduce this, we only make the connection in the specific case that we wish to record the whole dialogue for subsequent analysis (as we do in the case of MEDLINE; see below).

If the user gives correct answers and succeeds in connecting to the Host within the requisite time, QUES enters its third phase in which it attempts (at one second intervals) to reconnect to the port.

```

          .....
@C       * close connection to host
Open     * message from TIP
NEXT HOST NUMBER OR RING OFF NOW >
```

Figure 1—A Typical QUES Scenario

When the user closes his connection to the remote Host, QUES is once more able to connect to him and requests the number of the next Host required (name and password are not requested again). This procedure is then repeated continuously.

The only exception to this procedure is in the special case where the Host the user wishes to access is the National Library of Medicine (NLM). The British Library, as part of its Short Term Experimental Information Network Project (Ref. 8) has a number of centres which access the MEDLINE system on the NLM IBM 370/158. This machine is not connected to ARPANET as a conventional Host, but rather simulates five interactive terminals on the National Bureau of Standards (NBS) TIP.

Since this makes the process of connection extremely inconvenient and also provides little status information, we have written a program which also runs under our network software on the PDP-9 and which automates the connection procedure. This program will be described in detail elsewhere; however, it should be noted that, if a user specifies that he wishes to access the MEDLINE system (by giving the NBS-TIP number or MEDLINE when asked for Host number), he is automatically routed to this program. If this program is unable to make the connection (or if the user states that he does not wish to use the program by specifying the Host as NLM), QUES allows the user two minutes rather than the standard twenty seconds to make the connection since the procedure is considerably more complicated in this case.

All the data supplied by the user are printed by QUES onto a paper tape (thus obviating problems such as closing files after a system crash); similarly, when the user disconnects from his Host, his connect time is recorded on the tape.

In the unlikely event that the system does crash, it is convenient to know the time, and this may prove difficult at night when there is little activity. For this reason, QUES prints a message to indicate that it is still running every half-hour.

A sample of the output from the program is shown in Figure 2.

DESCRIPTION OF THE ANALYSIS PROGRAMS

A paper tape, as in the above section, is converted into a 360 job by the addition of a few lines of Job Control Language. This job is then sent to the RL machine via our other PDP-9.

Such tapes may have many errors. For example, due to system crashes, the "MONITORING TERMINATED" message may not have been printed; due to hardware problems, characters may be missing etc. Also, each interaction has generated two lines of out-

Figure 2—Sample PDP-9(B) log output

put, the first when QUES interrogated the user, the second when the user closed his connection to the remote Host.

Therefore, the first phase of analysis consists of a program called LOGB. This program checks the input for errors, removes superfluous lines (e.g., "QUES OK"), removes lines where the user has given an incorrect password or Host (these are printed out for inspection, but not passed onto the analysis programs) and compresses the data. In particular, the connect time is appended to the message generated when the user logs in. Two problems arise. The first is that monitoring may be terminated while a user is still logged in; in this case, the QUES program prints out the connect time up to the termination and so the time recorded is an underestimate. This of course presents no problems to LOGB, since there is no difference between such a message and a genuine log out. The second case, when the system crashes while users are logged in, does present a problem; in such a case, LOGB detects this by the occurrence of a "MONITORING STARTED" message not preceded by a "MONITORING TERMINATED" message. It generates the latter and the associated logout messages at the last time for which it had a valid message (hence the reason for the production of the "QUES OK" messages).

The program also produces messages indicating the number of ports in use. Due to a temporary restriction on the number of channels available in the PDP-9, QUES only monitors six ports at present. It is a simple matter for LOGB to record the number of ports in use except for one case, when QUES starts monitoring. In this case, ports may already be in use; the version of QUES to which we are referring did not attempt to distinguish whether the port was in use by a genuine user or not (e.g., someone having dialled the TIP number by mistake). This distinction can be deduced by QUES with a reasonable degree of certainty by knowing the TIP timeout period. This will be done in future, but the timeout period is not guaranteed to remain constant and the method is not completely reliable. In the data we present here this was not done, and LOGB had to deduce the number of ports in use. Due to the mode of operation of the telephone system, a user is allocated to the lowest numbered free port on dialling up. At present, we monitor ports 70 to 75 (octal). If the first port to be used after QUES was initialized was 71, LOGB would assume that port 70 was in use at that time. LOGB takes steps to ensure that such an error is not propagated if the port was not in genuine use.

Thus LOGB produces an output file, an example of which is given in Figure 3 (the output is that produced with the data in Figure 2 as input). This file is in a standard format and may be assumed to be error free. It is then passed to a set of analysis routines called XFSTATS for analysis. It was not expected that all the analysis functions which might at some time have been required could be specified in advance; therefore XFSTATS was written in a flexible, table-driven manner. The initial phase of the program consists of reading a file of control cards which are parsed. It then

Figure 3—Sample output from the data reduction program LOGB

reads the file output by LOGB, selecting only data between the dates specified by the control file. These data are mapped into a structure in core, then, depending on the control cards, various analyses are performed, for example, a matrix of connect times for each host and user (see Figure 4).

RESULTS OF ANALYSES

In a paper such as this, it is neither possible nor desirable to give a full analysis of the results we have obtained (these are available in Reference 6), and we concentrate on three aspects of the results. In the following, the data to which we refer is, in the main, that obtained in July 1975. A single month provides a reasonable volume of data covering various times of day. July was chosen specifically since it was the month in which we did most monitoring; PDP-9B is also used for system development and monitoring is only performed when it is not used for that purpose. Thus the amount of monitoring varies considerably from week to week and much of the monitoring is at night and weekends with few users; at such times, the main value of the system is for controlling improper access. In the month concerned, we monitored the TIP for 525 hours (70 percent) broken down in the following way:

	0000- 0800	0800- 1300	1300- 1800	1800- 2400	Week- ends
Total (mins)	9120	5571	1713	4426	10674
Mins/day (av)	397	242	74	192	1334
% of time monitored	82.7	80.7	24.8	53.5	92.7

Figure 4

The three aspects with which we will concern ourselves are:

(i) The global picture: overall usage and general statistics
(ii) The pattern of usage by one specific user
(iii) The pattern of usage of one specific host

On the global picture, we monitored the TIP for 31,504 minutes in the month. The total time users were connected to various Hosts was 10,761 user minutes, giving a usage of the six ports monitored of 5.7%. However, much of the time monitored was at weekends and night and the breakdown of this figure over the time periods used above is:

	0000- 0800	0800- 1300	1300- 1800	1800- 2400	Week- ends
Time*ports	94	8039	1443	462	723
% ports used	0.2	24.1	14.0	1.7	1.1
Logins	2	435	62	42	44

(where the percentage referred to is the percentage port utilization). The high figure in the 0800-1300 time is due to the non-availability of many US hosts to us in their prime shift (1300 onwards, UK time). This restriction applies to the two Hosts that were used most heavily, NLM and the Information Sciences Institute (IST) PDP-10X. A general matrix is produced of the usage at each Host by each user group. The complete matrix in our case would be 100×40 and would be quite unreadable. A partial matrix is shown in Figure 4. The two most heavily used Hosts during this period were Host 147 (64 percent) and ISI (9.4 percent). The reason that the former was used so heavily was that it had been unavailable for most of June; in addition, the general university usage was low in July because of the onset of holidays.

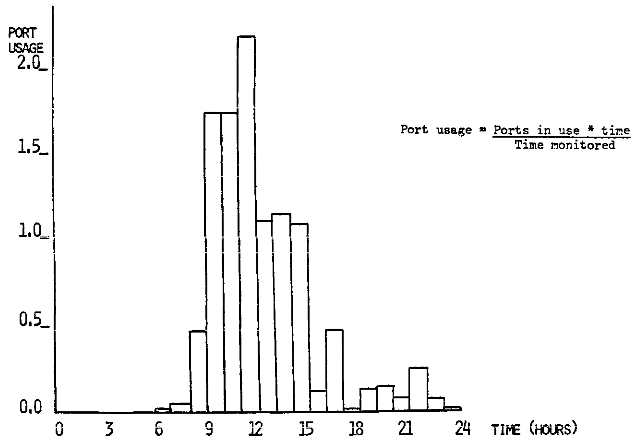

Figure 6

The pattern of usage overall is much as expected and is shown in Figure 5. In this, attempts to connect to a Host which was not available are excluded (QUES records this as a connect time of zero; there were 115 such occurrences in July). The second histogram shows the zero to ten minutes segment on a larger scale; the zero to thirty seconds time period contains many users who, although connected to the Host, were unable to log-in either due to the Host refusing to allow the log-in or rejecting it due to illegal account parameters.

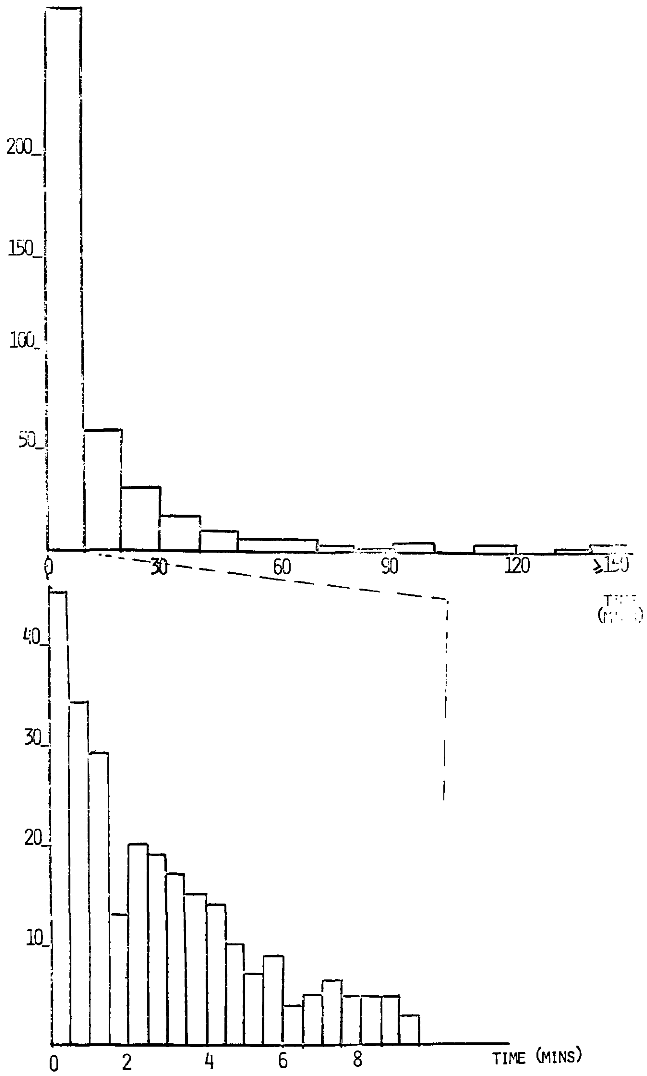

Figure 5

It is of considerable interest to determine the number of connections made and ports occupied and these are best normalized with respect to the average number of ports in use. Typical results of the ports in use over particular periods are shown in Figure 6. We also have histogram information on the number of ports in use at any one time. This information can be used to guide the TIP owner on the number of dial-up ports he should provide.

The second aspect which we wish to examine is the pattern of one specific user (Peter Kirstein). His usage this month was confined exclusively to one Host, ISI, and there were three types of usage; these are clearly reflected in the connect times (Figure 7). The first is

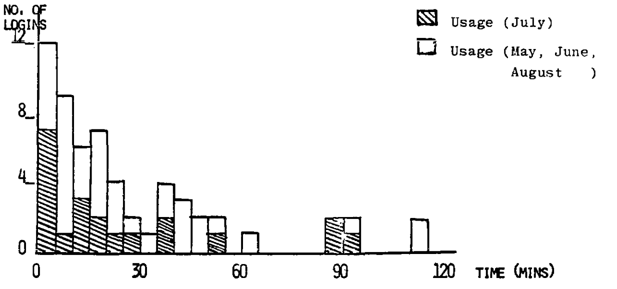

Figure 7

usage such as reading mail or sending messages. This takes a relatively short time, of the order of ten minutes. The second usage is editing documents and this gives rise to connect times of the order of half an hour. The third usage is entering documents and, to a greater extent, teleconferencing where connect times are of the order of hours. This pattern shows up clearly in the histogram of Figure 7 but, since there were only nineteen logins recorded in the month, we also give the corresponding histogram for the four month period May-August 1975 when there were 59 logins.

The last usage we consider is that of a specific Host. As we mentioned above, a number of centres in Britain access the MEDLINE system on the NLM IBM 370/158 to perform bibliographic searches. In addition to the QUES monitoring, we are able to monitor other details since each line from the user and from NLM passes through the PDP-9. In particular, we monitor the number of characters and lines each way. We also record the number of searches carried out, but this depends on the user specifying this number accurately to NLM; also, the actual number is, to a certain extent, subjective. Therefore, we do not make significant use of this information.

In the month we are considering, we recorded 148 logins to NLM, giving a total connect time of 7385 minutes. Eliminating those logins where MEDLINE was not available (shown by a very short connect time —of the order of a few minutes—and the user specifying that no searches were done and giving no "PRINT" commands), we had 87 logins.

Although the number of observations is reasonably high, the variation in the parameters was surprising. The greatest consistency was in the time spent logged in, an average of just under 33 minutes with a rms deviation of 11 percent of this value. Two parameters which might have been expected to be fairly consistent, the average number of characters per line to and from NLM each session, showed wide variations over the recorded sessions. The averages were 16.64 and 13.65 respectively with rms deviations of 31 percent and 49 percent of those figures. Similarly high deviations were shown in the ratio of the lines from NLM to lines from the user (52 percent), the time per line from NLM (46 percent) and the time per line from the user (58 percent). These results are tabulated in Figure 8.

The results we have presented above for the use of NLM are our initial results and will be supplemented with more detail when our current extensions to the monitoring system are completed. In this, all interactions with NLM may be copied onto magnetic tape and hence a complete analysis may be performed. These data will be used partially to check the data generated by some of the users under the project of Reference 8. They will be of particular use in providing a quantitative basis for certain subjective criteria, for example, response times. It is hoped, at a later date, to extend this system so that it may be used to monitor the interactions with any Host on ARPANET.

	Total	Average	RMS Deviation
Time logged in	171 349	1969.53	216.83
Characters from NLM	551 925	6343.97	5318.70
Lines from NLM	32 569	374.36	284.04
Characters from user	105 979	1218.15	2087.59
Lines from user	8 554	98.32	171.23
Average time per line from NLM	—	5.66	2.57
Time per line from user	—	42.01	24.26
Characters per line from NLM	—	16.64	5.16
Characters per line from user	—	13.65	6.65
Lines from NLM/Lines from user	—	7.86	4.05

Figure 8—Characteristics of NLM usage (times in seconds)

CONCLUSIONS

The method of monitoring and access control we have developed is not of general application, particularly since it requires a dedicated processor in addition to the one being monitored and, in the general case, it is obviously simpler to put these functions in the latter. However, the introduction of monitoring and/or access controls into a computer brings with it a loss of reliability (since, not only does it increase the complexity of the software but also it requires additional hardware). This loss of reliability may not be acceptable and so our technique may be of more general applicability.

An example of this is evinced by ARPANET. Access controls were introduced into the TIPs in late 1974 and, for a number of reasons (in particular, the decrease of reliability that backing store would introduce and the problems of maintaining the password data base) it was introduced in a way that led to inconvenience for users and large network overheads. Although our approach would not obviate the problem of maintaining the data base, it would certainly not decrease the reliability of the TIPs. At the present time, the LONDON-TIP is the only node on ARPANET on which monitoring of users and access control is being carried out.

By use of this technique, we have obtained considerable monitoring data and have used this to explore the methods of usage of the network. We are currently developing other means of monitoring in conjunction with QUES to enable us to obtain a more complete view of the usage of our node. The above types of figures are useful in giving a general overview of the extent of usage of the network for different applications. The measurements give an excellent cross-check on subjective reports from user groups on their usage of specific Hosts (Reference 9). Over a period of time, we expect these measurements to be extended also to leased line ports and so to give us a complete picture of the usage of ARPANET via the UCL node.

ACKNOWLEDGMENTS

We wish to acknowledge support by the British Library under grant SI/G/093. Also, such research would not be feasible without support of the many bodies for the ARPA project at University College, in particular, the Science Research Council (B/RG/5981), the US Advanced Research Projects Agency (N00014-74-C-0240) and the UK Ministry of Defence (AT/2047/064).

We also wish to acknowledge the contributions of many people of the INDRA group at University College to this project, in particular, to Roger Gould and Peter Mott who did much of the coding and debugging of the programs mentioned.

Office automation project—A research perspective

by HOWARD LEE MORGAN
University of Pennsylvania
Philadelphia, Pennsylvania

ABSTRACT

This paper attempts to place some perspective on the research and developments going on in office automation. It describes the functions which can be assisted by computers, and indicates where more research may be needed. A brief description of the Office Automation Project at the Wharton School is provided. The systems being developed include word processing, electronic mail, decision aiding technology, and integration with various databases. This effort is compared with some of the other, complementary research projects in office automation under way around the country.

INTRODUCTION

Having successfully occupied the accounting and financial centers of business for almost two decades, and the production control centers for one decade, the computer industry is finally beginning its march on the office. Until now, this was the last stronghold of human activity in many of our large business and government organizations. Office automation, of which word processing is but one element, is one of the fastest growing segments of the marketplace. A large number of companies have entered the field, and sales of word processing equipment alone should reach $.75 billion in calendar 1976.[10]

This paper is an attempt to place some perspective on the research efforts going on in office automation, with some emphasis on structuring the many different services which can come under this heading. It also tries to indicate where there are problems of research rather than development interest, with the hope that this may stimulate various groups to begin work on them. Finally, it describes the efforts under way at The Wharton School in this area, the Office Automation Project(OAP).

ASSUMPTIONS

This author has based his research on the following assumptions. These are not all universally accepted, although I have found agreement on some of them in each of the major research efforts studied.

1. More efficient production of paper is *not* the ultimate goal of office automation. While a side benefit may be that documents, letters, etc., can be produced and changed more efficiently, one hopes to eliminate more paper than is produced in order to attain a truly automated office.
2. The burden of proof is on those making changes. Whenever we propose to make radical changes in the way in which offices function, we should be prepared to justify these changes. Technology itself is not sufficient reason to introduce change. A corollary to this assumption is that in order to have the change accepted, there must be some short term payoff to those who must use the system (managers and clerical workers).
3. Office problems are not well structured. The reason that computers have been able to take over accounting and financial departments is that the problems there are relatively well understood and structured. The type of activity and decision making which characterizes most offices does not lend itself to such clear structuring, and thus demands different solutions.
4. Both technological and organizational research challenges remain. Because of the semi-structured nature of office problems, new data structures, program structures and even hardware may have to be designed to really attack the problems. Also, since telecommunications may permit automated offices to exist in quite a different physical manner than at present (e.g., offices in the home), the impact on organizational designs and strategies require much research.

These assumptions have led us to the particular analysis and development approaches used in my contributions to the Wharton Office Automation Project.

FUNCTIONS

Top down methodology is much in vogue these days, for its supposed clarity and completeness. Here, a top down analysis would begin with the functions performed and the people performing them. We should note that the actual system development and implementation at Wharton is being done in Ness' "middle out" approach,[16] which tends to lead to greater user involvement and short term payoffs.

Since office functions are in some sense dependent on the particular business, we must describe the environment in which we work. The impetus for the Wharton project came with the formation of the new Department of Decision Sciences at The Wharton School. This consists of 15 teaching research faculty, about 25 support personnel (secretaries, research assistants, etc.) and has a consolidated budget of slightly under $1 million/year. There are several middle managers (typically principal investigators on projects) and a department chairman, who may be considered a more senior manager, since he must worry about the consolidated budgets from teaching and research grants. We suggest that our office is therefore similar to offices in information oriented companies, e.g., banking, insurance, R&D, rather than product oriented companies. We are aiming at aiding the middle manager in performing his or her functions. These functions fall into six major classes. For each, we discuss what has been done by the industry to automate it, and what might be done.

Communications

Mintzberg, in his study of managerial functions, reports that almost all of most managers' time was spent on communication.[14] This is borne out by the fact that it is in this area that the most work on office automation has proceeded. We divide communications into a number of categories for purposes of discussion.

1. formal/informal
2. reply required/no reply required
3. message/document (short/long)
4. internal/external
5. voice/text/graphics

The word processing industry has realized the amount of time and money spent in the average office on communications and has attempted to automate some of these tasks. They have had much success with long, formal texts, as typified by legal contracts, large reports, and mass letter writing examples. The main technology involves text editors, about which we shall have more to say later.

The informal message area has proven of tremendous value to those organizations that have implemented systems such as electronic mail. In one large New York bank, for example, the time to get messages and memos from Wall Street to Midtown was cut from four hours to five minutes. The ARPANET community has also noted the powerful sense of community which the mail facility can create.[5]

In the Wharton system, features for extracting replies are a part of the electronic mail system, but are just beginning to be used. The phone or voice communications area is untapped. Services such as logging calls, handling of phone messages, etc., could be provided. Some recent research,[2] has indicated that for office type of problem solving, voice may be more effective than face to face communications, even given the lack of graphics.

One West Coast research group is working heavily in the area of computer graphics integrated into a word processing system, and the Binary Image Processor created to store and retrieve technical manuals also is attacking this area.[15]

Information storage and retrieval

Almost all of us keep files of one sort or another in our offices. Names and addresses, correspondence, task related work, all seem to accumulate in our file drawers. An informal survey of the faculty members in the Department reveals that the middle managers have on the order of 1,000 files, and the chairman has about 2,000 separate file folders. Most of us seem to be able to index the information in these files in our heads, or with simple filing schemes. The research literature on information storage and retrieval tends to lead to strategies which may be more rigid than those we use when searching our own files. For example, I may store a letter in a folder with the recipient's name on it, or in a folder with the name of a paper he or she has written, or in some other task related file. Yet I can usually retrieve all correspondence to a person by remembering the subjects of the letters.

There are basically three problems to effective storage and retrieval. First, storage of full texts is expensive. For the number of times which I typically reexamine a letter, it would be hard to justify online storage, even with the relatively cheap terabit memories. This can be alleviated by storing only the index online, perhaps with abstracts, such as is done for document collections.[21]

Second, there is the problem of data input. Letters or documents prepared on an automated system can be easily stored. However, material received on paper from the outside incurs additional costs for input. As the use of electronic mail increases, this problem too may be overcome.

Finally, there is the problem of indexing. Automatic indexing of the type done in library systems[22] is content oriented. The degree of success of the automatic methods depends greatly on the threshold values in the algorithms. Short letters are quite hard to index, because few of the terms occur frequently enough to exceed thresholds.

One research group has suggested that the best aid would be to simply show the user a large number of file folder headers, much as one would see them as one opened the drawer, and let the human pattern recognition and search process be used to select from that set. Depending on the hardware, one could show from 50 to several hundred such folder names simultaneously. This scheme should work for the few thousands of files discussed so far. If we wish to integrate several people's files, this approach is not the one to follow.

Data analysis

Tools for analyzing numeric data have been available and in use by sophisticated managers for years. Regression, statistical packages, forecasting models, etc., have all been well developed to suit this market. Analysis of the other types of data which a manager sees, such as newspapers, magazines, reports, etc., is still beyond present day capabilities.

The Very Large Database (VLDB) project being sponsored by ARPA,[7] is attempting to examine some of the problems of analyzing this "intelligence." For example, we may wish to examine all of the data linking our company and research in computer databases. This necessitates bibliographic searches, calls to friends in other universities, etc. Learning to use even the available systems (NY Times Index, MEDLINE, etc.) is hard enough without trying to integrate these and automate access to them.

Decision making

Most middle managers are not making repetitive, routine decisions but rather are making semi-structured decisions which recur on an irregular basis. These tend to be tactical rather than strategic decisions. As part of an ONR sponsored effort we are building DAISY,[13] a decision aiding information system. This attempts to automate the memory of an organization to support a manager making decisions, while still giving the manager the freedom to make the decision. Some examples of such semi-structured decisions are choosing an acquisition partner, deciding upon a battle plan, or trying to allocate fire fighting units in a municipality.

A budget planning process has been implemented and partly integrated with the OAP and DAISY by Purves and Godard.[20] With this, a professor can learn how to budget for a research proposal, go through the calculations with a program, and dump the results in text format into the budget pages of a formal proposal. We are working with other decision processes, but are excited about the potential for linking this type of system to both the communications and the information storage and retrieval functions of the OAP.

Personal assistant

Goldstein[9] has described an artificial intelligence system for aiding in preparing schedules. This type of activity is categorized as a personal assistant. It understands some portion of the manager's decision rules, priorities, and requirements, and attempts to maintain schedules. In the Wharton OAP, Ness has implemented a simple scheduling system which permits a person to store and retrieve his or her calendar for any day or group of days. It also automates the reminder function, by printing, in priority order, items which users have placed on lists (e.g., Write letter to x, Buy wife's birthday present, etc.).

The short term payoff and appeal of a personal assistant is quite high. It tends to draw less computer-oriented people into using the system. Other possible personal assistants might include arranging travel reservations, maintaining working paper distribution lists, and choosing appropriate referees for journal papers.

In the long run, such applications of Artificial Intelligence and knowledge based systems[12] will be routine. They offer a great potential area for research in the fertile office automation applications area.

Linkage to corporate databases

Under communications, we discussed the interactions between people. Managers and other office personnel also routinely examine and update various corporate databases. These databases are maintained by and under the control of other offices, typically the data processing department.

It is desirable to permit the office automation system to have direct access to these databases. For example, the budget planning system described under decision making should not only feed the text processing parts of the office system, but should be able to create the proper entries in the accounting database to create the new project which has been proposed and budgeted. Other examples of such linkages might include moving name and address information from personal mailing lists into corporate customer databases, and examining personnel databases for skills required on particular projects.

The key research problem posed by providing this function is that of designing a simple query language for the databases. This is being examined at the present time by the End User Facilities Task Group of the CODASYL Committee.[4]

PRODUCTS

The functions described above have led to the development of a number of products in attempts to automate one or more of these. First and foremost are *text editors*. These have been around for a long time and are the backbone of most timesharing systems. Unfortunately, few of these line oriented editors are very good for office automation. Several major research groups (SRI-ARC, Xerox, USC-ISI) have all realized that good editors require separation of the editing commands from the text being edited. This can be done on CRTs, but not on the typewriter like devices which most timesharing systems have to support. The NLS system[1] is an excellent example of sophisticated editing. This system also changes the way in which people think about documents, emphasizing the hierarchical nature of long documents, and the ability to view a document at various levels of detail, i.e., chapter headings, section headings, etc., down to sentences and paragraphs.

The sophisticated editors at another installation not only separate command and text being edited, but also always try to show the user final formatted copy, even if this involves multiple fonts. The VyDec word processing system also works in this mode, which is quite appealing to secretaries and other initial document entry personnel. Since they can see an attractive, finished form as they enter a draft, a reward is present, reinforcing their desire to use the system.

One conclusion that can be drawn from studying the best editors available is that they require much more in the way of CPU and memory resources than most people estimate. To present an 8.5 by 11 inch screen with several type fonts may require one million bits of storage for the image alone.

Electronic mail packages are provided on ARPANET and have been developed in house by a number of companies[8] and timesharing bureaus. Except for the Wharton system, most of these seem to treat all mail the way the US Postal Service does, i.e., as first class mail, without any real indication of the type or content.

Integrated word processors are machines combining an editor with some minicomputer and storage devices. These go under a number of names, but are really automated typewriters. Unfortunately, most of them lack communications ability, and hence could not serve for the full range of functions mentioned in the FUNCTIONS section.

Database managers for handling the semi-structured types of information used in organizations are available. Many firms market name and address list maintenance programs, and the general database management systems can easily be used for these purposes. It is important that these systems permit easy addition of fields, storing of textual information, and extraction from files.

These are just some of the products under development or available for commercial use. We next describe briefly the first product of the Wharton OAP, the Office Automation System (OASYS).

OASYS

Figure 1 is a block diagram of the major functional pieces of the Wharton Office Automation System, designed and developed for the PDP-10 in MACRO by Professor David Ness. Those marked with asterisks are being reprogrammed or added by the author and others, using higher level languages, and DBTG database technology.

The text processing and runoff systems are a set of extensions to the DEC Runoff program for producing formatted text. Some of the more interesting features created by Ness are in the personalization, history and profile areas.[19] Each of the programs in OASYS is designed to deal with several people. The "for" user is the manager for whom the program is being used. The "by" user is the person who is actually at the terminal, e.g., a use of the schedule program *by* a clerical worker *for* a manager. The profiles tell these programs what input forms the *by* user desires depending on level of skill, etc., and what output forms the *for* user demands. The history features permit the system to inform each user when any of the questions or commands have changed, or when new features are added to the system. This is done by recording for each user, module, and command, a level number. Before the system asks a question, it determines whether or not the user has seen this version. If not, it is prefixed by (NEW).

The profile permits users to further personalize the modules by specifying a user/module combination which questions or prompts may be skipped. Thus, in creating name and address files I am asked for home address, which I routinely keep, but Professor Ness is only asked for business address.

The electronic mail system has several types of mail. A user is told how much of each class is waiting for him or her at login time. Currently, the system permits us to distinguish among BUG mail, relating to system bugs, regular mail, return receipt mail, which auto-

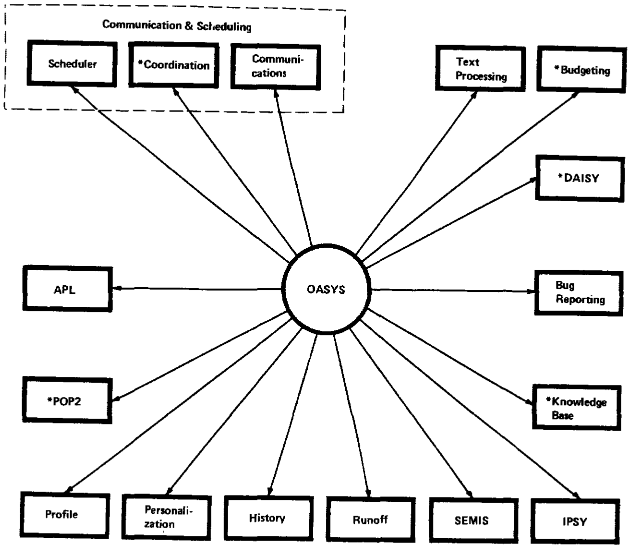

Figure 1

matically sends a receipt to the sender when it is examined, control mail, which deals with system operation, and LOG mail, which deals with account usage. In addition, regular mail is prefixed with an indication of the mailing list used to send it, or (PERSONAL), if it was individually addressed.

Users report bugs by specifying the module with the bug and writing a message. The system sends this to a responsible party, noting that users have reported bugs. Users are automatically notified through the mail system when the staff has received the bug report and when they have disposed of it.

Working in the POP[2] language, the author and Mike Zisman have recently integrated processing of databases, letter writing, and complex processing for handling manuscripts being considered for publication in professional journals. This includes selecting referees for papers and writing the appropriate correspondence for the referees and authors from the editors.

More information on OASYS is available in de Blasis[3] and in Ness.[17, 18]

TECHNOLOGIES

One of the key questions in office automation is the type of hardware and software technology which should be used for developing products. Wharton and SRI-ARC have both chosen to work on large central processors with communications facilities and relatively unintelligent terminals. Others have chosen more distributed technology, emphasizing minicomputers and some communications ability. This author feels that the latter route is the one likely to triumph in the medium term, but that we are likely to see a relatively large minicomputer supporting a cluster of terminals in one office, rather than one at each terminal. All of these minicomputers would, of course, be connected together for mail and database access.

As noted under products, some form of video display terminal (CRT, plasma panel, etc.) which can handle full graphics is required for the long term solution. It is not clear whether or not we should retain the present aspect ratio dictated mostly by the availability of cheap television (525 line scan) devices. In any case, the speed with which the display communicates with the machine for output should be as high as possible. Graphical input devices are also required, and the "mouse,"[6] a device which is rolled around on a hard surface and tracked by a cursor on the display, seems to be an attractive current answer.

On the software side, systems have been developed in languages ranging from assembly to INTERLISP. One would hope that higher level languages would be used more extensively, but since editing is often character oriented, reasonable efficiency can be achieved on many machines only by staying close to assembly level. Languages such as BCPL and BLISS permit this, while still retaining advantages of high level languages.

Sorting is such a fundamental operation that it must be considered a part of the software technology. In a similar vein, good man/machine dialogues are needed for any system which is going to have unsophisticated users. Martin[11] describes these techniques in quite a bit of detail.

RESEARCH AREAS

While much has and continues to be done in the office automation area, I have identified three major technological and two major organizational areas which are ripe for research. Some of these areas are beginning to be examined by members of the OAP at Wharton.

1. Input processing. Almost all of the functions which have been automated involve the production of output. How can we efficiently handle input in automated ways? Some OCR technology, some automatic indexing technology, and man/machine interaction technology must be brought to bear on this problem. Even if we begin to receive a large portion of our mail electronically (and several ARPANET users now get more than 50% of their mail through the network), the time and difficulty of entering externally supplied information must be cut down.

2. Integration of databases. Integrating databases more complex than names and addresses is not available in most office automation systems. How to present a clear and simple interface to the end user is the major problem here.

3. Using artificial intelligence methods. We have begun work on a knowledge based system to assist me in processing papers for the journals on whose editorial boards I serve. This will "understand" the types of interactions I have with authors, referees, and other editors, and will try to generate the proper correspondence, database updates (i.e., correspondence logging), and action requests. There are many other places where AI can contribute.

4. Amount of personal communications needed. Organizational studies on the effectiveness of dispersing the office personnel to separate locations, communicating only through the system, must be made. Chapanis[2] has done some work on problem solving with various communication modes, but we really know very little about the best ways to do this. Should the people meet face to face once a week? Once a month?

5. Who gets the terminals. For years people in the MIS field have seesawed on whether or not the managers or their staff assistants will actually have the terminals on their desks. Someone should attempt to answer this question through controlled experiments.

SUMMARY

Office automation is a growing area of concern for computer and organizational researchers. The efforts to date have focussed mainly on word processing, which is only a part of one of the office functions. Much more attention needs to be directed to the other, higher impact, less structured activities which take place in offices. This should yield a set of high quality products which will change the way in which offices are run over the next two decades.

The Wharton Office Automation Project is attempting to attack some of the non-word processing areas, paying particular attention to database integration, good user interactions, and handling of decision processes. We realize that our comparative advantage is not in the hardware area, and hence are trying to build modules of a system which can be grafted onto good hardware as it develops.

It is only a matter of time before most of us will be interacting with other people with the aid of computers as an everyday occurrence. We owe it to ourselves and the field to ensure that this happens in an efficient and socially responsible manner. This paper has not discussed the obvious privacy/security requirements which will be necessary in office automation systems, but they must be thought of at the beginning of any design projects.

This paper has attempted to set down something of the state of research in the area in late 1975. Functions, products, and technologies have been characterized with an eye towards possible research topics. The author hopes that those who work on these topics will communicate with him.

ACKNOWLEDGMENTS

The Office Automation Project was the result of necessity and a number of discussions among Professors David Ness, E. Gerald Hurst, Jr., Thomas Johnson, Rob Gerritsen, and myself. Dave Ness has spearheaded the effort and did almost all of the programming for the first generation OASYS. The author has benefited from the above individuals' comments, as well as the recent programming and intellectual support of O. Peter Buneman and Michael Zisman, and the editorial assistance of Dorna Caskie.

Evaluating the impact of office automation on top management communication

by JAMES H. CARLISLE
University of Southern California
Los Angeles, California

ABSTRACT

This paper is concerned with the impact of new communication technologies on the effectiveness of top management decisionmakers. Word processing technology is only the beginning of a revolution in office automation and managerial communication which will include teleconferencing, electronic mail, and wide availability of personal computer-based systems. The potential problems and benefits must be considered in the context of the overall communication system and management needs of an organization. A research methodology is described which leads to the development of organizational models within which: (1) management communication problems can be anticipated, (2) solutions can be proposed and compared, (3) specific office automation systems can be designed, and (4) the impact of alternative systems on organizational effectiveness can be predicted and evaluated.

INTRODUCTION

Office automation is one of the new buzzwords used to describe the computer augmentation of day-to-day office functions. Most of these functions involve some aspect of the increasing volume of interpersonal and formal communications which take place within organizations. Facsimile, electronic mail, word processing, teleconferencing, on-line calendars, information storage and retrieval and general management information systems are available today to top management and even to middle management in many organizations. The combination of these (and more) functions into an integrated, computer-based system for use in managing organizations is likely to bring about an organizational revolution for white collar workers comparable in magnitude to that resulting from the introduction of the assembly line to blue collar work.

Anticipation of the organizational impact of this new communication technology is essential to the long range planning of both system developers and eventual user organizations. There is currently a lack of any generally accepted theory and methodology for evaluating the impact of today's office automation systems. Between now and the time when computer terminals and digital voice coder boxes sit on every manager's desk, there is an opportunity to study and improve the effectiveness of such systems. We need to study how and why the early systems are being used. More importantly, we need to understand how these systems impact the overall communication system of an organization and its management.

This paper describes the design of a scientific analysis of top management communication. This analysis results in a model of communication activity for the particular organization and manager studied. This model then supports a strategic analysis of management problems arising out of increased demands for communication and the evaluation of new communication technologies coming onto the market to "solve" those problems.

The orientation of the research described in this paper is top management effectiveness, not computer technology. Office automation should not be studied as an end in itself, but as a means to improved managerial performance. Top management stands to gain or lose the most from this new technology. Their valuable time and energy is largely devoted to communication activity of one sort or another. Freeing up time for top management and giving them increased potential for effective and rapid communication within and among organizations are attractive payoffs. On the other hand, if office automation is developed and introduced incorrectly, it could disrupt office communications, making them even less efficient, and create serious resistance to all of the new communication technologies. If office automation fails to gain acceptance and demonstrate value in the executive suite, it is unlikely to receive adequate financial support to be properly used throughout the organization and throughout society.

THE NEED FOR OFFICE AUTOMATION

One of the most significant problems facing management in the coming years is the rapidly increasing complexity of the information environment in which both long range and day-to-day decisions must be made. In his article on "The Future-Oriented Corporation," Dr. Burt Nanus observed that

> *We live in an age of increasing complexities, an age of macrosystems in which everything of importance that occurs anywhere in the world is immediately known everywhere else, thereby precipitating consequences which, in their own turn, provoke still other changes. The recent energy crisis is an excellent example of the interrelationship of political, economic, and technological factors and the enormous significance for corporate decision making.*[1]

So far these crises have been few and temporary in nature. Structured management information systems have, unfortunately, proved inadequate to supply the information needed. Much of the communication in such crises is unstructured, informal, and contains subjective and up-to-the-minute data. Today's organizations, with their traditional methods of processing letters and reports and their reliance on telephone, telex, mail and personal meetings for informal communications are ill-equipped for the volume of critical information flow during even a minor crisis. The problem is already with us, since past crises have been merely amplifications of the normal day-to-day flow of structured and unstructured communication within our increasingly interconnected communications environment.

Few managers escape the daily avalanche of unstructured communications from both inside and outside their organization. Fewer still have a clear enough model of their communication environment to support efficient and effective utilization of their time through scheduling and monitoring selectively those communications with the highest priority. There are secretaries and managerial assistants who perform this function quite well. The drawbacks to this solution are that it is becoming increasingly expensive and it leaves the manager highly dependent on that other person.

POTENTIAL PROBLEMS IN IMPLEMENTATION OF OFFICE AUTOMATION

The realization that we are rapidly entering an era in which information and communications are the limiting factors in performance of a majority of organizations is reflected in the recent excitement over office automation. Corporations are reaching for the elusive carrot of "cost reductions in word processing"—often irrationally and often with little understanding of the far reaching effects that the new communication technologies are having on their users. Most automated office projects up to this time have been fiascos.[2] Major suppliers of the hardware and software for "word processing" seem to know almost nothing about the informal organizational environment into which their systems have brought chaos. Not only have customers had serious organizational problems, but even the vendors themselves have had trouble with inhouse implementations of their text-editing and document preparation systems. The computer industry vendors seem to think that management communications can be improved just by speeding up the production of error-free text.[3,4] It's important to keep in mind that the "word processing" aspect of office automation is to communication automation what keypunching was to management information systems—only the tip of the iceberg.

There is a strong possibility that all the mistakes of the management information system era of the '60s will be repeated with office automation due to the zealous marketing of computer companies and management consultant firms hoping to jump on the bandwagon of this new communication technology.

One of the reasons which has been most frequently pointed out for the failure of management information systems and management science in general has been the lack of understanding on the part of top management itself of the theories on which these decision support capabilities were based. A second reason is the lack of understanding on the part of the system developers of how people within the organization actually do their work. Too many computer-based systems have already been designed on the basis of technological breakthroughs and innovations which were insensitive to the limit on man's rationality and the social needs that must be satisfied within organizational structures.

It is as if Russell Ackoff's plea to avoid the development of "Management Misinformation Systems" was ignored by computer system designers.[5] It is as if Chris Argyris' analysis of "Management Information Systems: The Challenge to Rationality and Emotionality," was understood only by those managers who had personally suffered the neglect or outright sabotage of management databases.[6,7] The computer industry has not responded adequately to the real challenges of providing useable and responsive management decision support systems. We are now at a point in time where,

> *The managements of using organizations are becoming hardened to the computer as they see frequently unfulfilled promises on the part of the vendors and their internal staffs. The net effect is a diminished esteem and an increased skepticism about the potential of the computer.*[8]

Despite the skepticism, which is probably only really a reflection of despair, the automated office is on the way. A U.S. Department of Labor report in 1970, describing patterns of U.S. economic growth, indicates that office computing and accounting machines are the fastest growing industry in the United States, with an average annual growth rate of over 10 percent.[9] Recent introduction of digital data networks such as the ARPA network, and value added networks such as TELENET, offer new telecommunication services which are highly competitive with telex, telephone, and the post office, as well as a viable alternative to at least some business transportation.

WHY IS RESEARCH ON MANAGEMENT COMMUNICATION NECESSARY?

The question of paramount importance is how do we get to the office of the future without destroying the social fabric of today's organization and without further dehumanizing communication within our society? To answer this question we must have a better understanding of the office of today, based on scientific examination of management behavior. The needs for any new communication technology should then be derived from analysis of that behavior and consideration of personal and organizational values.

Most of what little we do know of managerial behavior has been learned with primary concern for leadership style, rationality of decision-making and determinants of satisfaction and motivation. The communication needs and behavior of management are only a recent focus of investigation. Henry Mintzberg, who conducted one of the most extensive investigations of managerial work, recently noted that

> *I was struck during my study by the fact that the executives I was observing—all very competent by any standard—are fundamentally indistinguishable from their counterparts of a hundred years ago (or a thousand years ago, for that matter.) The information they need differs, but they seek it in the same way —by word of mouth. Their decisions concern modern technology, but the procedures they use to make them are the same as the procedures of the nineteenth-century manager. Even the computer, so important for the specialized work of the organization, has apparently had no influence on the work procedures of general managers. In fact, the manager is in a kind of loop, with increasingly heavy work pressures but no aid forthcoming from management science.*[10]

With the exception of Mintzberg's study, which proposed and supported an intriguing theory of managerial work roles, most of the research on management communication has attempted to measure attitudes and preferences among alternative communication media. This latter research has been supported or conducted primarily by the telephone companies of the U.S., Canada and Great Britain as a form of market analysis for picturephones. It should be noted that attitudes are not always correlated with behavior. Even behavioral studies with college sophomores conducted in research laboratories offer only limited insight into the needs and behavior of top management in today's organizations, let alone the office of the future. We currently lack theories and models with substantial empirical support with which to anticipate and evaluate the impact of office automation on organizational communication systems.

WHAT ARE THE OBJECTIVES OF CURRENT RESEARCH?

The remainder of this paper describes a project under way to anticipate and evaluate the impact of office automation on top management communication in a large decentralized organization. This project is designed to lay the groundwork for management planning concerning the use of information technology to support unstructured management decision making and communication. The primary objective of the project is the development of a behavioral science model within which

- management communication problems can be anticipated,
- solutions can be proposed and compared,
- specific office automation systems can be designed, and the
- impact of alternative systems on organizational effectiveness can be predicted and evaluated.

Such a model provides top management with an alternative to computer vendor systems analysis. This project incorporates several theories of organizational behavior and human performance. It is directly responsive to recent proposals for designing more people-oriented computer systems. Most importantly, the model addresses the complexity of management behavior and of the organizational environment onto which any computer based management support system might be imposed.

This approach to the improvement of managerial communications is based on the contentions that (1) human resources in organizational management are more valuable and less well understood than the hardware and software that might be designed to support them, and (2) that person-computer communication can best be understood and improved by developing a better understanding of how people communicate with each other.

This is an ambitious project. No behavioral science or management science theory has offered a viable solution to the problems we are addressing. Surprisingly few have even tried. Our confidence in success is based on development of a new research methodology and on asking, at the outset, what we believe to be the right questions. For example, the models developed in this project should be able to answer the following questions regarding the need for or evaluation of alternative management communication or decision support systems:

1. How would the nature of management behavior be changed?
   A. How would overall efficiency be improved?
   B. How would overall effectiveness be improved?
   C. How would tasks be redefined by the management?
   D. How would behavioral alternatives be redefined and expanded or limited in number?
2. How would manager interaction be changed?
   A. Which responsibilities and interdependencies would be affected?
   B. Which communication patterns would be affected?
3. How would resource consumption be affected?
   A. How would travel patterns be altered?
   B. How would telecommunication patterns be altered?
   C. How would computer resources be utilized?
   D. How would secretarial resources be utilized?
   E. How would managers' time allocation be affected?
4. What would the impact be on attitudes and morale in the organization?
   A. What aspects of the system would meet with strong resistance?
   B. What aspects of the system would be readily accepted?
   C. In what ways would the system support management growth in communication?
5. How would the important relationships between management support, management behavior, and managerial performance be affected?

The development of models to guide the examination of these and related questions is a necessary first step to rational strategic planning for the office of the future. As Peter Drucker has pointed out,

> *The future manager will find the computer as much a fact of life as children today find the telephone . . . the computer is a tool of liberation if used correctly. Otherwise, you become its servant. It should liberate you from being chained to operations and to your desk and enable you to have time for people and for the outside, where the results are.*[11]

Drucker's optimism is encouraging, but unfortunately not supported by the history of the computer industry.

Improperly anticipated and poorly designed, the office of the future may lead to alienation, job fragmentation, regimentation and the 1984 horror of monitoring of all electronic communications. Properly designed, the office of the future could, instead, increase the manager's control over his or her information space, expanding the rich array of communication channels and formats available for effective organizational management. This project is investigating unstructured managerial communication as a first step in anticipating and evaluating the impact of office automation on organizational communication systems. Four basic goals guide this research:

1. Increased ability to deal with more complex information environments without increasing the number of managers in an organization.
2. Freedom for the manager from his or her desk and office as the central communication and information processing station.
3. Consolidation of management communication, scheduling, and decision making activities and support technology.
4. Increased effectiveness and efficiency in dealing with unstructured management communication tasks.

RESEARCH METHODOLOGY

The methodology used in this research is both empirical and theory-driven. It involves unobtrusive observation and analysis of managerial behavior, on the job, over a period of one or more weeks. From this analysis, a scenario is constructed which highlights key management communication activities. Both structure and content of these communications are analyzed to identify opportunities for increasing managerial effectiveness and efficiency. The critical part of the analysis is the construction of models of the individual manager's task and communication structure. Based on these models, additional scenarios are constructed, showing the impact of alternative management communication support technologies for each manager. This approach is holistic in that the full range of organizational and decision making activities is considered. It uses case study analysis to model the complex reality of individual managers.

This data collection process, referred to as "structured observation," derives from anthropological and sociological research. More recently a research group at the USC/Information Sciences Institute has been using a form of structured observation to study human dialogue as a means of improving man-machine interaction.[12,13]

The most significant application of the structured observation methodology in the area of management work activity was a study conducted by Henry Mintzberg, while a graduate student at M.I.T.[14] That study involved the detailed observation and analysis of work activity of five chief executives over a period of a week each. His results provide important motivation and direction for the development of models of managerial communication. Whereas Mintzberg decided to omit from his analyses all interaction between the manager and his secretary and to classify individuals with whom the manager interacted only as outsiders, superiors or subordinates, this project will analyze communications with respect to specific individuals and tasks.

The theoretical foundation on which data collection and analysis are based in the current project includes a novel conceptualization of managerial activity as communication acts intended to accomplish some specific purpose. These purposes are characterized as tasks which may be in various stages of completion, once initiated. The actual model of tasks, their states, and the effects of individual communications will be formulated out of the analysis of structured observation of individual managers on the job. Thus, the data collection is partially structured prior to its initiation and is augmented by interpretations made during and after the actual observation.

One of the compelling virtues of this methodology is its inclusion of far more of the manager's work environment than a typical laboratory study or questionnaire survey would permit. This approach requires cooperation and a high degree of trust between researcher and manager, but offers significant joint learning opportunities for both. This methodology requires a minimum of conscious effort on the manager's part to generate data while maximizing the opportunity for interpretation of ambiguous behavior by the manager. Perhaps most importantly, the methodology eliminates any need for deception by the researcher and assures the manager of full confidentiality at all stages of data collection and analysis. The most serious drawback of the methodology is the enormous amount of time involved in coding and recoding detailed observation data. This extensive analysis is justified by the insight gained into the managerial process with respect to the particular questions and problems being investigated.

Following preliminary analysis of the structured observation data, models of the manager's communication activity and sample scenarios are presented first to the manager and then to a group of managers in the organization. These scenarios are revised and personalized by the group as part of the generation and evaluation of ways for improving unstructured top management communication in the organization. There is considerable evidence that managers react to idealized scenarios about the future with considerably more insight and enthusiasm than they respond to other needs analysis techniques (such as questionnaires and interviews) or functional specifications of proposed systems.[15]

The collection of scenarios agreed upon as representing information processing activities for a variety of managers are then used to define a set of primitive information processing capabilities and a set of necessary hardware capabilities for making the scenarios possible. These primitives and this functional analysis form the basis for an information system design to support and improve managerial communications.

CONCLUSION

An important advantage of this methodology is that it gets many, if not all, of the organizations' top management involved in the iterative design of their own communications system. When an operational system is finally available they should already be knowledgeable as to its functional capabilities and cognizant of the likely organizational impacts.

The action research approach described above leads to the development of systems custom-tailored to the needs of users, even if the primary hardware and software still come from established computer manufacturers. Several key characteristics of the approach deserve reiteration:

1. The spirit of the project is one of cautious and rational planning for the future by development of a necessary understanding of today's top management communication activities.
2. System design proceeds by interpretation of an holistic model of managerial activities. Scenario evaluation and development brings out the values and perceived needs of the managers themselves.
3. Structured observation of management communication behavior and preliminary design specification are not "technology driven," but reflect characteristics of the client organization.
4. The research methodology has the open intention of gradually educating the managers themselves so that they can contribute knowledgeably and efficiently to any eventual system design and implementation.
5. The project focuses on top organization management on the assumption that their time is most valuable to the organization and thus can most significantly be affected by the quality of unstructured communications support systems.

The evolving market for word processing and typesetting systems

by J. CHRISTOPHER BURNS
Arthur D. Little, Inc.
Cambridge, Massachusetts

ABSTRACT

The word processing, text editing and typesetting industries have become an important market for computers and computer software. Industry installations are described and sales are forecast for major systems components over the next five years. An evolution is suggested which will link word processing, in-plant publishing, text editing and business data processing systems over the near future.

More than 100 billion words are set in type each year in the United States—about 10,000 times what an average person could read if he did nothing all year but read. There are two interesting facets to this figure: first, it seems to be rising, not only in absolute terms but in proportion to the population. As nearly as we can tell words set per capita in the United States has risen 16 percent in the last ten years, this in spite of increased television broadcasts and a decreasing percentage of the population attending public and private schools and colleges.

The second facet is that with all this information to exchange we are still choosing to set it in type. Over the past ten years we have seen the development of inexpensive display terminals, high-speed non-impact printers and microprocessors which could bring this information directly into the home, bypassing the centuries-old tradition of typesetting. Yet, except for specialized financial applications, we are not using the new technology. Today nearly 70 percent of what you read has passed through a computer in machine readable form at least once, and yet the product does not differ much from its 14th century Chinese ancestor. We are here talking about typesetting not as a dusty curio but as a market for computers, and the reason for this is fundamental to an understanding of how the market will evolve and the demands it will make on the successful vendor.

Let's look for a moment at typesetting: This is an example of how the news might look if it came over communications lines to a home terminal (Figure 1) and this is how the news looks on a typical newspaper page (Figure 2).

Or this example: An entry from a parts catalog as it might appear on a computer printout (Figure 3) and the same data displayed using typography (Figure 4).

The point, of course, is that typesetting makes it possible to mix sizes, type styles and different layouts in order to present information with greater efficiency, leading the eye, providing ready visual tags to aid retrieval, defining the nature of the information and organizing it for ready reference. Typography is a complex language which can support or overwhelm the message it carries, and mastering this language requires similarly complex commands.

The catalog entry shown, for example, required 104 separate instructions imbedded in the text to select type style, size, line length and so forth, all in composing a block of about 210 words. The development of computer systems to control typesetting has been a surprisingly difficult task. In the ten years since the first work was done on computer assisted typesetting we have only accomplished half the things we knew then to be possible. Hyphenation and justification have been done as well as stored formats, tabular work, run arounds and rudimentary pagination, but there is still no generally accepted system to handle the simultaneous composition of multiple columns, copy fitting, layout assistance, complex chemical and technical typesetting or proofreading, through each was foreseeable as early as 1967.

Typesetting systems today are about where business data processing systems were in the days of the 1401, batch oriented, close operator involvement, lots of home-grown software around, little or no full systems integration and occasionally brilliant installations in a general population of ill-fitted, commonplace and troubled efforts.

There are about 800 such typesetting systems installed in the United States today (Figure 5). The earliest of these—the IBM 1130—was equipped with excellent field developed software and became widely popular in the late 1960's although it was only a pro-

Power Pioneers

Some Small Innovators Heat Homes by Sun, Light Them by Wind

Experimenters Find Gadgets Expensive but Satisfying; Research Funding Elusive

Disguising a Tank as an Urn

By DAVID BRAND
Staff Reporter of THE WALL STREET JOURNAL

TIJERAS, N.M. — So far as Robert Reines is concerned, Arab countries can turn off the oil tomorrow and electricity costs can go through the roof. He is insulated from all that.

Mr. Reines lives in a igloo-like white dome that gets its heat from the sun and its electricity from the wind.

The dome home is on a hillside some 20 miles from Albuquerque. At night, with the inside lights shining through the dome's portholes, the scene is reminiscent of an H. G. Wells futuristic novel. In fact, Mr. Reines sees himself as pioneering an age when whole communities will be energy-sufficient.

"I have freedom because I have all the energy I need, and that's real freedom," he says with a fervor that almost bristles.

Sun Businesses Blossom

Already in the U.S., according to a University of Colorado survey, are nearly 200 solar-heated houses built, under construction or planned. To equip these homes, more than 100 solar-equipment makers have emerged, many of them small, backyard concerns. The solar-power market, according to a study by the research firm of Arthur D. Little, could reach $1.3 billion by 1985 "if industry, with effective government support, moves ahead promptly to introduce solar hardware into the marketplace."

Now this hardware is high-priced. It's largely handmade from expensive materials such as copper, and large amounts of the materials are necessary. A commonly used rooftop solar panel is a glass-covered aluminum or steel tray in which antifreeze, water or air is heated as it moves through blackened copper tubing. In many parts of the U.S., such heat collectors must cover at least 50% of the roof surface to provide about 80% of a house's central heating.

Bonanza forecast for US communications

CAMBRIDGE, MASS: An explosive growth in electronic business communications, brought about by a combination of advances in technology and changes in regulations, has been forecast by two members of the staff of

vice for less money."

One implication of new developments is that the volume of mail now associated with business operations may be limited as electronic devices with increasingly attractive cost/performance characteristics offer this opportunity.

ADL Predicts U.S. Telecommunications User Bonanza

"In the early 1980s, U.S. telecommunications users in business and government will be treated to a bonanza—new services, more service options and flexibility, much wider choice among suppliers and significantly revamped rate structures. In some cases they will literally be

TELECOMMUNICATIONS,
Mar., 1975

Communications Services To Expand in the Next Decade

attractive cost/performance characteristics will offer significant opportunities to limit the volume of mail now associated with business operations. In 10 years they may even begin to affect the amount of business travel if the result of current teleconferencing experiments prove encouraging.

According to Roetter and Shapiro: "In 1974 total U.S. telecommunications expenditures by business and government were approximately $18-20 billion, compared with mailing costs of $8-9 billion and travel

In the early 1980's US telecommunications users in business and government will be treated to a bonanza—new services, more service options and flexibility, much wider choice among suppliers, significantly revamped rate structures. In some cases they will literally be getting more service for less money, Martyn Roetter and Peter Shapiro predict in their current Arthur D. Little IMPACT study, *Business Communications, 1975-1985.*

New telecommunications services only now in their infancy will play a major role in business communications by 1985, they observe. Electronic devices with increasingly attractive cost/performance characteristics will offer significant opportunities to limit the volume of mail now associated with business operations. In ten years they may even begin to affect the amount of business travel if the results of current teleconferencing experiments prove encouraging.

According to the authors total US telecommunications expenditures by business and government were approximately $18-20 billion in 1974, compared with mailing costs of $8-9 billion and travel expenditures of $16 billion. Even though telecommunications expenditures may be a bit slow in 1975, they should experience healthy growth through 1980, reaching some $30 billion by then.

duction system and allowed no text editing or formatting.

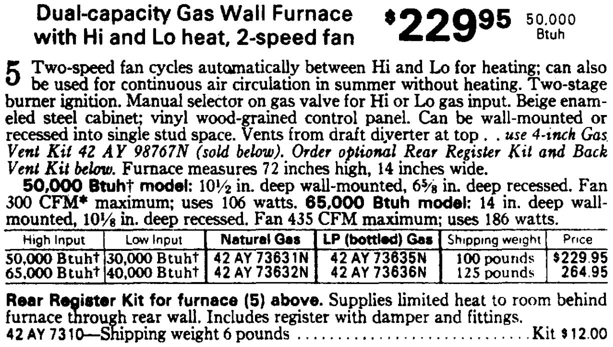
The CSI Photoset and the Digital Equipment Typeset 8 were competitors to the 1130, the Logicon and Sun Com systems were imitators—literally selling the same 1130 with slightly different software. All of these products did hyphenation and justification and formatting, much of which can now be done within the typesetter itself.

Group C on this table represents the main contenders in the market of the early 1970's. Typically they use a 32K PDP-8 or Nova to support a 2.5 megabyte disk, 8 video terminals, an optical scanner and an interface to the phototypesetter. These are dedicated systems with vendor software and almost no general-purpose capability. Rarely are these systems even sold with a compiler. They handle classified ad production for newspapers, text editing, limited file management and occasionally crude operator statistics and production reports.

In Group D are the larger systems in the market today: DEC's Typeset 11, the large Hendrix text editing system, SDC and the large Tal-Star system. Products in this group typically support 32 to 64 video terminals and have been sold almost exclusively to large metropolitan newspapers. Some of them do limited business data processing.

The last group includes the very big systems. DEC has written a full typesetting system for its PDP-10. Harris has built several large systems based on the PDP 11, and there are several major daily newspapers who have written their own software for the IBM 370.

A note on systems which do not appear on this table: IBM has announced but to my knowledge not delivered a typesetting system for the 370 called Printext 370. Univac has announced a typesetting system called Newscom. Dolphin Graphics has acquired the U.S. marketing rights for MOPAS, a European system of some promise and there are at least six other suppliers of typesetting systems in varying stages of specula-



Dual-capacity Gas Wall Furnace with Hi and Lo heat, 2-speed fan **$229.95** 50,000 Btuh

5 Two-speed fan cycles automatically between Hi and Lo for heating; can also be used for continuous air circulation in summer without heating. Two-stage burner ignition. Manual selector on gas valve for Hi or Lo gas input. Beige enameled steel cabinet; vinyl wood-grained control panel. Can be wall-mounted or recessed into single stud space. Vents from draft diverter at top . . *use 4-inch Gas Vent Kit 42 AY 98767N (sold below). Order optional Rear Register Kit and Back Vent Kit below.* Furnace measures 72 inches high, 14 inches wide.

50,000 Btuh† model: 10½ in. deep wall-mounted, 6⅝ in. deep recessed. Fan 300 CFM* maximum; uses 106 watts. **65,000 Btuh model**: 14 in. deep wall-mounted, 10⅛ in. deep recessed. Fan 435 CFM maximum; uses 186 watts.

High Input	Low Input	**Natural Gas**	**LP (bottled) Gas**	Shipping weight	Price
50,000 Btuh†	30,000 Btuh†	42 AY 73631N	42 AY 73635N	100 pounds	$229.95
65,000 Btuh†	40,000 Btuh†	42 AY 73632N	42 AY 73636N	125 pounds	264.95

Rear Register Kit for furnace (5) above. Supplies limited heat to room behind furnace through rear wall. Includes register with damper and fittings.
42 AY 7310—Shipping weight 6 pounds . . . . Kit $12.00

Figure 4

Systems		Systems Installed	Average Price
Group A	IBM 1130	300	$50-75K
Group B	CSI Photo Set, DEC Typeset 8 Logicon-Intercomp, Sun Com	225	$60-150K
Group C	DECset 8000, Dymo CPS 500 & 700, Tal-Star 1000, CSI 24/32, Hendrix, Harris, Atex	180	$100-300K
Group D	DEC Typeset 11, Hendrix 3400, SDC Text II, Tal-Star 4000	60	$300-700K
Group E	DEC Typeset 10, Harris, IBM 370 with field developed software	35	$700K-1.6M
		800	$136.3M

Figure 5—Computer Typesetting Systems Installed 1975

tion, product announcement, and field testing. The most interesting non-system is the Newspaper Systems Development Group, a consortium of eight U.S. newspapers who have contracted with IBM's Federal Systems Division to design and build a full page composition system capable of halftone composition, layout assistance, full page make-up and multi-column composition. It does everything we think a computer can do for a newspaper and a few things over which there is healthy debate. The project is over budget and at least two years behind schedule.

But the U.S. Printing and Publishing Industry has been willing to spend over $700 million on new technology in the past five years (Figure 6), primarily on phototypesetters and small production oriented computer systems. Newspapers have been the most aggressive sector here, and for good reason: payout on a typical newspaper system can be achieved in less than 18 months if the labor situation is right. Newspapers report that conversion from hot metal to computerized photocomposition has cut as much as 50 percent off their composition and production costs, often equivalent to an increase of 10 percent in profit before taxes.

Over the next five years the market is likely to behave somewhat differently. A major increase in small word processing and text editing systems sales is expected, with floppy disk-oriented systems available for below $50,000. Optical scanners are likely to lose sales momentum and may in fact experience declining sales by 1980, functionally replaced by communicating terminals and word processing equipment. And I think it's clear now that Xerox, Redactron, IBM, Digital Equipment and others intend to turn memory and display typewriters into a billion dollar a year business by 1980 with the probable result that at least 25,000 communicating and display typewriters will become terminals for typesetting systems. Phototypesetters will continue to sell, though at a lower price. At the center of this growth is an enormous potential for small and distributed computer systems which not only can meet the composition needs of the user but also can perform file management, message switching, data storage and retrieval by key word or subject as well as inter-computer communications.

It is probably useful at this juncture to point out that there are more than 30 suppliers now trying to capture a share of this market, with only four achieving annual sales over $10 million and at least 12 operating on sales of $2 million or less.

Who will the customer be over the next five years? (Figure 7) Certainly the printing and publishing industry is the primary target and within that the daily newspaper continues to be the most attractive sector, although our own figures are now suggesting a greater saturation of that market than most other forecasts indicate.

COMPOSITION SYSTEMS SALES: 1970-1975

Component	Unit Sales	Value
Typesetting Computer Systems	500	$100M
Optical Scanners	2,000	$60M
Editing Terminals	3,500	$35M
Phototypsetters	20,000	$500M
		$695M

COMPOSITION SYSTEMS SALES: 1976-1980

Typsetting Computer Systems	1,500	$220M
Optical Scanners	2,000	$50M
Editing Terminals (including video display word processing equipment)	25,000	$250M
Phototypesetters	25,000	$400M
		$920M

Figure 6

Market Sector	Number of Establishments	Establishments with 20+ Employees	Annual Composition Volume	Percent of Market
Daily Newspapers	1,770	970	55M Words	86%
Weekly Newspapers	9,500	300	.9M	1
Magazine Publishers	2,500	500	.5	1
Book Publishers	1,200	300	1.9	3
Miscellaneous Publishers	2,000	250	.4	1
Commercial Printing	22,400	3,800	1.0	2
In-Plant Publishing	48,000	5,000	3.8	6
	87,340	11,120	63.5	100%

Figure 7—The U.S. Market for Typesetting Systems

While there are a great number of establishments—an astonishing number, really—less than 13 percent of these shops have more than 20 employees, a minimum number in my opinion to qualify the establishment as a potential site for a computer-based typesetting system. (Smaller shops will certainly buy phototypesetters and some may buy stand alone editing terminals, but few will be able to spend more than $30,000 on composition systems.) We have to ask a second question: How much typesetting is done? Fewer than a thousand newspapers, for example, set 55 million words a year while more than 3,800 commercial printing shops set only a million words. Analyzing the market this way suggests that of establishments with more than 20 employees, 970 daily newspapers set 86 percent of the type and therefore still constitute the giant share of the market. But the same 970 newspapers probably account for 650 of the typesetting systems already installed, leaving an untouched market of little more than 300.

Weekly newspapers, magazines and book publishers present perhaps a more interesting opportunity. There are 1,100 potential systems sites here and we estimate that only 150 systems have been installed. The opportunity for composition savings is not as great in these sectors and the publications are less sensitive to deadlines, therefore less demanding of speed. But major magazines have installed such equipment and are looking now for communications capability, and book publishers are trying to sort out the choice between word processing and communicating text editing.

The In-Plant market at the bottom of this figure is a tantalizing puzzle. Major corporations maintaining their own print shop will certainly buy typesetting systems. How medium-sized businesses ($25 million to $100 million) respond will be influenced dramatically by the shape of new word processing systems. Let me take the last few minutes to describe how I think this market will evolve. (Figure 8)

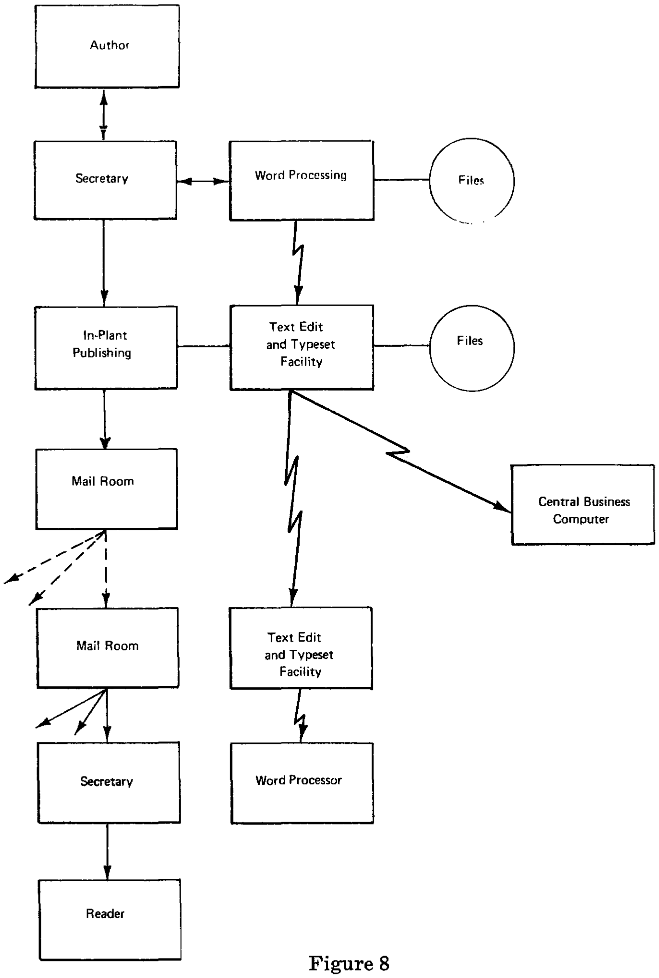


Figure 8

It is probable now that the sale of memory and communicating word processors will grow at a rate of 21 to 25 percent per year, reaching an installed population of 750,000 in 1980. The equipment will be used by secretaries and in administrative service centers to prepare reports, letters, legal documents, telephone directories and memorandums, many of which will be simultaneously stored in machine compatible media like magnetic card, cassette or floppy disk. This is the so-called word processing market.

We expect another development to occur at the same time: the general adoption of mini-computer based text editing and composition systems. By 1980 there will be as many as 1000 of these in medium to large businesses preparing formal reports, pamphlets, manuals, large directories and catalogs. This is what we refer to as the in-plant publishing market. It is obvious, I think, that in a short time these two independent components—the word processing world and the text editing world—will begin communicating. Material drafted on word processors will be composed in a central facility, long contracts stored in a central computer will be retrieved by the word processor to be revised. Product definitions will blur—"Is it an intelligent terminal or a communicating word processor." Alert suppliers will identify and provide a full range of compatible products and we will hear advertising slogans that talk about a "total information system."

And there is another development possible. In our own work evaluating and sometimes designing such systems we have seen cases where communications capability was required not only from the remote terminal to the central facility, but from the central facility to the main business data processing system and occasionally from facility to facility over packet switched communication networks or even dial-up lines.

What we are talking about here is a new business communications system that will provide a rapid, low cost alternative to the present process of typing, duplicating, mailing, distributing and filing. This has some important implications for those who would participate in the market. It means message switching, privileged access, hierarchical organization of files and cross indexing, all this in addition to the communications and support systems.

For years we have used the phrase data processing to mean the manipulation of measurements. With the rapid introduction of computers to typesetting, text editing and word processing we are beginning to process ideas, to gather and select them, store and retrieve them, to format and present them in a way that will enhance their meaning. The associational structure of ideas and messages differs profoundly from the structure of numbers and we will need new strategies for storage and retrieval. The typography of an idea is no less important than the design of a complex statistical report, so we will need new commands, perhaps a new composition language. But the opportunity is enormous and the rewards for both business and society are rich. As computers become smaller, cheaper and more powerful we have the chance to use them for more than the measurement of work accomplished, we have a chance to move them out to the work site itself to speed and clarify the communications on which that work is based.

The computer as a tool in the processing of text for periodical publications

by WILLIAM J. HAMMOND
Publisher's Compu-Type Service, Inc.
New York, New York

ABSTRACT

This paper traces the introduction and initial applications of computer technology into the magazine publishing industry. It reviews developments leading up to our present state-of-the art. It continues with an overview of today's systems. And, it concludes with a preview of future advancements designed to enhance the publishing of periodicals.

Since its introduction into the typesetting process in the early 1960's, the computer has proven itself to be not just a useful tool, but an almost indispensable one, in all areas of the publishing field. The techniques of setting type photographically had been successfully mastered in the late 1950's. The marriage of the computer to phototypesetting freed both the typographer and the publisher from the limitations and the constraints of three dimensional "hot metal" typesetting.

The first functions assigned to computers were those involving "end of line" decisions resulting in the justification of a line of type. Justification is the process of making a line of type fit evenly within the specified line measure. The computer freed the keyboard operator from having to determine when and how to hyphenate words, and from calculating how much space to allow between words. Thus freed, the operator could concentrate on improving the speed with which he could convert a manuscript into coded paper tapes to be processed by the computer. A new, justified paper tape version of the story could then be typeset on a phototypesetting device.

In the late 1960's, automation of typesetting processes began to make real progress as a result of the introduction of minicomputers. The "minis" may not have been as fast at internal computations as their big brothers, but they were fast enough to perform the many repetitive calculations involved in the justification process tirelessly and accurately, and still keep up with the relatively slow speeds of input and output peripherals. The comparatively low cost of minicomputers permitted the widespread introduction of computerized typesetting systems into an industry composed largely of small shops.

Initial acceptances of computerized typesetting in the publishing field were in the newspaper, book and catalog fields. Newspapers were quick to capitalize on the speed advantages offered by computers while books and catalogs found justification in their use based upon reprocessability for republication purposes. Periodical publishing lagged behind in its use of the computer because of its one-time usage of typeset matter and the relatively high degree of alteration of text prior to publication.

The introduction of "minis" not only permitted the widespread use of computers in the industry, but allowed systems to be developed with sizable on-line mass memory and more sophisticated programs to handle storage and editing requirements as well. Let's look at editing for a moment. Editing is the process of making words suitable for public presentation. It does this by performing a number of functions such as: selecting, compiling, writing, rewriting, altering, and formatting. The purpose of editing is to bring about conformity with a set of standards to suit a particular purpose. These standards, generally set by the publisher, might include: clarity of meaning; accuracy of spelling and hyphenation; and an effective or pleasant appearance of the final printed product. Editing is, in fact, a process of manipulation; manipulation of text, of words, of data. And, data manipulation is a process that readily lends itself to the electronic technology of computer processing. It is only natural that computers should prove to be useful and valuable tools for facilitating the text editing process.

Today's computerized typesetting and text processing systems are a far cry from those of 10 years ago. A modern system will include one or more powerful minicomputers. It will accommodate a wide variety of input and output devices. It will employ large random access disc systems for one-line storage and video displays for on-line editing and updating of files. And, it will have data communications capabilities to handle remote input and output to remote printing and publishing locations.

The modern computerized typesetting and text processing system affords periodical publishers and editors a number of facilities to improve their functions.

First, and foremost, is control. For the first time in many instances, control of how, when, and where typesetting is done is in the hands of the periodical publisher. Consistency and accuracy in typographic specifications and style integrity can be guaranteed. A publisher no longer has to depend upon a particular shop, or more likely a specific individual, to interpret an editor's marginal notes concerning style. A few simple control codes can cause the computer to recall preprogrammed rules concerning: the type faces and sizes to be used; the relationship of various elements of the story; rules for the usage of intraword spacing; specific rules for word hyphenation and exceptions to those rules, etc.

The physical layout of text columns on a page is easily controlled. A predetermined size and shape for any column of text can be given to the computer and it will mold the text to fit the desired configuration. Both regular and irregular shapes of blocks of text can be used, resulting in more artistically pleasing relationships between text and illustrations on a page. Entire pages can be composed electronically with all typographic elements assembled in their proper position, thus saving both time and cost of assembling the elements by hand.

The correction processes are greatly facilitated by changing only the words or the individual characters requiring change. Formerly, changing even one letter on a line necessitated resetting the entire line; changing a word often involved resetting several lines. One of the great dilemmas of a publication editor has finally been resolved. Often, an editor had to decide between making the most effective change from the point of view of clarity of meaning, which could result in massive resetting of type, or making a less effective change and avoiding costly and time consuming resetting. Since in today's systems, the text stream and configuration of text columns operate independently, the editor no longer need hesitate to make the most effective changes.

We are living in the midst of what has often been referred to as an "information explosion". The need to know is steadily growing, and timeliness is being equated with newsworthiness. This is as true of the monthly trade magazine as it is of the national news weekly. The modern computer system is satisfying this need too. It has permitted tightening of schedules to the degree that news stories can break within hours of the time the presses must roll and still make the edition. Turn-around times for both original typesetting and corrections are such that many news magazines have justified systems on that basis alone.

Freedom from fear was promised 200 years ago, but it has only recently found its way into periodical publishing. With a modern computer system incorporating a high speed data communications network, publishers of large volume national news weeklies have been able to print identical, accurate versions of the news in multiple printing locations. They can now enjoy the advantages of multiple distribution points without the fear that different printers may have slightly different versions of the news. Control is in the hands of the publication. All magazine publishers, at one time or another, know the fear of having to move from one printer to another. Invariably, the most traumatic part of the move is the disruption and chaos resulting from moving the typesetting operation. "That little old typesetter with the green eye shade is the only person in the *world* who knows what the editors want!" With an in-house, or nearby service bureau handling the typography, the transition can be made without having to change editorial practices or procedures. Possibly the greatest fear of a publisher is the sudden, unexpected loss of services of the printer. Again, with the service bureau at hand, the publication is free to locate and switch to a new printing facility on a moment's notice without fear of major disruptions in its editorial process.

Control, freedom, and flexibility make the computer an invaluable tool in the periodical publishing industry. These factors have taken typography out of the manufacturing process and put it back into the publishing process where it started.

What of the future? What additional benefits can the publisher look to derive from the computer?

Many of the future benefits of computer usage are on the drawing boards and in the laboratories right now. The periodical publisher can look forward to systems that not only generate his typography, but also produce his illustrations; thus giving him the ultimate in control of the pre-press processes. In the area of marketing and distribution, computers will permit the manufacturing of personalized editions of his magazine for each individual subscriber. Advertisers will be able to direct their messages to highly specific audiences getting maximum effective exposure for their advertising dollar. Through modeling techniques, publishers will be able to specify the optimum combination of components in an issue, or they will be able to predetermine which of a number of suppliers is best able to produce a particular product. Of course, data base publishing will come into more and more sophisticated use. Libraries of past issues can be easily retained on magnetic tape with possibilities opening up for indexing, abstracting, and reprinting in new formats. Finally, with the perfecting of graphics generating typesetters, micro-publishing will begin to make inroads into conventional publishing methods. Someday, maybe soon, magazines will be entirely produced on microfilm or transmitted electronically directly into the subscriber's home.

If this sounds like "blue sky," just reflect for a moment on how far electronic technology has progressed in the past ten years, or even in the past five years. As technology continues to make giant steps in progress, that "blue sky" will rapidly come down to the solid reality of ground level.

The integration of microfilm and the computer

by DENNIS R. NEARY and TERRENCE H. COYLE
Eastman Kodak Company
Rochester, New York

and

DON M. AVEDON
National Micrographic Association
Silver Spring, Maryland

ABSTRACT

A discussion of the nature of information and how data flows through a basic data processing system. The key functions of INPUT, PROCESSING, and OUTPUT are reviewed, with emphasis on data capture and output reporting. After a typical information system is described, the various places where micrographics fits are analyzed. Microfilm is shown as a complement to the modern information system. The basic micrographics concepts are discussed. Rotary and planetary cameras are explained, as well as the various microforms that they can be used to create. Coding techniques and retrieval equipment are reviewed, and the value of microfilm as a storage medium is explored. The nature of the COM concept is explored to establish where and in what situations it may, or may not, be valuable. Cost justification is explored as well as systems benefits. COM technology is explained, and the future of COM will be projected. An exploration of the concept of capturing source documents in random sequence on microfilm and using a computer generated index to assist in retrieval. The actual hard wire interface of a computer and a microfilm display device will be discussed. The future of computer assisted retrieval will be projected. The integration of data capture and microfilm will also be discussed. A projection on the status of data processing five years from now, and how microfilm will fit in the information systems of the 1980's.

INFORMATION FLOW ANALYSIS

In analyzing any basic data processing system, the major operations can be divided into input, processing, and output. Data is abstracted and captured from source documents, converted to machine language, and electronically transferred to the central processing unit, which processes that raw data in conformity with a standard application program. As a result of that processing, master files are updated and maintained, transactions are reported, and current status is updated and reported. The reporting has been done historically on paper and more recently with video images on CRT terminals. A third output image that has gained prominence in the last few years is the micro-image, created through computer output microfilmers.

The data processing system has undergone an information explosion. Bulging files, misfiled papers, long searches through millions of manila folders in thousands of offices all over the world, reams and reams of computer output, and expensive, complex on-line systems have strangled the typical modern business. Let's take a closer look at a typical data processing system and see where the micro-image can begin to increase the effective utilization of the entire system.

Information is first abstracted and captured from the source document. Keypunching, key to tape, key to disc, on-line terminals, and optical scanning are the major ways in which information on the source document is converted to machine language and ultimately transmitted to the mainframe. After the information is fed into the computer, what remains is the staggering problem of sorting, filing, and controlling the ocean of source documents. See Figure 1.

Source documents can be categorized as bulk file (unit data) or folder file (co-related data). Generally, bulk file consists of one type of document, and retrieval requires manual search of a paper file for one or more of these documents. Examples include checks, sales slips, time cards, stock certification, and the like. Folder file describes those groups of source documents which contain several types of inter-related data and require merging or updating. Examples include loan application files, insurance policy files, order entry files, and so forth. A key point in the definition of folder file is that folder file information requires inter-active updating. When a folder file becomes a dead record,

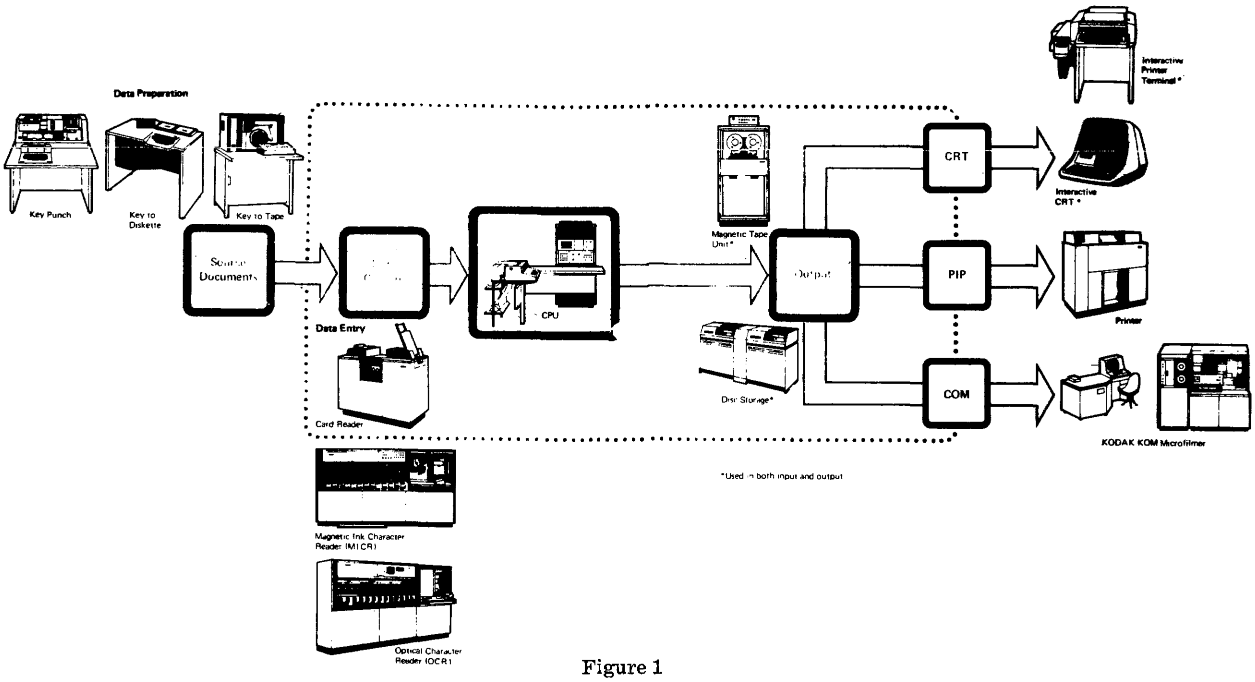

Figure 1

or purged information, it is then considered bulk file information. Regardless of whether a source document is maintained in a bulk or folder file, the micro-image can provide two major benefits: space savings and file management.

Space

The benefits of space savings are important to any growing business.

1. *Opportunity Cost*—The Micro-Image provides the opportunity to use expensive floor space for generating profit, not storing files.
2. *File Location*—The Micro-Image condenses files so that they can be located near the end user.
3. *Duplication*—Too many duplicate copies of dead records are a problem in many office environments. The Micro-Image solves the problem. The user can retain one microfilm copy and create paper copies only when needed. If duplicate copies of the entire file are required for several users, they can be generated at lower cost, occupying less space.
4. *Expansiveness*—Files can become so expansive that they not only occupy valuable space, but become unmanageable with both on- and off-premises storage. The Micro-Image can provide a 98 percent space savings, and virtually eliminate the need to selectively purge paper files.

FILE MANAGEMENT

The benefits of file manageability are benefits affecting the company's lifeblood, the flow of needed information.

1. *Operating Costs*—Paper files are labor intensive, making for a waste of talent in an organization. The Micro-Image with automated filing and retrieval helps reallocate talent, saving money for the prospect.
2. *Accountability*—Files document business operations, providing the basis for answering customer, management, or interdepartmental inquiries. The Micro-Image provides *audit trial control* over files, and eliminates the national average of nearly six percent of misfiles and lost documents in the source document area. The Micro-Image provides file integrity.
3. *Manageability*—The Micro-Image organizes files so they are of manageable size and format. And it pulls these files together so that they can be easily co-related on request. The Micro-Image manages the file through automated information handling.
4. *Security*—Paper can be easily tampered with, stolen, or destroyed. The Micro-Image is discrete, easily and safely stored, and can be duplicated with extra copies kept off-premises.
5. *Convenience*—The Micro-Image assures that the record is there, or it simply does not exist. Records can be accessed faster and more easily with any of the available formats.
6. *Human Factors*—Paper is essential. But after a message or order has been communicated and documented on paper, the *manual* filing process remains. Automated Micro-Image systems can also provide job enrichment to reduce employee turnover.

Microfilming of the source document can take place either prior to or subsequent to data capture. Microfilming can be performed in such a manner that the information is accessible through various techniques which will be described later in this report. However, one approach which is gaining prominence in the recent past is the filming of the source documents in random order, and the assignment of a film address, a roll and frame number. This film address is captured with the other information passed on to the computer which in turn creates an index to the address by any number of parameters which the end user might require. This index can be reported out on paper, or can be maintained on-line, and allows the user to access information from a random film file with the assistance of the computer generated index.

After the information is processed and master files are updated, the computer produces a large number of reports. These reports are typically printed out on an impact printer on paper. Another approach is to maintain the report information on-line in a direct-access storage device and reference the information selectively through a computer terminal. The disadvantage of printing on paper is the tremendous time it takes—approximately 1,000 to 2,000 pages per hour—and the cost of paper and printing, and the problem of maintaining large volumes of paper reports for information retrieval.

The disadvantage of the on-line approach is the tremendous cost to store all the information in the direct-access storage device, transmit the information through a telecommunications system to the terminal, and the software to control the entire teleprocessing system.

A third alternative which has gained prominence in the past few years is a compromise between the two. Rather than maintain the information on-line at extreme cost, it is printed out; but not on expensive paper through a slow printer; but rather on inexpensive microfilm through a high-speed computer output microfilmer. Through this technique, users are finding that they can provide much more information faster to a wider number of users at a much lower cost than they could with either paper output or on-line CRT display.

We have seen where microfilm is used to capture source documents prior to or subsequent to data capture. We also see the part that microfilm can play as an output medium instead of a paper or a CRT image. These two disciplines can also be integrated to provide a total information file which incorporates both paper, electronic image, and a micro-image. Consider source documents which are filmed and the address of that micro-image is passed through the computer to an output report. That output report is produced on a computer output microfilmer, and serves as the index to retrieve the source documents on microfilm. Another group of source documents is captured in the same way, but their particular output report is printed out on hard copy. A third group of source documents are microfilmed, and their address is maintained on-line in a direct-access retrieval system. Now the user can retrieve source document information by either inquiring to a file with an on-line CRT which directs the user to the image on film, or the user can reference a hard copy report which provides direction to retrieval to the source document on film, or the user can reference an index on microfilm created by the COM, which also keys the end user back to the source document on film.

To take this inter-relationship one step further, a CRT terminal can be interfaced to a microfilm retrieval device so that when an inquiry is made to an on-line data base, the resultant micro-image of the source document can be electronically transmitted directly to the microfilm reader and the image subsequently displayed automatically. Systems of this type have been installed and operating for several years, and promise to proliferate in the near future. Now in order to better understand the advantages the micro-image can play in a data processing system, we will take a closer look at how microfilm is actually created and the various ways in which it can be retrieved. We will also look in more detail at the concept of computer output microfilming—how it is done and what advantages it provides over on-line access and paper printing. We will then review the advantages of computer assisted retrieval and project the future of the integration of microfilm and the computer over the next five years.

MICROGRAPHICS—INPUT AND RETRIEVAL

Subject

How microfilm is created and the various ways it can be retrieved.

Topics to be covered:

- Micrographic Concepts
- Rotary and Planetary Microfilmers
- Microforms
- Encoding Techniques
- Retrieval Techniques
- Microfilm as a Storage Medium

Theme

A basic microfilm system follows a parallel path to a basic data processing system. Our first speaker has presented a hypothetical data processing system consisting of input, processing and output. Since my topic follows a parallel path to this flow, I will use this same model to show "How Microfilm Is Created and Retrieved." See Figure 1.

While we are dealing with two distinct disciplines, there is some common ground. You are concerned with the creation, movement and use of "data records"; and we in the microfilm community are concerned with the creation, formatting and use of "film records."

For our purposes today, I will be discussing two types of "film records"—roll microfilm and microfiche. When I refer to roll film I am thinking of a reel of film 16 mm wide and either 100 feet or 215 feet long. And when we discuss microfiche I am thinking of a sheet of film 105 mm high by 148 mm wide. See Figure 4.

The parallel path I mentioned starts when we consider the data for the creation of both the "data record" and the "film record" is common—the same source document. You capture data magnetically and we capture the image photographically on film. The parallel continues until the end of the information path when you visually display "data records" and we visually display "microfilm records."

Let's begin our analogy by looking at input. You must extract pertinent data from source documents and enter it in your information system. You have a number of options—keypunch, key-to-tape, key-to-disk, on-line terminals and scanning. We are also interested in the input document, but from a different vantage point. We are not interested in extracting data, but in capturing the entire document image. To accomplish this task, there is one major option to consider—what type of microfilm camera do I use?

There are two basic categories of source document microfilmers—planetary and rotary. While there are numerous models of each, I will treat them in these two broad categories.

Planetary cameras are manual in operation. Documents to be microfilmed are placed on a copyboard and by depressing an exposure button the image is recorded onto microfilm. This procedure will be repeated from 3,000 to 4,000 times thus resulting in a completed roll of microfilm.

This type of camera is normally used when dealing with large documents or for precision microfilming jobs. Those of you from industrial or engineering firms may be familiar with engineering drawing applications utilizing 35 mm microfilms.

When dealing with normal business documents however, a rotary microfilm camera may be a better alternative. Rotary microfilmers can be used to greatly increase the speed at which microfilming takes place. This is possible because of automatic feeding devices which allow for creating microfilm images on the fly. In this instance, microfilming speeds of up to 615 documents per minute are easily achieved. Rotary microfilmers also offer other advantages, such as packing 15,000 check size images onto a 100-foot roll of microfilm and, at the same time, pictures can be taken of both the front and back of a document. These features, as well as automatic numbering and indexing, can be accomplished with no loss of throughput speed.

Now let's move from the input devices to the medium on which the data will be recorded. In our data processing model, data will be recorded on some magnetic medium—tape, disc, floppy disc, etc. While the medium is generally magnetic, the format does change. The same holds true for microfilm. While the medium is always constant, it can take different formats. See Figure 4.

16 mm roll film is still the most predominant format. Images are organized serially along the length of the film. We will explore how we locate an image in a few moments. However, if serial organization does not suit our needs, the roll of microfilm can be automatically cut up and added to a microfilm file folder called a jacket or film folio. This approach unitizes various pieces of data which have been received over a period of time. In this instance, the film file folder is identified by a descriptor such as account name or account number. The folder then becomes the repository for all documentation relating to that descriptor.

But let's go back to indexing. When you begin processing or moving "data records" you continually address (or index) the current location of that record. When microfilm is the medium, we must also be concerned with where images have been recorded. If a file is already serial we have no difficulty. A simple from-to label on the outside of the reel identifies the contents. The thousands of images on the roll can then be located by techniques such as codeline and odometer indexing. See Figure 4.

Codelines appear as solid bars between the microfilm images. Codelines equate to the parameter by which the file is organized. As the parameter changes to a higher value, the position of the codeline also advances. As film is advanced in a microfilm reader, the codelines appear as a solid bar on the reader screen. By establishing a scale on the side of the reader screen, film can be advanced until the codeline moves into the desired range of numbers.

Odometer indexing operates on much the same principle as a home audio tape deck. By noting the footage locations of where a given song starts, we can at any time go immediately to that piece. The same holds true with microfilm, except that we would be noting where a given range of numbers or names are located. Codeline and odometer indexing are generally used when dealing with general records retention applications. However, as we move into more dynamic environments the ground rules change considerably. In our data processing model, input is normally in a batch or random mode. If we are to microfilm these documents at random, we must then be able to establish film addresses for subsequent retrieval.

Our first speaker established one option for this type of retrieval. When a document is microfilmed it is identified by a "roll and frame number." In the microfilm community this approach is referred to as image control of item address. This film address is carried through your processing cycle and is available by interrogation of your master files, or on a report generated by your system. Once the microfilm address is identified, the proper roll of film is inserted in the microfilm retrieval device and the image control number is entered in the retrieval keyboard. The device then counts forward to display the information located at that address. See Figure 6.

A second alternative for random microfilming operates independent of computer processing for establishing the film location of a document. This technique involves the placement of a binary code on the microfilm adjacent to the image of the document. See Figure 4. The encoding takes place at the microfilm camera as the documents are being filmed. Retrieval is now accomplished by interrogating your film files by the descriptors which were encoded; example, account number, invoice number, etc. At this point we have followed our model system to the point of output. You are all well aware of your options for making information available to your users. Your options include on-line terminals, printed reports, audio-response, etc.

Our first speaker has already exposed you to Computer Output Microfilm (COM) as another option, and our next speaker will elaborate on the benefits of this approach. However, COM also introduces new microfilm formats and indexing techniques which I will cover briefly.

Earlier I discussed two microfilm formats—16 mm roll film and unitized microfilm file folders. Both of these formats are available when utilizing COM. The first roll film is available for serially organized files. The second, the unitized format, is accomplished by automatically inserting images in a microfilm file folder. But now I would like to introduce two formats available from COM—35 mm roll film and microfiche. See Figure 4.

35 mm roll film is similar to 16 mm roll film except that it is approximately two times wider. With 35 mm film, we can now print up to 16,000 images per 100 foot roll which is two and a half times our best alternative with 16 mm film. This is accomplished by printing five "tracks" of film images across the width of the film as compared to the two "tracks" available on 16 mm. The 35 mm five "track" format is particularly desirable where an extremely large data base or report is to be converted to microfilm via COM. Microfiche is a 105 mm by 148 mm sheet of film which can hold up to 288 data pages. Each microfiche is easily titled by report name and from-to report information. An index can also be created to locate the column and row location for each image on that particular fiche.

Microfiche is desirable for a number of reasons:

1. Large reports which will be used by many people are split into more manageable units. A person referencing a microfiche only removes up to 288 data pages from the file. By comparison, a person removing one roll of 35 mm film could be removing up to 16,000 data pages, thereby tying-up the file from any other user.
2. Small reports can be easily produced on one or two microfiche. Using 16 or 35 mm roll film would create many reels of film only partially filled which would have to be maintained in the microfilm file.
3. Perhaps the greatest advantage of microfiche is the low cost viewing devices which are available. Microfiche readers cost from $100 to $300, where a roll film reader could cost $1,000 to $2,000. I will come back to this point momentarily.

The introduction of COM into our model system also provides new opportunities for indexing our microfilm outputs.

Since the data to be recorded on microfilm is a product of your computer system, indexing can be accomplished under software control. Software has been designed by most COM vendors to:

1. Examine data fields to automatically generate code lines which correlate to the parameter by which the file is organized.
2. Examine data fields to automatically generate retrieval code used on Kodak Miracode equipment which corresponds to the descriptors known by the user of the file.
3. Abstract data fields to create an image control index to all data pages on a roll of film. This index page normally appears as the first image on a roll of film.
4. Abstract data fields to create an odometer index to key points in the given report.

An additional indexing technique not mentioned previously is also available when using COM. This technique,

5. examines data fields anywhere on a page and prints it anywhere on the microfilm image as a large eyeball code.

See Figure 4 for a complete review of all microfilming techniques.

The eyeball code is the technique used to generate the title and column heading information on microfiche. However, this technique can be used most effectively on 16 or 35 mm roll film applications to make these formats more retrievable for end users. In this case the large eyeball characters are normally printed at the bottom of a data page and correspond to the information by which the report is organized.

I fully realize that we have examined a great many concepts and new terminology in the past half hour. My intent has not been to confuse you, but to expose you to the tremendous flexibility of the microfilm medium. For you to use this information, it will be necessary for you to delve into the world of micrographics to determine which combination of microfilm cameras, microfilm formats, microfilm encoding techniques and retrieval options will best suit the needs of your organization. I will use an example to clarify this point.

A moment ago I said that one of the greatest advantages of using microfiche is the low cost of the microfiche viewer. However, if we are dealing with an extremely large and centralized microfiche file this may not hold true. In this case it is conceivable that so many microfiche are created that a filing and retrieval problem is created. The result may be that the look-up time to retrieve an image is too long to satisfy a customer telephone inquiry. To satisfy this situation maybe a more automated roll microfilm format will better suit your needs. Indexing and retrieval options such as binary code and image control can be used to support roll film applications. While these options may cost many times more than microfiche viewers, the improved response time may well justify the differential. Only a thorough analysis of all available options will result in the most cost effective format and encoding technique. When we go back and examine our model data processing system in Figure 1, I hope that you would now agree that the "creation and retrieval of microfilm" do follow a parallel path. In many cases the design of effective source document microfilm systems will be dependent on your cooperation and implementation. But hopefully microfilm can do something for you as data processing people as well. This is the subject of our next speaker, so I will turn the program over to Mr. Don Avedon who will be discussing the COM concept and those situations where it may, or may not be valuable.

COMPUTER OUTPUT MICROFILM

We are a computer-dependent society. Thanks to computers, information can be stored, retrieved, manipulated and otherwise dealt with at electronic speeds. We know the information we need is there—and we need it fast!

For computer information to become human readable in permanent form, the output typically takes the form of paper. These massive amounts of computer-produced paper contain more information for use in our society than ever before . . . but in a form that is extremely bulky, cumbersome to retrieve, time-consuming to produce, expensive to store and costly to duplicate. As you know computers operate electronically at the speed of light in manipulating information, but in the printing out of the information, these electronic speeds are shackled to the slow speed of the paper-generating printer. While mechanical printer technology continues to produce higher and higher speed capabilities, accelerated paper printout today falls short of solving the demand for information when it's needed.

Consider the large, familiar accordion-folded computer printout sheets. To get at this information in this form, pages have to be leafed through, heavy volumes must be removed from shelves or file drawers . . . to disseminate information in this form means carrying, mailing, trucking or otherwise transporting bulky, cumbersome material at appreciable effort and expense. To store information in this form means considerable expenditure of space and money.

It does present a problem. We've all become so dependent on the computer that it is now part of our everyday lives both at work and at home. Paychecks, bills, reports, medical records, charge account files, business documentation, scientific data and virtually every type of information we need is now produced by the computer. The net result has been a data bottleneck, instead of a smooth, even flow of information in immediate response to today's high-speed demands. To give us our information, impact printers grind out heavy, bulky, expensive reams of paper that we humans must spend time, bursting, collating, filing, binding, shuffling through and spending lots of money on moving from place to place. Then we have to spend hours looking for what we want in a sea of paperwork. Computers have solved a lot of problems for us . . . but along the way they've created a lot of new ones!

Fortunately, a way has been found to solve the data bottleneck dilemma . . . a way that gives us information when and where it's needed. It is based on the meshing of two of man's most modern technologies—computers and micrographics. We have a three-letter word for it—COM—Computer Output Microfilm. Briefly, COM is the process of converting the output of a computer directly into a human-usable form that can be read by people and recorded on microfilm. Think of COM as THE OTHER WAY to make the conversion. The paper way consists of the computer's familiar accordion-folded page—which may run for hundreds of pages. The COM process reduces the same information to microfilm, achieving an enormous reduction in size. The result is a microform that offers many advantages which we will soon discuss. While speed output is not the major advantage COM provides, it is significant that COM outpaces impact printers and even the newer page printers.

Let's briefly review some speed comparisons and then move on to discuss the many advantages COM provides to its users. The line rate of the COM recorder is 32,000 lines per minute. The typical impact printer in widespread general use in the average Electronic Data Processing installation prints 2,000 lines per minute. As we mentioned, there are page printers, expected to gain increasing prominence which can function at 12,000 to 18,000 lines per minute and beyond. So you see, one of COM's advantages is a speed factor 16 times faster than the impact equipment used in today's typical systems and twice the speed of the new page printers.

So much for speed comparisons. COM's major advantages emerge when we compare COM-produced information with the same information in paper form. We will show how COM breaks the information bottleneck by making information human-usable—cheaper and faster.

Let's consider a typical computer printout of approximately 3,600 pages of 11 by 14-inch paper. The paper alone will cost about $35 and will weigh nearly 40 pounds, filling a large carton. If you want to send it coast-to-coast, you have to spend approximately $11. If you COM-process the same amount of data into microfiche, it will weigh only two ounces and will consist of fourteen 4 by 6-inch microforms which can be mailed FIRST CLASS (and will actually travel as Air Mail) for less than fifty cents. Besides this, the materials cost for the microfiche is under two dollars. COM-produced information in such microforms as cassettes, rolls or cartridges will, of course, reflect reductions in comparison with our carton of paper. See Figure 2.

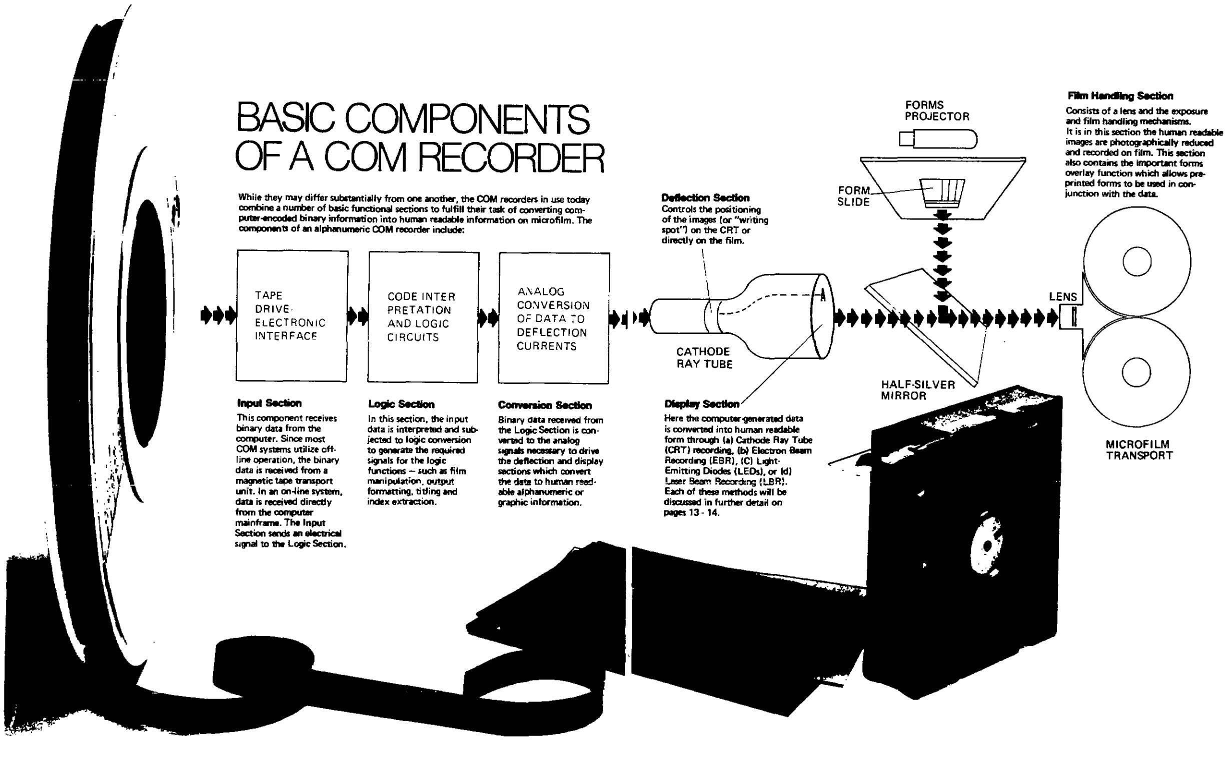
Approx. 3500 Pages (11"x14")	16mm Microfilm in a Cartridge	Microfiche	Computer Paper Printout (preprinted single part forms)
Weight (incl. container or envelope)	One Roll 7 Oz.	14 Fiche 2 Oz.	One Carton 40 Lbs.
Postage	1st Class One Roll 80 Cents	1st Class 14 Fiche 20 Cents	Parcel Post (1000 Miles) $4.25
Materials Cost	One Roll $4.50	14 Fiche $1.82	One Carton $35

Figure 2

We have talked about two advantages of COM: much greater speed and easier distribution. Before we go on to other advantages, let's pause and briefly examine the process by which data from a computer is converted into human-readable form and recorded on microfilm. Although the conversion process can initiate either directly on-line from the computer, it is usually done off-line from a magnetic tape unit for reasons which include not tying up mainframe time and equipment.

From the computer or the magnetic tape unit, the electronic signals that comprise the computer's data move to the COM recorder. In the most widely used method, the signals are reformatted to permit their processing through a cathode-ray tube . . . a CRT . . . where they become human-readable light images which are microfilmed by a camera built into the film handling section. See Figure 3.

The exposed film from the COM recorder now goes through processing. It is usually standard procedure at this point to make a security copy of the information to guard against loss or damage. See Figure 4. Let's look at the aspects of COM processing. For one thing, the system may be set to produce direct positives—that is black-on-white—or reverse forms in which the text or other printed matter appears as white characters against a black surface. Doing this is simply a matter of photographic chemistry. Micrographics specialists maintain that many microforms achieve higher visibility when viewed "in reverse," but a positive black-on-white is better for producing hardcopy.



BASIC COMPONENTS OF A COM RECORDER

While they may differ substantially from one another, the COM recorders in use today combine a number of basic functional sections to fulfill their task of converting computer-encoded binary information into human readable information on microfilm. The components of an alphanumeric COM recorder include:

Input Section
This component receives binary data from the computer. Since most COM systems utilize off-line operation, the binary data is received from a magnetic tape transport unit. In an on-line system, data is received directly from the computer mainframe. The Input Section sends an electrical signal to the Logic Section.

Logic Section
In this section, the input data is interpreted and subjected to logic conversion to generate the required signals for the logic functions – such as film manipulation, output formatting, titling and index extraction.

Conversion Section
Binary data received from the Logic Section is converted to the analog signals necessary to drive the deflection and display sections which convert the data to human readable alphanumeric or graphic information.

Deflection Section
Controls the positioning of the images (or "writing spot") on the CRT or directly on the film.

Display Section
Here the computer-generated data is converted into human readable form through (a) Cathode Ray Tube (CRT) recording, (b) Electron Beam Recording (EBR), (C) Light-Emitting Diodes (LEDs), or (d) Laser Beam Recording (LBR). Each of these methods will be discussed in further detail on pages 13 - 14.

Film Handling Section
Consists of a lens and the exposure and film handling mechanisms. It is in this section the human readable images are photographically reduced and recorded on film. This section also contains the important forms overlay function which allows pre-printed forms to be used in conjunction with the data.

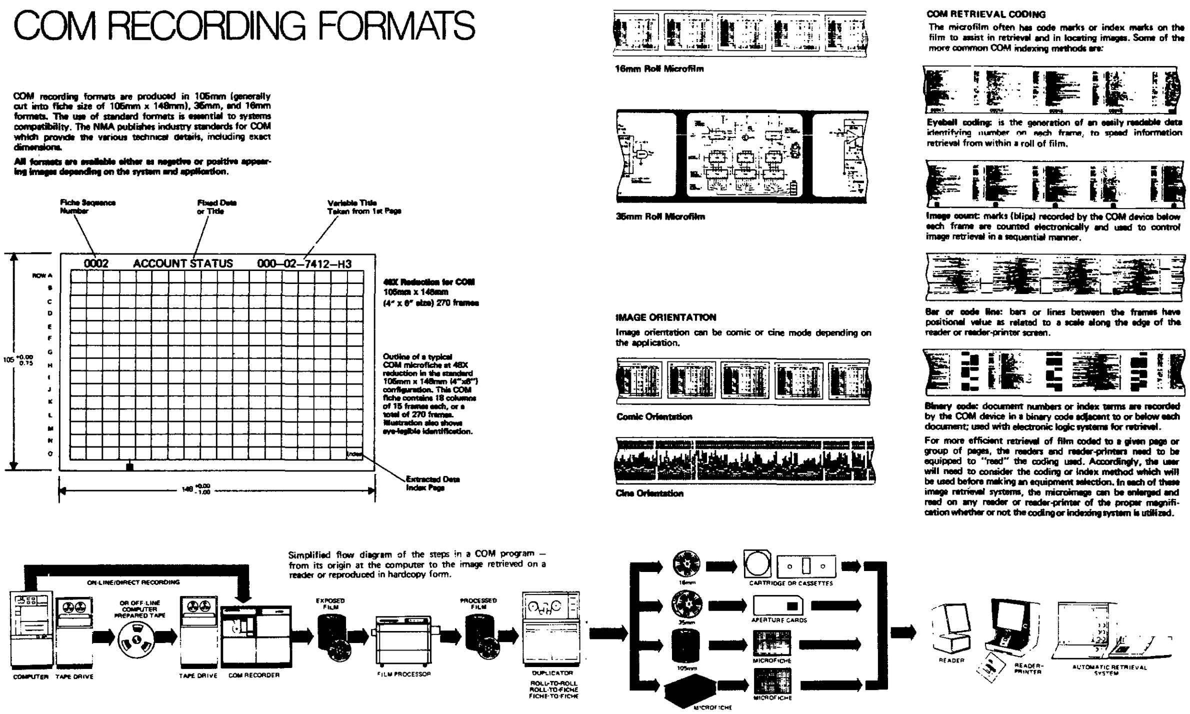
CODE INTER PRETATION AND LOGIC CIRCUITS
ANALOG CONVERSION OF DATA TO DEFLECTION CURRENTS
CATHODE RAY TUBE
FORMS PROJECTOR
FORM SLIDE
HALF-SILVER MIRROR
LENS
MICROFILM TRANSPORT

Figure 3



COM RECORDING FORMATS

COM recording formats are produced in 105mm (generally cut into fiche size of 105mm x 148mm), 35mm, and 16mm formats. The use of standard formats is essential to systems compatibility. The NMA publishes industry standards for COM which provide the various technical details, including exact dimensions.

All formats are available either as negative or positive appearing images depending on the system and application.

48X Reduction for COM 105mm x 148mm (4" x 6" size) 270 frames

Outline of a typical COM microfiche at 48X reduction in the standard 105mm x 148mm (4"x6") configuration. This COM fiche contains 18 columns of 15 frames each, or a total of 270 frames. Illustration also shows eye-legible identification.

16mm Roll Microfilm

35mm Roll Microfilm

IMAGE ORIENTATION

Image orientation can be comic or cine mode depending on the application.

Cine Orientation

COM RETRIEVAL CODING

The microfilm often has code marks or index marks on the film to assist in retrieval and in locating images. Some of the more common COM indexing methods are:

Eyeball coding: is the generation of an easily readable data identifying number on each frame, to speed information retrieval from within a roll of film.

Image count: marks (blips) recorded by the COM device below each frame are counted electronically and used to control image retrieval in a sequential manner.

Bar or code line: bars or lines between the frames have positional value as related to a scale along the edge of the reader or reader-printer screen.

Binary code: document numbers or index terms are recorded by the COM device in a binary code adjacent to or below each document; used with electronic logic systems for retrieval.

For more efficient retrieval of film coded to a given page or group of pages, the readers and reader-printers need to be equipped to "read" the coding used. Accordingly, the user will need to consider the coding or index method which will be used before making an equipment selection. In each of these image retrieval systems, the microimage can be enlarged and read on any reader or reader-printer of the proper magnification whether or not the coding or indexing system is utilized.

Simplified flow diagram of the steps in a COM program — from its origin at the computer to the image retrieved on a reader or reproduced in hardcopy form.

Figure 4

The next step is duplicating, where one of COM's major benefits becomes visible. With COM, once the master is produced, as many duplicate microforms may be made as needed, from one to hundreds. Instead of activating the computer or off-line tape unit for each set of duplicates required, the task is done by the COM duplicator at a fraction of the cost, and without tying up expensive EDP equipment time.

With COM, the user has a number of options in duplication. The most popular and widely used form typically produced at this stage is the familiar 4 by 6-inch microfiche which originates from 105 mm rolls. The COM user, however, may also select 16 mm rolls for loading into cartridges or cassettes, and another form—35 mm rolls—which are the most frequently used in tab size cards. And so, here you see another feature of COM systems—versatility. Many microforms for many uses! An insurance firm which needs to send data to 1,000 agents would use that many microfiche. A government agency might require a series of cartridges to keep track of personnel records . . . an engineering company can COM-produce its drawings on 35 mm film for mounting on aperture cards . . . and would generate that microform . . . it's all up to the user . . . and COM has the versatility to meet the need.

Now we are at the stage where the COM-produced microforms become the actual working tools for which they were designed. Distribution becomes simple, compared with handling and shipping bulky printed paper. The microforms can be mailed as easily as letters, saving time and expense. In filing, thousands of documents can be kept in a fraction of the space required by paper files . . . and in retrieval, information can be located instantly where it might take hours and sometimes days to hunt through unwieldy volumes of paper.

Now with COM-generated microforms in hand, we can gain access to this information with a microform reader. Selection of a reader is simply a matter of matching the reader to the microform system being used. There are compact, portable readers powered by house current or by self-contained batteries—even some that operate from the cigarette lighter outlet in your car. Most offices make use of desktop readers for personalized use, while many firms maintain freestanding readers for shared use within a group or department—all to insure speedy access to needed information.

And today, there are reader-printers, dual-function units that not only display all of your microform data, but also permit you to make hardcopy printouts when desired. Made at the touch of a button, these printouts may be produced in all standard sizes, including the computer-format size of 11 by 14 inches—all at the same high speed.

Enlarger printers are now in use which print out as many as 2,400 copies an hour from microforms. This speed factor adds high-volume production to their many other advantages and, of course, the over-all COM process has eliminated the need to first print out high volumes of paper or to make multiple printout runs to obtain multiple copies. The ease in retrieving COM-generated information we spoke of earlier can be achieved by many systems now available. There are completely automatic systems which retrieve a microform at the touch of a few keys on a control console. For these automated systems using continuous roll microforms in cartridges or cassettes, COM methods are available to locate the desired images from coding placed directly on the film, an invaluable aid for rapid data retrieval. The user may choose among the various retrieval codes previously discussed.

Let's just pause here and review COM's major benefits.

Speed—Two million lines an hour as compared with 120,000 for impact printing.

Economy—Material costs drop to 20% of paper printouts.

Distribution—Pennies instead of dollars every time you must handle, transport, ship or mail—all with a speed of movement impossible with the former bulk and weight.

Retrieval—Data location in seconds instead of minutes or hours.

Storage—Reduced to less than 1% the space required by paper.

Copy—Hard copies of any microfilmed information on demand in selection of paper sizes, in a matter of seconds.

These advantages have elevated COM into increasingly prominent use in just about every area of business and commerce. Typical COM business applications using aphanumeric equipment include microfilmed parts catalogs, customer/employee/vendor lists, financial records, transportation schedules, accounts receivable/payable, inventories, name/address/account number lists—and general business and governmental documents.

In many applications, the system user requires information to be generated in a special format. When alphanumeric information and forms must be combined COM saves both time and money. With computer impact printers this means that the paper must first be imprinted in order to receive the alphanumeric output. COM eliminates this need by simultaneously generating the column headings, lines, charts, graphs or other special artwork, and blends this with the alphanumeric information in the format that is wanted as the system is receiving the computer output.

Now, COM graphics recorders are available, systems that combine the alphanumeric capability with an unprecedented ability to handle graphics for such applications as scientific, engineering and business needs. This equipment is ideal for visualizing computer output in the form of bar charts, graphs, maps and diagrams. Progressing well beyond their function as high-speed substitutes for impact printers, COM systems are in use that are complete graphic arts recorders. They are able to produce high-quality graphics in any form that can be generated by the computer. COM-oriented graphic arts recorders are now producing engineering plots, line drawings, schematic and wiring diagrams, three-dimensional drawings, color charts, and even pictures, photo composition and movies.

COM applications are virtually limitless. It almost seems that each time a computer specialist and a micrographics specialist meet another COM use develops. Government agencies using COM include the Social Security Administration, which is probably the world's largest user of micrographics, the Internal Revenue Service and many other entities at the Federal, State and Municipal level.

Here, in summary, is the story of COM . . . the story of the solution to a paradox . . . computers capable of providing us with so much needed information can now function free of the data bottleneck that impact-printing imposes. COM systems are now at work serving all of us with the vital information we need in our business and personal activities . . . and the number of systems is growing.

COMPUTER ASSISTED RETRIEVAL

We have seen now the micro-image fits in the data processing system. Microfilm is used to capture source documents and it is used for output reports. The two technologies, data processing and micrographics, can be combined to provide in extremely powerful information storage and retrieval system.

Source documents are filmed in random order and assigned a sequential roll and frame number, a film address. The address is captured along with the data normally abstracted from the document, and processed by the computer. A cross index to the source document by one or more search parameters is created and either stored on-line, or printed out on paper or microfilm thru a COM. See Figure 5. When the index is stored on-line, it can be accessed via a remote terminal which is, in turn, connected to a microfilm display terminal. The user can now request dynamic information from a data base and, thru the index, retrieve source documents to support the data base information automatically.

THE FUTURE

Most people in the data processing community generally agree that we have progressed thru three generations of computers. Some feel that the fourth will be characterized by the creation and effective utilization of the data base concept. The fifth generation will provide hardware and software that will allow the ultimate user to comfortably interact with the data base.

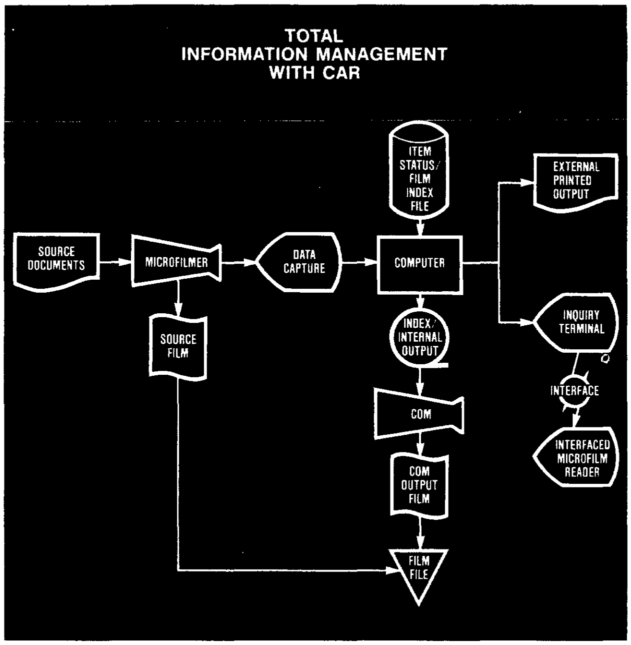

Figure 5

The trend toward large centralized computing systems with extensive data bases appears to be supported by the recent introduction of IBM's 3850 Mass Storage System, an automated tape cartridge library that provides up to 472 billion bytes of memory on line. In order to maximize the effectiveness of these massive systems, efforts will be made in the next five years to distribute processing capability and provide information at decentralized offices for convenience, improved service and reduced operating expense. One of the keys to the success of providing massive computer power to geographically dispersed users lies in the technologically complex area of telecommunications.

Although it is fair to say that problems in telecommunications have been a stumbling block to date, there have been some recent events that seem to project a brighter tomorrow. IBM, Aetna and Comsat have announced a joint venture to provide satellite communications service. Technological advances in the field of Packet Network Switching promise to cut the cost of data transmission in half and several independent networks are already in service. The explosion of microprocessor technology will lead to more intelligent computer terminals and by 1980, many of the inconsistencies that presently impede the progress of telecommunications will be resolved, primarily with the emergence of IBM's SDLC standard. By 1980, we should have a new generation of mainframes which contain millions of bytes of MOS internal storage and billions of bytes of auxiliary disk storage. Although bubble memory and charged-coupled devices also promise to provide vast amounts of inexpensive auxiliary storage, their universal acceptance is still over five years away. On the other hand, the next five years will see significant improvements in MOS and disk storage. We will also continue to strive toward the concept of one massive integrated data base which will be maintained on-line to support a variety of batch tasks as well as interactive inquiry. However, it is doubtful that this utopian approach will be achieved by 1980. Real problems in file protection, contention and logic still remain to be solved. In practice, we will continue to employ, over the next five years, several data bases which are connected primarily by program logic.

There will be a proliferation of a variety of intelligent terminals to provide access to these data bases. Data Collection techniques will also improve as the flexible diskette, optical scanners and electronic funds transfer all mature. There are, however, still some problems. Even though auxiliary storage is decreasing in unit cost, we seem to have a multiple propensity to consume all available storage. After we load in the extensive data bases of the future along with a file of current records, we will still have to find a place to store documents, archival records, and reports of the processed transactions. The micro-image can play an extremely important part in satisfying that need.

The speed of output also continues to retard effective utilization of the computer system. Impact printing is not expected to progress to any great extent. However, non-impact printing should continue to enjoy technological advances that will increase its current capability. Computer output microfilming in particular will adapt to the computer environment and provide more convenient output at reduced cost. This trend in COM will further stimulate the integration of microfilm and the computer.

Most large computer installations and many moderate and small installations have already accepted COM as a viable solution to the expensive cost of paper forms and the bottleneck of impact printing. They are processing transactions, updating the data base, and reporting the transactions on microfilm thru COM. Retrieving the recorded transaction still presents a problem. A potential solution is to use the data base as an indicator of the address of the transactions on microfilm. Thus, the on-line interactive system will use the data base to assist in the retrieval of the micro-image. The computer will also serve to temporarily update the micro-image until it can be re-created.

And what about all those source documents? A discernible trend has already begun. That is to capture the source document on microfilm in random order and assign it a film address, a roll and frame number. This address becomes another element of collected data and is stored in the data base or is processed and incorporated in an output report that serves as an index to the original source document.

The problem today is that it is usually a two step operation, microfilm and data capture. But the philosophy of synergistic design will surely prevail and by 1980 we can expect hybrid, if not integrated devices that simultaneously capture the data for the mainframe and capture the document on a micro-image. Both the data and the document will be forever connected by the film address. Already today, high speed scanners are available with a microfilm camera option.

The discussion thus far, has been oversimplified. There are a multitude of variables and alternatives that will produce many variations of the basic theme. Will the computer be a mainframe, or a minicomputer, or a timeshare service? Will the inquiry be batch processed or interactive? Will the user be local or remote? Will he use a CRT, printer, audio response, or something else? Will the input camera be rotary or planetary, and at what reduction ratio? Will the micro-image medium be roll, microfiche, jackets, aperture cards or something new? All of these alternatives will provide tremendous flexibility in designing information systems to satisfy the needs of tomorrow.

And so what about the question of when to use microfilm versus on-line interactive terminals versus some other alternative? Well, that answer will be dictated by the specifics of each individual application. As we progress, trends will evolve. The integration of microfilm and the computer already has established a viable means to store, retrieve and update source documents in such vertical market applications as law enforcement, order entry, accounts payable and scientific files. Computer assisted retrieval is also currently being used on such computer output files as telephone information, financial statements, inventory control reports and computer generated accounting documents. The number of source document and computer report applications will continue to grow and the scope of their coverage will also expand.

The integration of microfilm and the computer will take time, but it has already begun. The next few years will see several vendors testing the market with hybrid systems that interface computer terminals to microfilm retrieval displays. The terminals will, in turn, be connected to a mainframe, or a mini computer, or a timeshare service. By 1980, integrated devices should evolve that combine the functions of the terminal and microfilm reader. In fact, some are already available today. Data capture microfilmers should also be a reality by 1980, including both the manual and automated high speed variety.

The most significant challenge will be in the areas of system design, software, and file maintenance. Software will be required to generate screen formats to make the terminal easy to use for data collection and retrieval.

Search routines will need to include and/or logic with range capability, as well as the ability to handle update messages. Because of the size of the average file, unique techniques will be required to pack millions of characters into a minimum of storage. As these challenges are met, computer assisted micro-image retrieval systems will flourish.

What the computer and microfilm industries need most now is mutual understanding. They need to realize that they are not competing with one another, and that if they are successful in getting it together, we will all benefit.

The integration of microfilm and the computer will require the cross-training of the EDP and Micrographic communities. This training, in the form of seminars, lectures, formal curriculum and correspondence type courses could be provided by the various EDP and Micrographic vendors. In fact, some commendable work in this area has already been done and has been well received. Now what is needed is a cooperative effort on the part of the various national organizations representing these two disciplines. When workshops on data processing techniques are delivered at microfilm conventions and micrographic seminars are offered at data processing meetings, we will be well on our way to ultimate integration.

The AIDUS system—Automated capture, update and republication of maintenance manuals

by ARNOLD K. GRIFFITH
Information International, Inc.
Culver City, California

ABSTRACT

The AIDUS system is a hardware/software configuration which reads printed aircraft maintenance manuals, provides computer text-editing facilities for their update, and automatically republishes them onto microfilm. Page layout information is entered by a human operator at a digitizer tablet. This information is used to guide an OCR system in the capture of the text. The layout data is merged into the text output file, resulting in a computer readable file containing all the information from the original manuals except for the illustrations. The latter are captured photographically on a roll of 105mm film, which is keyed to the text/page-layout information file by means of bar codes on each frame. Updating of any aspect of the text or layout of the manual may be performed at CRT terminals using text editor programs. Illustrations may be modified by re-drawing, re-photographing, and splicing the resulting frames of film into the 105mm illustration film at the appropriate locations. After revision, the data file and 105mm illustration film are presented to the photocomposition portion of the system, which automatically produces a revised version of the manual, complete with optically merged illustrations and an index accommodating the revised pagination. This system, in use in an actual working environment, allows the update of technical manuals at about one sixth the cost, and with a fraction of the turnaround time, of previously used cut-and-paste methods.

Update and distribution

The motivation for the use of the AIDUS system is the increasing volume of maintenance manuals for out-of-production aircraft in use by the Navy. It is the Navy's responsibility to keep these manuals updated and to distribute updated versions to remote points on land and to ships at sea.

Today fewer new aircraft are developed and only a limited number of each are built. As a result, the Navy keeps them in service for a longer time. This trend to shorter production runs, longer in-service life and the increasing complexity of each new generation of aircraft has placed an ever-expanding burden on the Navy for accurate and timely documentation.

To illustrate the problem of increasing complexity faced by the Navy in publication activity, consider the A-3 aircraft built around 1955. It required 69,000 pages of documentation which was distributed across some 460 manuals. Ten years later the A-7 aircraft required 135,000 pages in over 1,000 manuals. Currently the Navy has approximately 17,000 technical manuals for the maintenance of these out-of-production aircraft, consisting of over one million pages and requiring continual update. This represents a formidable publication task and it is expected to more than double in scope over the next few years.

To facilitate distribution of these manuals, the Naval Air Rework Facility, the unit responsible for aircraft maintenance, implemented a prototype system by which the manuals would be reduced to microfilm and distributed in the form of extremely compact cartridges containing about 2700 pages each. Initially, 22 sets of paper manuals, each comprising 101 volumes, were removed from the A-4 assembly line and replaced by five microfilm reader/printer devices. The paper manuals having been updated and microfilmed, each set of manuals (101 volumes) was now contained on 16 microfilm cartridges, consisting of some 48,000 pages. After a one-year evaluation period, the system was funded and implemented for NAVAIR-wide use and designated MIARS (Maintenance Information Automated Retrieval System).

Having demonstrated the utility of the use of microfilm as an aid to distribution, the Navy turned to the problem of devising a means for the efficient and timely update of the contents of the manuals. After a three year study, it became apparent that this could be effectively accomplished by a total conversion of the text portions of the manuals, with update being accomplished by computer word-processing procedures.

THE ANATOMY OF AN AIRCRAFT MAINTENANCE MANUAL

A major problem in the conversion of the 17,000 maintenance manuals under Navy jurisdiction is the fact that virtually every page of every manual has a unique layout. This is due in part to the intrinsic complexity of the subject matter. In addition, the manuals were created by numerous different manufacturers over a span of more than a dozen years. Finally, the manuals have a variety of purposes ranging from the cataloging of parts to the description of maintenance procedures.

Simple text, constituting less than half of the total page area, is set in any of several dozen type faces and point sizes. This kind of text may be set on a page in two side-by-side columns, or be set in a single half width, one-third width, three-quarter width or full width column. In addition, the text contains figure and table references, whose location must be explicitly captured, since their location affects how the corrsponding figures and tables may be laid out relative to the text.

Approximately one fourth of the total page area of these manuals consists of tables of one sort or another. The most prevalent type of table consists of a running parts list accompanied by a sequence of parts breakdown illustrations. These tables consist of up to a dozen tabulated columns, with a common heading on consecutive pages to identify the contents of each column. Although these tables continue for up to several dozen pages, their handling is complicated by the fact that the contents of the table must remain in step with the accompanying illustrations. In addition, the entries in certain columns of these tables are indented to varying degrees according to which level in a sub-assembly hierarchy the corresponding item belongs. Another type of table consists of a number of text passages or numerical data within a grid of ruled boxes. The structural constraints on such tables are minor. For example the heights of two boxes at different vertical positions within the table need not be the same, and a dividing rule need not extend all the way to either edge of the table. A third type of table, quite common in running text passages, consists of a number of lines of data tabulated in two or three columns.

More than one fourth of the manuals' page area consists of illustrations. These may be halftones or line drawings, or both. They may occupy any position on a page, and either extend the full width of the page or occupy only one column. There may be several different illustrations on a single page with text interspersed.

Besides these major components, the manual pages also contain numerous items such as: running page titles at the top, or bottom, or both; page numbers; chapter titles; section titles; and centered captions over warning and caution notices.

INPUT PREPARATION

The data input process performed by the AIDUS system involves in the reduction of a paper manual to a computer readable data file containing all the text and page layout information, and a roll of 105mm film containing all the illustrations. Although the filming of the illustrations is a relatively simple one-step process, the capture of the text and layout information requires a series of steps. This series of steps may be divided into two phases, the first of which is termed the "Data Preparation" phase.

The first step in the "Data Preparation" phase is the punching of registration holes in the original pages. These holes are punched in a fixed relation to the material printed on the page, and are necessary for controlling the alignment of the text during reading, as well as the alignment of the illustrations during filming. In addition, unique serial numbers are printed on each page. Since each page is processed as a separate unit, three numbers are used as a common identifier for the various files created as the page passes through the successive stages of the data input process. The numbers are used to identify the illustrations as well. When a set of illustrations from a particular page is captured on a frame of 105mm film, it is this number which is bar coded at the edge of the frame.

The next step of the data input phase is the filming of all pages containing text on a 35mm planetary camera. GRAFIX I, the OCR component of the AIDUS system, reads only from microfilm, so that paper documents must be filmed prior to being read. There are, in general, several important advantages to this approach. The most important factor is that pages of any size may be optically reduced to a common film size, making page advance and page finding—the first, crucial stem in the recognition process—fast and accurate. Moreover, measuring the transmitted light passed through the film achieves a more consistent image quality than can be obtained by reflected light from the original paper documents. Another advantage is that the data can be filmed at the originating site and checked for completeness, avoiding the risk of lost or damaged material.

The final step of data preparation is called the "Page Descriptor Entry" procedure, and involves the entering of page layout data by means of a data tablet. Prior to the actual entry, a page is marked up by an editor to record which fonts are present, as well as to resolve certain unusual or ambiguous situations which might slow down the data tablet operator. After markup, the page is aligned on registration pins on the data tablet by means of the holes previously punched in the pages. The data tablet operator enters geometric information by touching various points on the page with the data tablet stylus. Logical information is entered by touching one or another of a "menu" of captioned boxes fixed permanently to the data tablet next to the page. For example, the page number is entered by touching, in order, the various boxes on the menu which contain the digits of the page number. The location of the text is entered by touching a box marked "text" on the menu, and touching the upper left and lower right corners of the actual blocks of text on the page. The layout of the various types of tables is entered by a similar, but more elaborate process, as well as the locations of the tab stops, titles, locations of cautionary notes in the text, various fonts, and other features of the page. The entire Page Descriptor Entry process, exclusive of markup, requires on the average of less than a minute per page.

TEXT CONVERSION

The second phase of data capture consists in reading the text of the manual pages to produce an output file containing text and page layout information, and subjecting this file to a proof and edit cycle to insure its accuracy and completeness.

The reading of the text is carried out on the GRAFIX I,[1,2] a commercial optical character recognition system. GRAFIX I consists of three components. The first of these is a high precision flying spot scanner. The second component is a medium-scale general purpose time-shared computer. The third component is a slave processor called the Binary Image Processor,[4] which performs a wide range of inner-loop recognition and image processing tasks at very high speeds. GRAFIX I has been successfully employed for numerous other multi-font character recognition tasks, and even reads intermixed alphanumeric handprint.[3]

Recognition of the individual characters of the text is performed by a mask-matching algorithm. Recognition is dependent on the successful location of the successive characters in a line of text. This is performed automatically, sometimes by rather complex character separation algorithms, once the appropriate location and angle of the baselines of the entire line of text has been established. This baseline is, in turn, found automatically, given the location and orientation of the entire paragraph or column of text. This latter information is supplied to the computer during the Page Descriptor Entry procedure. The output file contains the passages of text together with imbedded typographical commands, which incorporate all of the page layout information entered during the Page Descriptor Entry procedure. In general, the structure and form of the page layout information, as entered during the Page Descriptor Entry procedure, is quite different from the corresponding layout commands as they appear in the text. But the process of generating these latter commands is rather straightforward. Certain additional commands are put into the output stream based on factors determined during the character recognition process itself. One such is the command indicating the beginning of a paragraph, which is generated by detecting the level of indent, and from certain textual clues.

Besides the text and layout commands, the output file from OCR contains the images of every character, which the system did not recognize, imbedded in the text at the point at which the character occurs.

The second step in the data capture phase is to subject this output file to a "Reject Conversion" process whereby a new file is created identical to the previous one except that the appropriate ASCII codes replace the images of the unrecognizable characters. This procedure is performed by reading in the successive lines of text until one is found with a "rejected" character, displaying this line of text together with the image of the character at a CRT display terminal, and having the operator key in the correct identity of the character at a keyboard. By this process more than 3000 rejected characters may be identified per hour.

The third step attempts to automatically identify recognition errors in the text output file. In certain instances, a positive identification of an error may be made, such as in the case of a numeral "1" appearing in the middle of a lower case word, which almost certainly is actually a lower case "L". These errors are automatically corrected. Another procedure, using a dictionary, flags seemingly unusual words as possibly containing letter substitutions.

The entire file, complete with embedded layout commands, is now printed out on a high speed lineprinter for proofreading against the original. When the dictionary procedure is used, words flagged by the dictionary process are underlined in the listing, and proofreading is largely a matter of examining these underlined words and checking for completeness. The layout commands are also subject to proofreading at this point, since the layout command language was specifically designed with this in mind. Proofreading is followed by an editing of the file at a CRT/keyboard station to incorporate any necessary modifications.

REPUBLICATION ONTO MICROFILM

At this point a manual is transferred to magnetic tape, which is mounted, together with the appropriate 105mm illustration film, onto the COMP80. The manual, including all text, tables, and illustrations, is automatically republished onto microfilm in a recomposed form, complete with illustrations and an index revised to accommodate the new pagination.

Simultaneously, a data tape is created which is virtually identical to the input tape except that page and line breaks are in the same places as in the version being written onto microfilm. This tape is transferred to the GRAFIX I system where it is converted to a slightly different tape form for archival purposes. This archival tape is stored as the digital version of the manual; and it is retained and retrieved at a later date when a revision of the manual is necessary.

The process of creating a file for input to the COMP80 includes the checking of all composition and format statements for validity and plausibility of their respective numerical arguments. In the event that a statement does not pass these tests, an error message is printed, the file in question is edited, and the process is repeated. Since each page of text is converted as a separate data file, the various files constituting a manual are appended in the course of creating this output tape. In addition, since in general several manuals are composed on a single film, the various constituent manuals are concatenated onto a single tape. The selection of manuals to be placed on a single film is based on factors of convenience, and on the restriction that the total number of pages per film must not exceed 2700.

Since output is composed and typeset automatically, hand stripping and pasteup are eliminated. The labor and time normally associated with book make-up operations is drastically reduced. Rather than a six to 18 month production cycle, manuals can be updated and distributed in as little as 60 days.

Another aspect of GRAFIX I/AIDUS output capability is that publication formats can now be standardized uniformly or modified for new distribution requirements. The updated Navy technical manuals will now have a uniform format as documents from a wide variety of sources are recomposed and republished. In addition, a proportionally spaced type font was designed for the microfilmed manuals which attempts to be compact but maximally readable with the MIARS film reader.

UPDATE FOR PUBLICATION OF REVISED VERSIONS

When it is necessary to revise a manual, its archival tape is read back into GRAFIX I disk storage and divided into its individual pages. These pages are edited, and the publication cycle described in the preceding section is repeated. In addition, any revised illustrations are re-filmed and spliced into the 105mm illustration film.

Editing is performed on a per-page basis by GRAFIX I's special editing software. Using on-line CRT/keyboard terminals, editors may work from either the terminal display, hardcopy printout, or composed film proofs of the converted text. Material to be updated can be accessed by manual, section, chapter, and page number. Updated portions on film may be identified by vertical change bars in the margins; previous change bars are automatically deleted in update runs.

Updating functions include text deletion, replacement or insertion; arbitrary layout changes, accomplished by modifying the page layout commands imbedded in the text; modification of tables including content and layout; illustration additions, deletions, replacements or size changes.

New or updated illustrations are filmed and merged with the illustration file previously filmed during Input Preparation. When a particular illustration is supplanted, its successor is assigned a number higher than any so far on the film, and this number is bar coded on the edge. The frame is spliced into the film in place of its predecessor. A simple change of reference number in the text file completes the process. New illustrations may be added by a similar procedure.

CONCLUSIONS

We have described the AIDUS system, which consists of an OCR device, CRT/keyboard facilities for performing text editing, and a photocomposition system. We have shown how, with a judicious combination of filming, human interaction, and optical character recognition, this system is capable of reducing the entire contents of complex technical manuals, including layout data, to an illustration merge film and a computer-processable data file. In this form, the manual may be easily revised and subsequently republished onto microfilm. We have described an actual working environment in which this system is used, namely the update of maintenance manuals for out-of-production Naval aircraft. In this environment, the system performs update and republication at a projected long-range cost of 15 percent of that of cut and paste methods previously employed and at a fraction of the turn-around time.[2] This system appears to have a wide range of application such as parts catalogs, and maintenance and technical manuals of all sorts.

ACKNOWLEDGMENTS

Designers of the system include, besides the present author: Richard Martin, Russell Ham, Ron Traver, David Meredith, Carol Gillespie, and Dan Forsyth. Other contributions were made by: Steve Gray, Mary Strobel, Glen Williams, Nada Berger, and Norm Gilbreath.

The CMU RT-CAD system—An innovative approach to computer aided design*

by DANIEL P. SIEWIOREK and MARIO R. BARBACCI
Carnegie-Mellon University
Pittsburgh, Pennsylvania

INTRODUCTION AND MOTIVATION

As technology has evolved the primitive components available to a digital system designer have changed dramatically. Twenty-five years ago the designer constructed systems out of circuit level components such as resistors and diodes. Subsequently switching circuit level components, as represented by gates and flip-flops, became available as small scale integration (SSI) components. With the introduction of medium scale integration (MSI) register transfer level components appeared: arithmetic and logic units, registers, shift registers, etc. The advent of large scale integration (LSI) has made memories and even processors primitive components from which systems are designed. Two trends can be observed from this technological evolution: (1) primitive components continue to increase in complexity and (2) the rate of introduction of new components continues to increase.

In response to the first trend, designers have been limiting their excursions into switching circuit level design to only small portions of the system (e.g., bus controllers, etc.). In some register transfer level module sets,[1,2] these excursions have been completely eliminated.

Because of the second trend, rapid technology evolution, there is a need to shorten the delay time between the introduction of a technology and its effective use in new computing systems. The design process must, therefore, be accelerated if the potentiality of the improving technology is to be realized.

This paper describes a set of design programs, the RT-CAD system, developed at Carnegie-Mellon. The ultimate goal is to minimize the effect of changing technology by building a Computer Aided Design System that implements a technology-relative design process.

OVERVIEW OF THE AUTOMATIC DESIGN PROCESS

Given the complexity of a digital system, designers have sought to develop automatic means to reduce the cost and time of the design process. The objective was to relieve engineers of repetitive, time consuming tasks such as:

(1) The generation of detailed design information (gate and chip types, etc.)
(2) The control of changes in the design documents
(3) The checking of the system for electrical, logical, and physical compatibility (fan-out limits, etc.)
(4) The generation of detailed manufacturing information (chip placement, board layout, etc.)

This early view of design automation limited itself to filling the gap between the low-level design specifications and the manufacturing data. Behavioral specifications were in the form of Boolean equations and the design programs translated them into their equivalent logic diagrams and wiring lists. Most of the synthesis algorithms at this level dealt with the problem of reducing or simplifying the Boolean equations.[3]

Subsequent efforts were directed towards a system capable of accepting a higher level of behavioral description, although still oriented towards a gate level implementation.[4,5]

Current design automation effort is shifting from implementation in terms of the switching circuit level to implementation in terms of the Register Transfer Level (Although the components have changed, the specification of fabrication information such as PC board layout, chip placement, wiring and cabling, still has to be performed in more or less the same fashion as before). Register Transfer level simulators have preceded this trend by several years.[4,6,7] The closeness of

* This work was supported by the National Science Foundation under Grant GJ-32758X.

RT level descriptions to conventional programming accounts for this early success. Register Transfer level descriptions are easy to transliterate into executable programs in a conventional programming language (e.g., FORTRAN, Algol, etc.), thus providing inexpensive and fast simulation (although in many cases RT languages are compiled directly). Register Transfer level synthesis algorithms have been less successful. A few programs have been developed that take an RT level description as input and compile it directly into a known set of RT level hardware modules (for instance, CHARTWARE[8] and AHPL[9]). Figure 1 depicts a typical RT design automation system. The RT level description serves as input to several software modules. Syntax checking insures a well formed description. Static checking attempts to locate logical design errors (such as deadlocks, redundancy, etc.). The simulator is used to debug the design dynamically. Finally, the description is cast into hardware via the physical design programs.

The essential feature lacking in conventional RT Design Automation (DA) systems, and DA systems in general, is the exploitation of alternative implementations derived from the initial behavioral specification. Consider the augmented DA system depicted in Figure 2. The inputs are the RT level description and designer given constraints. The output is the specification/simulation of the hardware that attempts to optimize the system according to the design constraints. By allowing the description of alternative module sets the system can perform design relative to technology thus speeding up the incorporation of new technology into the design process. Also, such a system will allow experimentation with multiple module sets, each tailored to a specific class of problems. The system would also facilitate the design of the module sets themselves. Since the system operates on a symbolic description of the modules, a non-existing module set can be fed to the system for experimentation purposes. Such experiments will point out the advantages and disadvantages of a proposed module set.

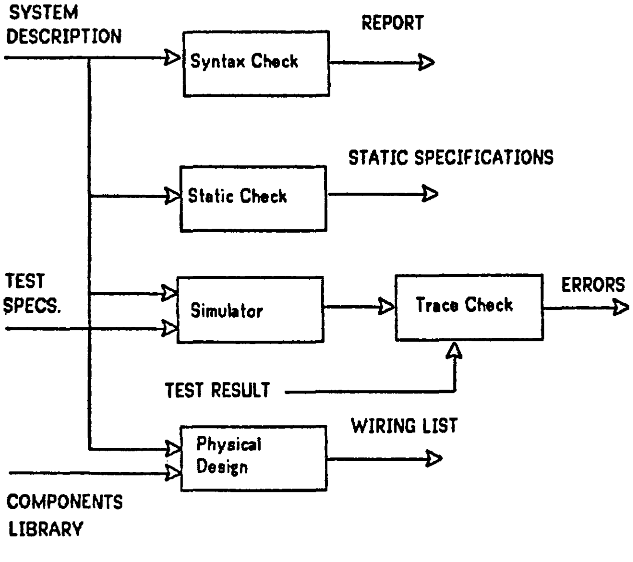

Figure 1—A conventional register transfer level design automation system

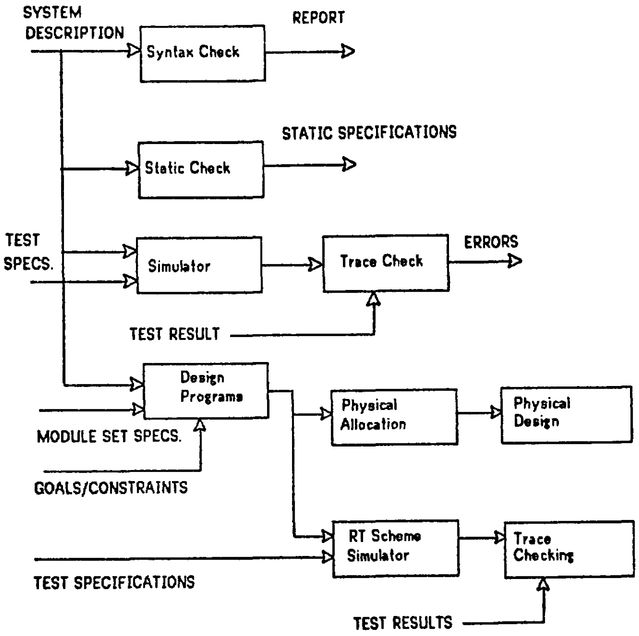

Figure 2—An augmented register transfer level design automation system

At this point it would be instructive to describe the order in which the DA programs are typically used in the design process. This will serve to place subsequent discussions in perspective. Given a computational task, there are usually several algorithms that can be employed. The algorithm that is selected by the designer is described to the design automation system (Figure 3) and placed in a data base. Subsequently all design automation programs will use this data base. A high level simulator can execute from the data base to facilitate user debugging of the initial description.

Next some evaluation and reshaping of the algorithm is undertaken. Analysis tools have been developed to check the algorithm for well-formness (e.g., deadlock conditions, etc.).[10] Perturbations of the basic algorithm can also be attempted such as: series-to-parallel transformations, replacing loop counters by wired-in control, and using table look-up in lieu of computing the value of functions. Thus attempts are made to first

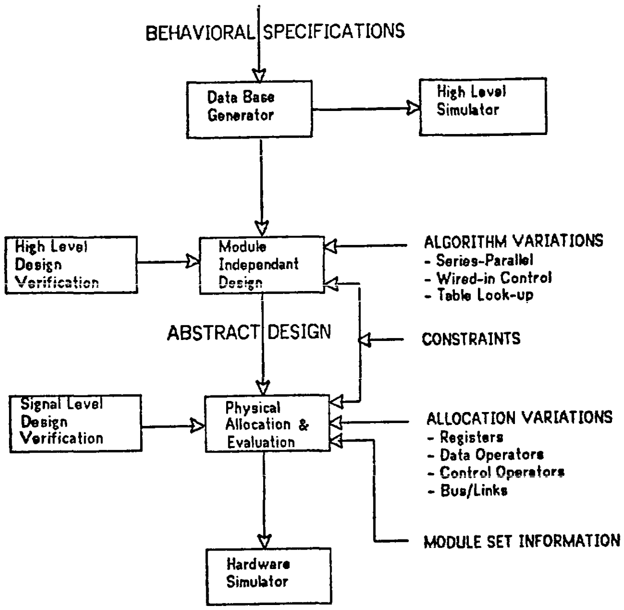

Figure 3—The design process in a RT level design system

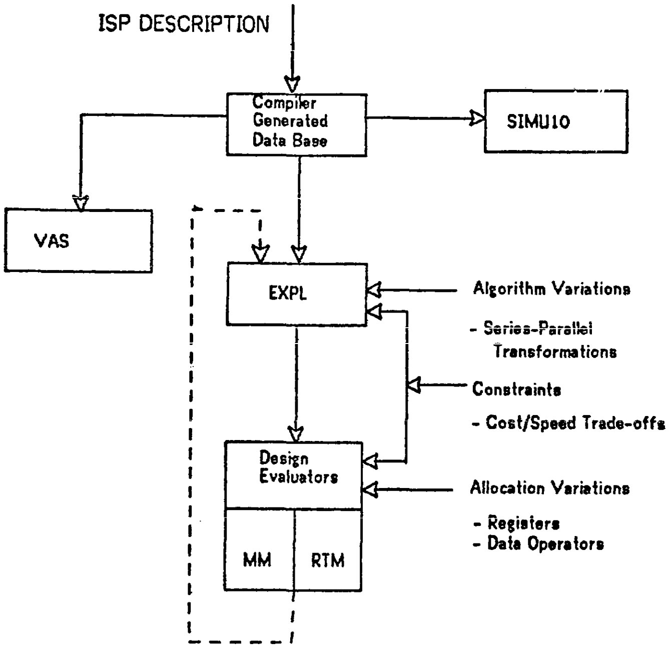

Figure 4—The design process in the CMU-RT-CAD system

bind those design decisions with global implications. While these perturbations can be performed independent of the physical design, the evaluation of their ultimate desirability may depend upon the module set used to implement the final, physical design.

Finally, the actual physical design is performed in terms of RT level modules. The module set can be selected from a library of module sets or a user described set. At this level several forms of allocation variations are encountered:

—Registers. Determine the allocation of the abstract variables to registers and memory.

—Data operators. Determine the number of operators of each type in the design.

—Control. Select control schema from among unary state encoding, binary state encoding, microprogram control, etc.

—Bus-Link clustering. Many RT designs start with a set of registers for variables and interconnect them with links to operators (add, shift, multiply, etc.). After a point the interconnections between certain registers and operators become numerous enough to warrant replacement by a bus.

—Operator interconnection. The interconnection of operators has been shown to have a significant effect on the test generation effort required for the physical implementation.[11]

The signal level design verifier can be used to analyze the intermodule signal relationships in proposed module sets. Even well-established module sets have exhibited deadlock behavior in what appear to be straightforward interconnections.[10]

A first version of the above system has been implemented at Carnegie-Mellon and is shown in Figure 4. The behavioral specifications of the system to be designed are provided in terms of the ISP language.[12] The compiler produces an "object"* program which is then loaded into the data base and manipulated by the different design programs.

The next six sections will treat the applications programs in detail. The third section describes EXPL, a module independent design program that examines series-parallel variations in the original algorithm. The fourth section presents the physical allocators for two existing RT module sets—RTMs and Macromodules (MM). The fifth section discusses the heuristics used by EXPL to explore the design space. Sample design spaces, examples of the application of the heuristics, and some observations are presented in the sixth section. Design verification is discussed in the seventh section. The last section concludes the presentation of the existing system by briefly outlining the remaining application programs.

AUTOMATIC DESIGN SPACE EXPLORATION

EXPL[12] takes as input the object code produced by the ISP compiler, together with a set of user given

* The compiler produces an "object" program in terms of a set of Register Transfer level primitive operations. This program appears in the form of an executable BLISS program where each Register Transfer operation is represented by a call to a user-provided subroutine. By changing the set of subroutines, the compiler can support many diverse activities. The creation of the data base is, in fact, done by a specific set of subroutines. The compiler and the language are therefore independent of the applications. The uniform compiler output and the flexibility of the subroutine-call mechanism has simplified the interfacing to other application programs.

speed/cost constraints/tradeoffs. The compiler output is used to generate a graph representation of the behavior of the system. Subsequently, various series-to-parallel and parallel-to-series transforms on the graph are attempted to establish a new design. Several alternative designs are generated and passed to module set evaluators which complete and evaluate the design in terms of its hardware module set. Using this evaluation and a set of heuristics, EXPL decides which solutions should be kept to generate other solutions by yet another application of the graph transformations.

Figure 5 is the ISP description of an 8-bit multiplier that will be used as a running example to illustrate various aspects of EXPL. The algorithm is a variant of the shift-and-add algorithm. The multiplier is in the P register and the multiplicand is in the MPD register and is assumed to occupy the leftmost 8 bits of the register. The product will be in the P register. The partial products are formed in the left hand side of the P register and shifted to their appropriated position in the final product. A counter, C, is used to keep track of the number of times the basic multiplication step has been performed. Additional details about the algorithm can be found in Reference 1.

The description begins with the specification of the label for the program (MULTIPLIER). Labels are used in ISP to identify activities so that they can be branched to, or used as subroutines.

The program itself is enclosed in parentheses, and consists of two parts. The declarations and the specification of the behavior. The former are specified as a list of individual component declarations (multiplicand, multiplier/product, and step counter), using the reserved identifiers DECLARE and ERALCED as brackets. The specification of the activities of the system is given as a list of two sequential steps. The first step (C←8) initializes the counter and the second is given by a labelled (L1) block of activities. These consist of a sequence of three steps. The first one performs the basic multiplication operation; the second step decrements the counter; the third step tests the counter to see if the operation has been completed. If the value of the counter has not reached 0 then a jump to the label is indicated by using the label as an activity. If the counter is 0 then control flows out of the labelled statement and reaches the end of the program.

```
MULTIPLIER:=
(declare
    MPD<15:0>;
    P<15:0>;
    C<15:0>
eralced
C←8 next
L1:=( (decode P<0>=>
            P←P↑SRO 1;
            P←(P+MPD)↑SRO 1) next
        C←C−1 next
        (if C neq 0=>L1)
    )
)
```

Figure 5—The ISP description of the multiplier

The basic multiplication operation is described using the DECODE control operation. It implements an n-way branch depending on the value of the expression following the operator. The alternative paths selected by this operation are given as a list using the ";" as delimiter. The first path (P←P ↑SRO 1) is selected if the value of the controlling expression (P<0>) is 0; the second path (P←(P+MPD) ↑SRO 1) is selected if the value is 1. The operator ↑SRO represents a shift right inserting zeroes. The number of shifted positions is given by the second operand (in this case the integer 1).

Figure 6 shows the graph representation of the ISP description. The mapping from the ISP description to the graph form is apparent from the example. The system graph contains a unique entry point (the START operation) and a unique exit point (the STOP operation). In addition to these two operations, there can be five other types of operations in the graph model:

—branch, activates one of the output paths depending upon the value of some operand.

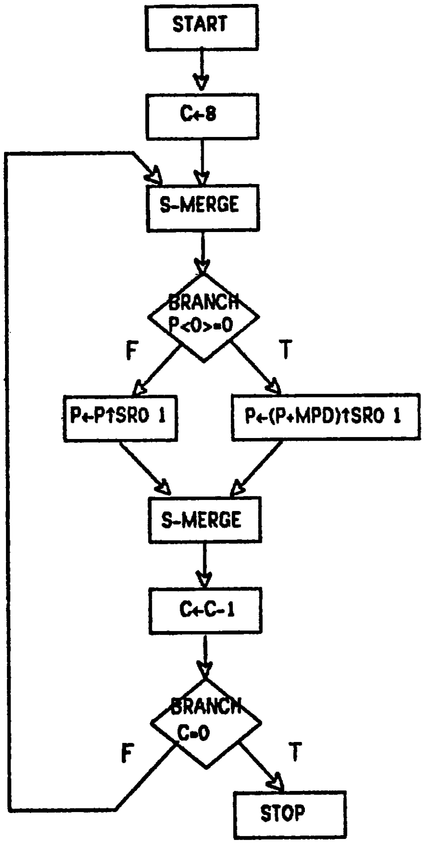

Figure 6—Multiplier graph 0 (original)

- —serial-merge, activates its output path when any of its input signals arrive
- —diverge, activates concurrently all of its output paths.
- —parallel-merge, activates its output path when all of its input signals arrive.
- —data-operation (other).

Examination of the graph for the multiplier example indicates several possible alternative designs. For instance, the computation of the loop count (C←C-1) does not depend on the shifting and adding steps (P←P ↑SRO 1 and P←(P+MPD) ↑SRO 1); the two sets of operations do not have variables in common. Thus the decrement of the loop counter can be performed in parallel with the basic multiplication step, as shown in Figure 7.

The graph thus obtained shows that the testing of the loop counter, although independent of the multiplication steps, cannot be performed in parallel with the decrement of the loop count. This fact rules out a transformation similar to the one used previously. However, it is possible to insert the testing step in the same path as the decrement. This preserves the required ordering of the counter operations but now the testing is done concurrently with the multiplication step as shown in Figure 8.

The last graph represents an "optimal" speed implementation. We are not considering, at this point, specific module-set-dependent optimizations. For instance, register allocation in RTMs or data operator allocation in MMs. This type of optimization is left up to the individual technology-dependent evaluators.

It should also be noted that, in the example above, although it took two steps to arrive at the final design we could have taken the two counter operations (decrement and testing) as one group, and place the group in parallel with the basic multiplication step. In other words, we can achieve the same final result in one step by varying the size of the graph partitions.

These graph transformations have taken us from an original solution, to two additional design alternatives. Both represent an improvement in speed with respect to the initial design. The design space, explored automatically by EXPL, can be represented as a two di-

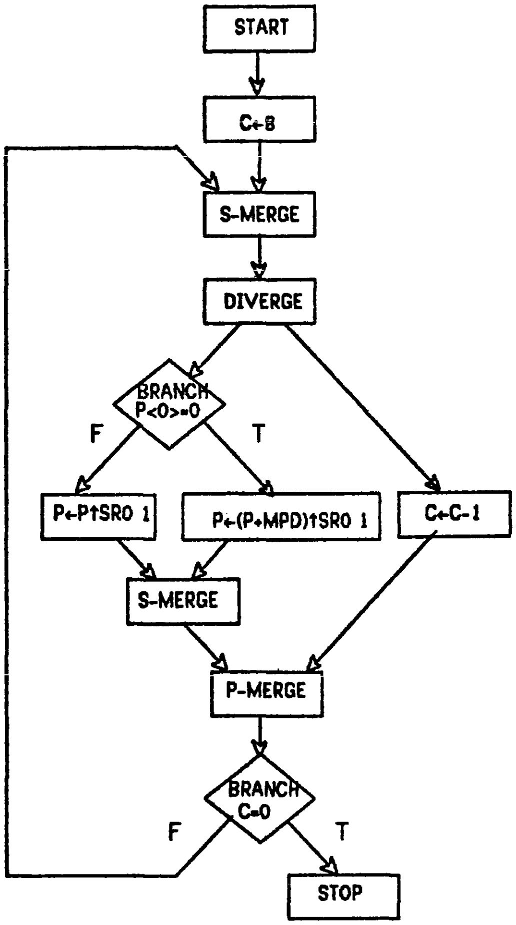

Figure 7—Multiplier graph 1

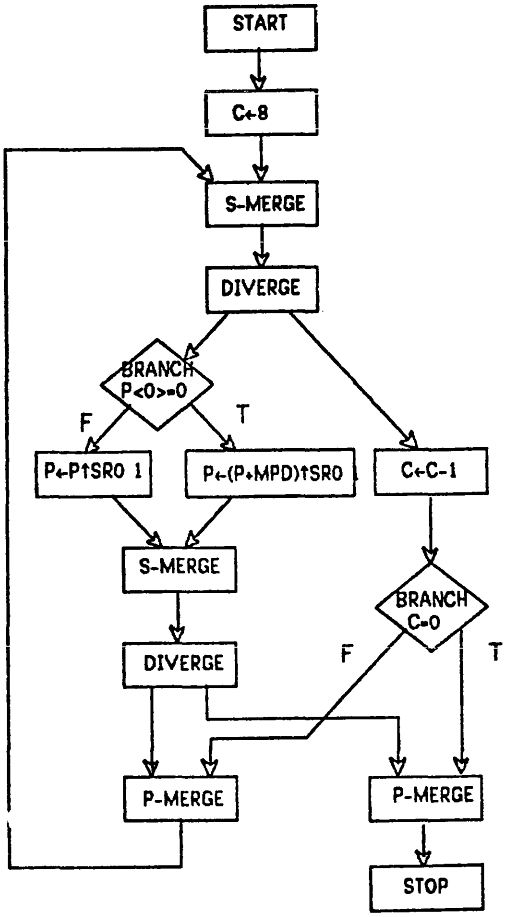

Figure 8—Multiplier graph 2

mensional plot. Each design is represented by its cost and time coordinates, computed by the technology-dependent design evaluators.

The multiplier example was implemented using both RTM's and macromodules and the design spaces are shown in Figures 9 and 10. In both plots, point 0 represents the initial solution and points 1 and 2 represent the alternative designs. Arrows indicate the steps taken in the derivation of the alternatives.

The position of the alternative design in the design space is dictated by the evaluation of its cost and speed. These two parameters are measured in terms of a specific technology, using specialized evaluator routines, as described in the following section.

MODULE SET EVALUATORS

Given a candidate design, whether it is the initial graph or one obtained by a transformation, its cost and speed must be measured to ascertain its relative position in the design space. This position indicates the quality of a solution. The evaluation process is clearly dependent on the module set used and is currently performed by ad-hoc routines, independent of the graph transformation algorithms. This section describes the evaluation procedure used for RTM[1] and Macromodule[2] systems.

The candidate design is represented by a description of its behavior i.e., a graph. In this representation the control and data operations are not bound to specific physical components. The evaluation is performed by applying a series of binding algorithms that map this (abstract) behavioral description into a physical description. This is the representation which is then evaluated. It should be pointed out that the design space we are dealing with is really an evaluation space, not a structural space. In other words, for each point in the evaluation space there may be more than one structure.

Different design spaces are explored by using either the RTM or Macromodule evaluator. The reason for this is inherent in the interconnections of the data and memory components allowed by each module set. Specifically, in the RTM set (Figure 11b) the inputs to the data operators are permanently connected to memory outputs (DMgpa). This means that some form of register allocation must be done to insure that at all times the proper operands are present at the input of the data operators. The RTM set also provides a common bus interconnection between the modules. This allows memories not directly connected to data operators to share the centralized DMgpa much as a computer's main memory shares the data operators connected to the central registers. In contrast, the Macromodule set represents a different style of design. Memory and data elements come in separate modules that are directly connected with data cables or links. Instead of sharing the data operators, each operand is bound to a register with only the necessary data operators connected to it (Figure 11a). The resulting Macromodule system has relatively expensive data operators and links for each operation, whereas an RTM system will share data operators and links (buses) with all of the operands.

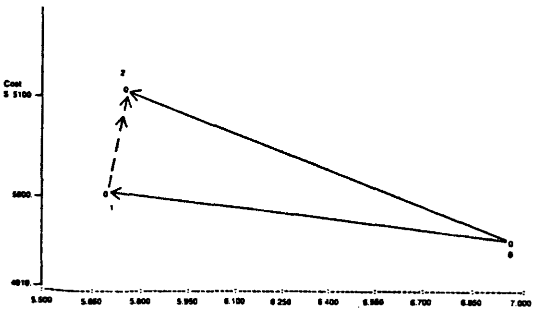

Figure 9—The multiplier design space (macromodules)

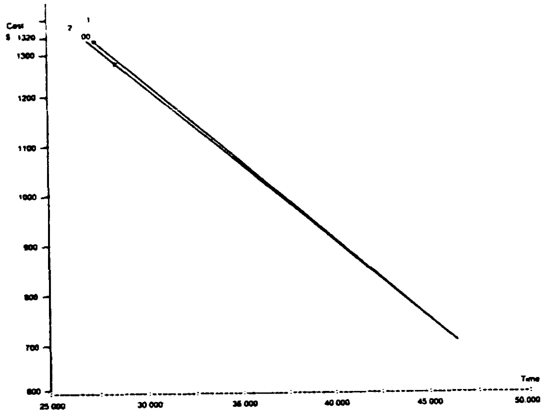

Figure 10—The multiplier design space (RTM)

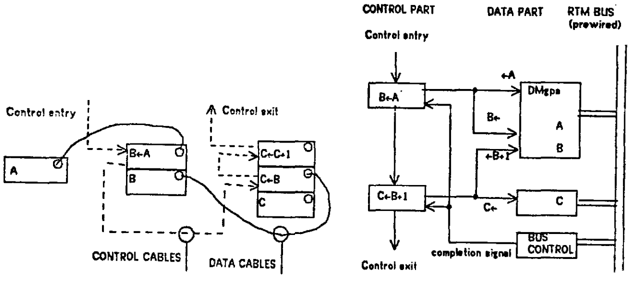
Figure 12 illustrates how the concept of a *design style* is incorporated in the physical allocators of the RT-CAD system. RTM and Macromodules represent two differing register transfer level design styles:



(a) Macromodules

(b) Register Transfer Modules

Figure 11—Macromodules and RTM systems to implement B←A next C←B+1

central accumulator, and distributed data and memory, respectively. In addition, other design styles such as pipelining can be defined. An abstract system description is presented in graph form to one of the design style allocators. Each design style allocator has its own procedure for allocating operands to memories and data operations to operators. Temporary registers and extra register transfers might be added to the abstract design so that it will conform to physical design constraints. The result is a perturbed graph that reflects a specific design style and module set. The graph, which now represents a physical design, is evaluated using the costs and speeds given in the module set description. The results of the evaluation are then used by EXPL to produce an alternative design.

The allocators must be able to work interactively with the module independent subcomponents, designing and evaluating at varying levels of detail in the design process. At the style level, the allocator begins binding variables and operations to physical components using a set of allocation algorithms specific to the design style but general enough for any module set reflecting that design style. At the module set level, information specific to an individual module set is read from the module set description and used to help complete the allocation. In this way the allocator can function with several different module sets reflecting the same design style. An example of this can be found using the RTM set. Consider a module set similar to RTM except that the A and B registers of the DMgpa are symmetric. The allocation algorithms are very similar except for a few details such as not being able to produce <–B–A in one register transfer in the real RTM (although <–A–B is available).

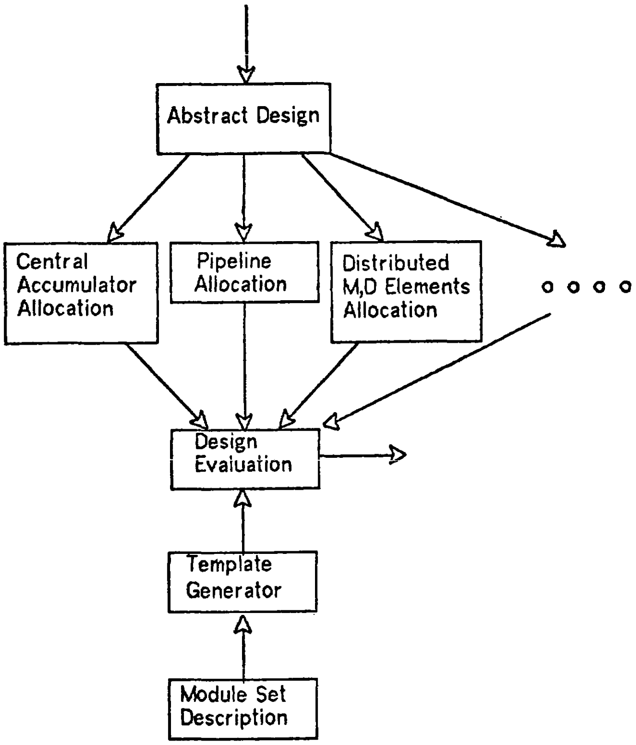


Figure 12—Module set relative design process

The module set level of the allocation uses a set of templates to map the abstract operations in the graph into a module set specific structure. These templates, produced by the template generator from the module set description, act like macros in an assembly language. For each abstract data operation in the graph there is a set of templates that indicate, for example, the different groups of RTM operations that can be executed in order to achieve the desired effect. An operation like A<–B+C, where A,B, and C have been allocated to memories without data operators (central accumulator design style allocation) is mapped into a sequence of RTM primitive operations like: DMgpa/A<–B; DMgpa/B<–C; A<–DMgpa/A+DMgpa/B (module set level allocation).

Templates of this nature are used by the Macromodule evaluator, although the nature of MMs allows more flexibility than RTMs. For instance, using the above RTM example, there are several ways of implementing the statement in MMs and the choice may be critical. With all variables allocated to registers and the necessary data operators connected between the registers (distributed data and memory design style allocation), the statement A<–B+C can be implemented alternatively as A<–B; A<–A+B, or A<–C; A<–A+B, since at the module set level of allocation it is found that all data operations have the destination variables as one of the source variables. (A module set without this restriction could use the same design style allocator.)

This decision is critical and depends upon the data operators already connected to a given register (in this case, register A) or which will be connected in order to implement subsequent operations. If the operator A<–A+C has already been placed in the stack of register A, the first option is clearly the one to adopt. On the other hand, if none of the operators exist then the template adopted depends upon the future uses of the operator, a decision based on a global analysis of the graph.

In addition, a module set may contain a data operator which cannot be described in a simple ISP statement. For instance, the RTM DMgpa can operate on two operands and then shift the result right in one register transfer. Operations such as this require that the allocator scan the graph for occurrences where the special operator can be used. Detecting these occurrences usually accounts for major optimizations in the final design. In fact, most good designers look for special features of module sets and try to utilize them wherever possible. The Macromodule allocator was written to search for special operations such as:

—Invariant bit mapping within an operand (field extraction, bit swapping, etc.)
—Comparing with constants,
—Comparing constants with bit fields,

Macromodules have special physical constructs that allow the above operations to be done easily. This specific information about the Macromodule set injected at the module set level of the allocator allows the automatically generated designs to approach designs produced by a good designer.

Table I compares some sample designs produced by hand and by the RT-CAD system.

HEURISTICS AND DESIGN SPACE TRADE-OFFS

Due to the interaction between series/parallel transformations in EXPL it is a difficult task to formalize the optimization (improvement of alternative structures) as a mathematical optimization problem. The main difficulty is the fact that transformations apply to subgraphs of arbitrary size and, as a consequence transformations in a given alternative structure may or may not be feasible or desirable in structures derived from it. It is also the case that new cases of transformations become feasible or desirable only after a specific sequence of transformations has been applied.

Two parameters will be used to describe the design space: The cost of the hardware involved and the operational time. The former is obtained by adding the costs of the components used in both the data and control structures. The latter is obtained from the average speed of the operations involved.

For a straight sequence of operations the time required is the sum of the individual times. In the presence of concurrent activities, the operation time is that of the longest (timewise) sequence.

When computing the times required by the alternative paths of a branch operation EXPL assumes, by default, that all such paths have equal probabilities of being executed (the probability being 1/n for n-way branches). This default can be overruled by the user by specifying the branching probabilities for the individual paths. The computation of the times required by the paths is then weighted by the branching probability associated with the path. The execution time is then the sum of these weighted path times.

The presence of cycles (loops) adds some complexity to the estimation of the operation time. In this case the level of nesting is assumed to be proportional to the frequency of execution of the operations. Conceptually this is equivalent to replacing the cycle by a sequence of multiple copies of the individual operations. Since the number of times a loop is executed (i.e. the number of copies) is usually unknown, a default (2) is assumed (this is a consequence of the default 50 percent probability of branching back to the loop head). This default may be overruled by the designer by specifying an estimate loop count or, alternatively, simply the branching probabilities if the loop count is not known.

TABLE I

Design		Hand Design	RT-CAD Design
Minicomputer	*Cost*	$6250	$6500
	Time	3.90usec	3.92usec
MSG	*Cost*	$6000	$7450
	Time	7.1usec	13.1usec
Multiplier	*Cost*	$3900	$3900
	Time	5.7usec	5.7usec

Having defined the parameters of the design space we can now describe the trade-offs involved in the transformation rules. Connectivity and data dependency are used in the system to indicate the feasibility of a transformation. Feasible transformations, however, do not imply necessarily any advantage in their application and the desirability of such a transformation is indicated by a different set of conditions.

The exploration of the design space in our system is performed by a group of heuristic routines that produce alternative designs in a goal oriented fashion; the goal being specified by the designer. Ideally, the goal is to find an alternative structure whose position in the design space is as close as possible to the origin (0 cost and 0 time). This ideal case is, however, not easily found in real solutions. The usual case is that the least expensive solution is not the fastest and vice versa. This characteristic provides a rough classification of the design objectives into two classes: minimal cost and minimal time.

Although a designer's aim can be classified according to these objective functions, it may be the case that the real objective is more complicated in nature, namely, some combination of time and cost. For instance, the objective could be something like: "the fastest alternative structure not costing more than x dollars".

For simplicity, the subspace of acceptable solutions will be defined by a set of straight-line segments whose slopes reflect the objective functions. In the example above a single straight line, parallel to the cost axis, would be used to divide the space in two halves. Only those solutions that lie in the semispace containing the origin are considered acceptable. These solutions represent improvements along the design goal.

More complex constraints can be described by using lines of the form $C=m*T+b$, where m is a parameter indicating how many dollars the designer is willing to pay for each time unit saved (if time is the primary goal) or how many time units the designer is willing to sacrifice for each dollar saved (if cost is the objective). m is termed the cost/speed trade-off factor. An example, Figure 13, will clarify this description.

Assume that the primary objective is a reduction in time and that the designer wants a cost/speed trade-off of at most m dollars for each time unit improvement. Furthermore, assume that the original design is characterized by C1 and T1. The "acceptable trade-off" subspace would thus be delineated by two line segments: one parallel to the cost axis starting from

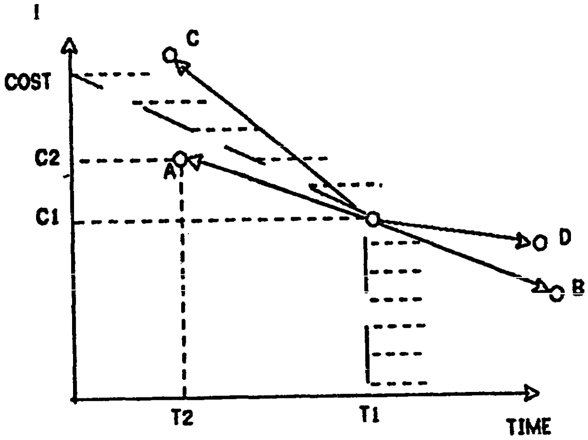

Figure 13—Design space reduction

(T1,C1) to (T1,0), and the other through (T1,C1) with slope −m. Further assume that by studying the control flow and data dependencies in this original structure, four transformations are available which yield four alternative solutions derived from the original one: A,B,C,D.

By dividing the space according to the trade-off lines alternatives B, C, and D can be rejected because their characteristics are not within the acceptable subspace (i.e., they take more time or the decrease in time costs too much). The alternative left, A, represents improvement in time while the cost to achieve the improvement is under the cost/speed trade-off threshold.

The process can now be applied to A in an identical manner. Design A is taken as the new initial solution and a new "acceptable trade-off" subspace is defined by a line segment (T2,C2) to (T2,0) and a line with slope −m through (T2,C2). Since in some cases more than one alternative can be left for further exploration, this process takes the form of a tree walk where the nodes represent alternative solutions and the edges are the transformations applied. In some instances, identical structures can be obtained by different sequences of transformations and the exploration of the design space is a graph-walking process. In any event, a path ends when no alternative solutions worth exploring can be reached from a given point. When all possible paths have been explored the end nodes are measured against the primary objective and the best one chosen.

In general, the space of alternative solutions looks more like a graph than a tree. Several paths (i.e., sequences of transformations) may lead to the same solution.. Thus, it is important to detect points in the space that have already been examined. Other problems that arise in the exploration process have to do with the cost of the process itself. EXPL does not perform a brute force search. Accepting an alternative solution for further exploration depends upon the goals indicated by the user. Besides the main goals (speed, cost, and a trade/off factor) mentioned before, the user can also specify a minimum percentage gain for a transformation-derived solution to be acceptable. This is called the improvement factor. If the gain falls below the improvement factor, the new design is rejected.

This pruning process, when applied indiscriminately, can lead to an incomplete exploration. It may be the case that, although a derived solution is worse (according to the goals) than its parent solution, solutions derived from the former could in fact be better than the parent. EXPL handles the detection of this type of local optimality by allowing the user to specify a rejection level. The rejection level indicates whether or not non-improving solutions are to be further explored. The user specifies the maximum length of such non-improving paths.

The following section briefly presents several examples of design spaces. The examples illustrate some of the points discussed previously.

SAMPLE DESIGN SPACES

In this section we will present three examples of the design spaces explored by EXPL. We will not discuss the specific systems whose design spaces are depicted in Figures 14, 15, and 16. The examples will be used to show the characteristics of the design spaces and the exploration procedures.

Figure 14 shows the design space for a RTM system that is used as a controller for the X- and Y-plates

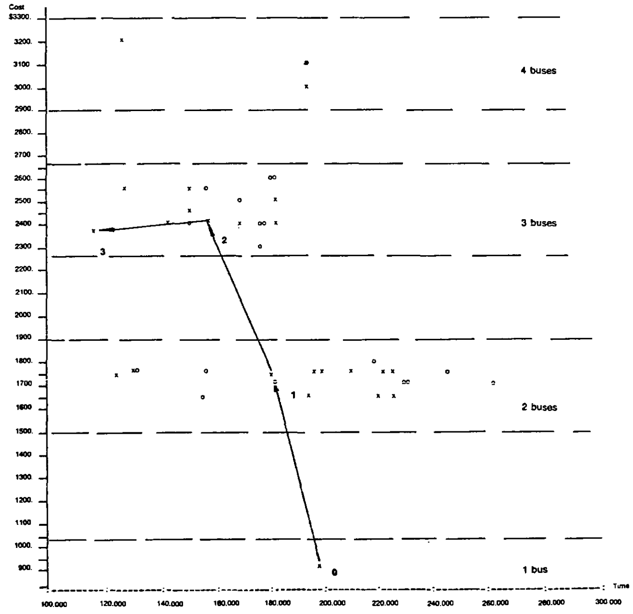

Figure 14—RTM design space (MSG system with 10 percent improvement factor)

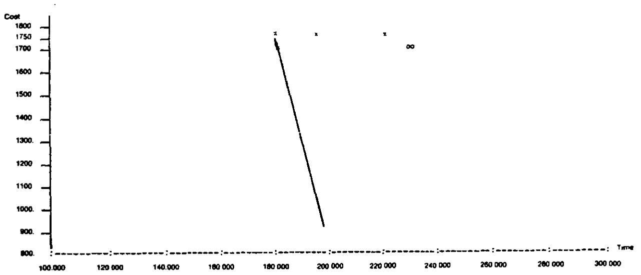

Figure 15—RTM design space (MSG system with 20 percent improvement factor)

of an oscilloscope. The system is used at CMU for RTM demonstrations (the "Munching Squares Generator"). Evaluations of individual designs are represented by a cross. A circle denotes that more than one design had the same evaluation. The first characteristic that can be noticed in this evaluation space is the stratification of the alternative designs. The solutions appear in horizontal bands representing solutions of similar cost. This is due to the high cost of the RTM buses compared with the cost of the other modules in the RTM set. The space is divided into bands corresponding to the 1, 2, 3, and 4 bus solutions.

The figure shows the degrading effect in RTMs of sharing variables between concurrent computations. The best solution (in terms of speed) used 3 buses and is faster than the 4 bus solutions. The algorithm is such that, although it allows a high degree of concurrency, when this degree exceeds a certain threshold there is a loss of speed in the total system due to the overhead of establishing the concurrency. The path followed to find the best solution is indicated in the figure. It is interesting to observe the transition from solution 2 to solution 3. There is a substantial gain in speed together with a reduction in cost. The explanation is that once the cost of a bus has been accepted as a reasonable price to pay for a given gain in speed it does not cost much to spread the load and perform more operations concurrently. Indeed, as the example shows, alternative allocation of the computations to the buses, for a fixed number of buses, is crucial.

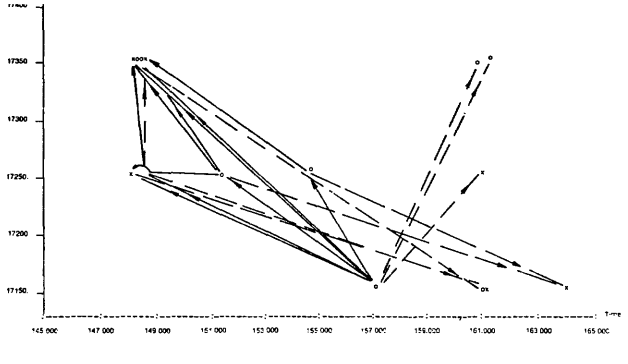

Figure 16—Macromodule design space (conveyor-bin system)

When a solution is analyzed the set of feasible transformations that can be applied to its graph is tabulated. The improvement factor specified by the designer is then used to prune this table. This pruning takes place before a transformation is applied and is based on a preliminary "best case" analysis of a candidate transformation. The solution derived by applying the transformation may or may not realize the potential gain indicated by the preliminary analysis. This reduction in the predicted gain is due to several causes. If the goal is a reduction of cost, performing two concurrent operations in sequence may not in the case of RTMs result in a reduction in the number of buses (other computations may require the bus that was thought to be expendable). If the goal is a gain in speed, adding buses may result in a loss of speed due to the time required to copy and move variables between the buses in the system. Similar considerations can be applied to the case of Macromodules.

Figures 14 and 15 correspond to the design space for the same RTM system explored using the same cost/speed trade-off factor ($100/microsecond) but using different improvement factors. In the space shown in Figure 15, the preliminary improvement factor was set to a higher level (20 percent) than in the space shown in Figure 14 (10 percent). An interesting phenomenon occurred. The transformation indicated by the directed line in Figure 15 had a very promising preliminary evaluation (over 30 percent predicted gain). When the transformation was applied, the new solution did not realize the predicted gain. It was, nevertheless, better than the original solution and was later chosen by the system as the best solution. All feasible (i.e., applicable) transformations to this new solution were then examined and none of them promised to be better than the improvement factor. All of these transformations were rejected and the exploration path was terminated. When the same situation appeared in the example of Figure 14, there were several transformations that were better than the new, lower, improvement factor. One of them led in fact to the best solution of the space of Figure 14. It is interesting to observe in Figure 14 that the slope of the transformation from solution 1 to solution 2 indicates a better cost/speed trade-off than the transformation for the original solution (point 0) to solution 1. The gain in speed produced by the transformation, although smaller than the improvement factor used in Figure 15, was achieved completely; there was no overhead added to the system by the extra concurrency.

This type of anomaly is not uncommon in the modular design spaces explored so far, if anything, they tend to be the rule rather than the exception. The pruning of the applicable transformations, based on a preliminary analysis, can lead us to ignore certain transformation paths that may yield better solutions. It is valid to ask, "why then should the system do any pruning at all?" The only reason we can provide is based on the analysis of the cases studied so far. Applying a transformation without any considerations to its possible gain is an expensive proposition. For any solution, branching factors (i.e., number of feasible transformations) of 30 to 50 are not uncommon. Applying a transformation implies a reconfiguration of the graph and the recomputation of several associated tables—an expensive operation in the current implementation. Applying each feasible transformation can lead to a very expensive design process. For example, when EXPL explored the design space of Figure 14, 454 transformations were analyzed. Of these, 337 were deleted for not meeting the improvement goal. The resulting 117 transformations (26 percent of the original) were applied to obtain new designs. Of these, 87 were deleted for not meeting the cost/speed trade-off or for being duplicated designs ("loops" in the design space exploration). As a result, only 30 transformations (6.5 percent of the original) produced designs that were improvements over their predecessors. For large systems, the combinatorial explosion of possible designs is prohibitively expensive. More intelligent heuristics are required to home in on the most interesting parts of the design space. Once these areas are located a near exhaustive search can perform the final selection. One such intelligent heuristic would be to identify the loop structure of the algorithm and apply transformations to the innermost loops. A variation of this might be transforming those loops whose (improvement factor) × (cycle count) product is largest. Furthermore, loop control and loop computation are parallelizable in many circumstances and their identification could speed up the transformation search which is seeking to identify any potential parallelism. Research into better heuristics is being actively pursued.

The system as implemented allows the designer to guide the exploration via an interactive command language. In the interactive mode, EXPL does not perform any pruning and the designer is free to order the system to perform any feasible transformation, regardless of its predicted gain. The automatic mode of exploration can therefore be used selectively under user guidance, assisting the application of the heuristics.

Figure 16 shows the design space for a system designed as a controller for a conveyor-bin unit. The design space corresponds to the alternative designs implemented using Macromodules. The figure is a good example of a design space with multiple paths leading to the same solution. The space configuration also indicates the characteristic of Macromodular systems. Once a basic design is implemented, variations in the level of concurrency do not present the radical changes in cost typical of RTM system. The basic costs of the Macromodular system are given by the memory and data operation modules (the "stack"). Variations in concurrency only imply adding or eliminating control modules and cables, a minor fraction of the total cost.

VAS AND DESIGN VERIFICATION

It is possible to develop an ISP description that is syntactically correct but that does not make sense logically. Figure 17.a depicts a syntactically correct ISP while Figure 17.b illustrates the corresponding graph. The graph is essentially the same one produced by the ISP compiler. The data operations have been deleted as a notational convenience (we can think of the data operations as being assimilated into the arcs connecting the control operations).

In the case of x=1 the right half of the parallel merge in the graph would receive two control signals (one from the right half of the diverge, the other from the left half via the branch). The other input to the parallel merge would not receive a control signal and the system would deadlock at the parallel merge. Analytical tools based on the vector addition system (VAS)[10] have been programmed to detect such design flaws.

The VAS is best introduced by example. Consider Figure 17.b. The arcs in the graph represent register transfers while the vertices represent control primitives. Each arc may contain tokens representing evocation of the associated register transfer. Graphically a token is represented by a dot on an arc. A marking of a graph with r arcs is a mapping from the set of r arcs to an r-dimensional vector of nonnegative integers, each of which represents the number of tokens on the corresponding arc.

A vertex with a token on its single input arc is said to be enabled. Only enabled vertices can fire. The firing of a vertex removes a token from the input arc and deposits a token on its output arc. For the case of multiple input arcs there is an associated logic condition, either disjunctive (signified by a+) or conjunctive (*). A vertex with disjunctive input arcs is enabled when any input arc has a token. Firing the vertex removes a token from one input arc. This corresponds to a serial merge in the compiler producer graph. A conjunctive input condition requires tokens on all input arcs before the vertex is enabled (parallel merge). Firing the vertex removes a token from all the input arcs. Likewise a set of output arcs can be disjunctive or conjunctive. When a vertex with disjunctive output condition fires it places a token on one of the output arcs (branch). The conjunctive condition places a token on all the output arcs (diverge). A simulation is a sequence of permissible vertex firings.

Simulations are conveniently represented by the Vector Addition System (VAS).[10] Figure 17.c depicts the VAS for the graph in Figure 17.b. The VAS con-

```
TEST := ( declare A<15:0>; B<15:0>; C<15:0>; X<>; N<15:0> [illegible]
        (N←2 next LABEL := A←B+C);
        (A←A+C next (decode X=> C←0; (C←1 next LABEL)))
       )
```

(c) The Vector Addition System for the Graph in (b)

Figure 17

sists of an initial marking vector Mo and a set of displacement vectors which correspond to vertices. Each component of the vector corresponds to an arc. All valid firings (new markings) of the graph can be determined by adding a displacement vector to the current marking Mi. Those additions which result in all marking vector components being nonnegative are valid markings and can be used to establish subsequent valid markings. For example, the only valid marking from the initial marking Mo resulting from the addition of a single displacement vector (e.g., D1) in Figure 17.c is (0,1,1,0,0,0,0,). The displacement vector D2 does not lead to a valid marking since the result of its addition to M0 is (1,0,0,1,0,0,-1).

A control flow tree depicting all possible markings (or states) of the VAS can be constructed. A portion of that tree for our example is shown in Figure 18. Nodes are appended to the tree until, for each leaf, either its marking is identical to that of one of its ancestors or no displacement vectors can be applied. In either case the node is called a leaf.

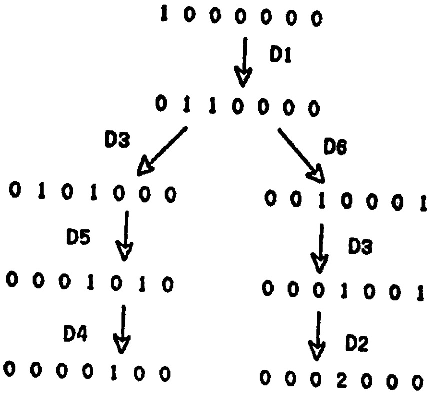

Figure 18—Portion of the control flow tree for the example of Figure 17

Properties of this tree can be used to detect properties of the graph. For example, the leaf (0,0,0,0, 1,0,0) represents a properly terminating sequence since there is a single token on arc 4. By contrast, leaf (0,0,0,2,0,0,0) represents two tokens on arc 3. No tokens are on the exit arc. This is the deadlock situation alluded to earlier. Furthermore, depending on the actual physical implementation of the graph, this leaf may indicate a lost signal.

OTHER DESIGN TOOLS

One of the traditional design automation tools has been the simulation of a digital system. The RT-CAD system includes a simple simulator (SIMU10) which interfaces with the machine descriptions stored in the data base. Data base objects consist of two components: a symbol table and a flowchart. The former contains the description of the digital system component (registers, flags, memories, constants, etc.). The latter contains the data and control operations describing the behavior of the system. By stepping through the flowchart, SIMU10 can emulate the behavior of any digital system stored in the data base. An interactive command language allows the user to set and display the contents of the registers and memories of the system. The command language allows the user to set and reset arbitrary breakpoints and to interpret command files, created off-line, instead of prompting the user directly.

It is also desirable to produce designs according to criteria other than the traditional cost/speed criteria. One such criterion is testability. The structure of the final design substantially determines the ease with which tests can be generated for the design. A testability measure[11] has been developed that correlates well with actual test generation effort. It is important to note that the common representation used as input to the various design programs is a critical feature that insures that the algorithm being evaluated is actually the one being implemented, verified, or simulated by the other design programs.

It is worth mentioning that some of the RT-CAD system components have been exported and are being used in places other than CMU. One of the more ambitious projects is the Computer Family Architecture (CFA) being developed by the Naval Research Laboratory. The objective is the implementation of a generalized Architectural Research Facility (ARF). NRL is currently using the ISP compiler and SIMU10. The ultimate goal is the implementation of a system that will emulate large machines described in ISP. Interactive facilities will assist the user in evaluating the described machine. Thus, proposed machines can be evaluated and their architecture tuned prior to production. The emulator will be entirely resident in the control storage of a dedicated PDP-11/40E (a commercially available, modified PDP-11/40 that allows the coexistence of user written microcode together with the standard, DEC provided microcode that implements the PDP-11 instruction set).

FUTURE DIRECTIONS

To achieve the goal of automatic design relative to technology a mechanism is required that would take the description of a module set and create the equivalent of the ad hoc module set evaluators currently in use. It was also noted earlier that the order of physical allocation (registers, buses, operators, etc.) is a strong function of the design style imposed by the module set. This information would also have to be extracted from the module set description.

This preliminary design automation system and a machine relative optimizing compiler-compiler project serve as a stepping stone to an even more ambitious project termed the Symbolic Manipulation of Computer Descriptions (SMCD)[14] depicted in Figure 19. There is a continual stream of new machines spurred by the advent of minicomputers and microprocessors. Each machine has a different instruction set. The emergence of microcoded systems with the option of user-defined instruction sets has increased this flow of instruction sets. Each new system requires supporting software and the amount of software grows for any individual system as user requirements grow.

One direction in which to seek a solution to ease the burden of software development is to relativize the production of software to the description of the machine. The central ingredient of this approach is the description of computer systems in a symbolic form, such that a range of problems can be solved by manipulation of these descriptions.

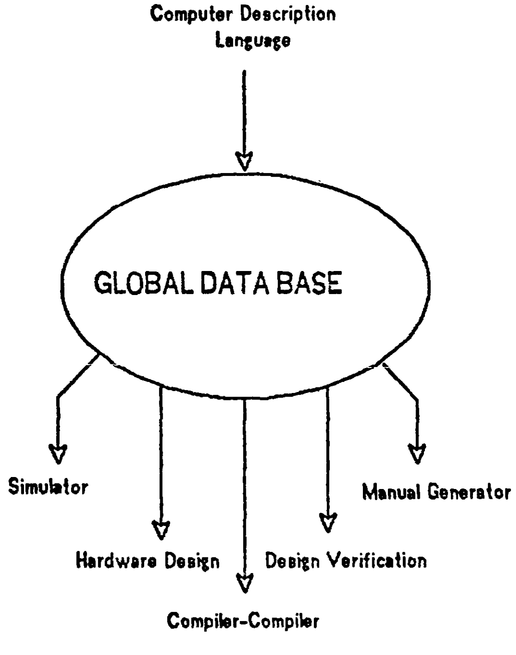

Figure 19—The symbolic manipulation of computer descriptions

Figure 19 depicts the scope of the SMCD project. The ultimate goal would be to produce and evaluate a computer system from its behavioral specifications, together with the documentation and system programs. Thus the delay from the conception of a new architecture to the time it is implemented and ready for users can be significantly reduced.

ACKNOWLEDGMENTS

We would like to thank the many individuals whose work contributed to the results described in this paper. Steve Goldman, Ross Scroggs and Phil Karlton assisted in the development of the ISP compiler. Vittal Kini implemented the VAS, Don Thomas implemented the MM evaluator, and Steve Rodkey implemented SIMU10.

Some computer-related advancements for enhancing U. S. shipyard productivity

by RICHARD B. WISE and DOUGLAS J. MARTIN
IIT Research Institute
Chicago, Illinois

ABSTRACT

An exciting new cooperative program for enhancing productivity in the shipbuilding industry through improved automation technology is described. This program, designated as the REAPS (Research and Engineering for Automation and Productivity of Shipbuilding) Program, entails joint efforts of the Maritime Administration and the U.S. shipyards toward new capability development.

Four on-going hardware/software-related projects currently under way are described in some detail. These include: a major software system (AUTOKON-71) for design and construction of ships; a specialized CAD/CAM remote batch graphics terminal to better serve shipyard needs; an interactive graphics system for pipe detailing; and a minicomputer-based numerically controlled frame bender.

A number of other hardware/software development programs currently approved but not as yet funded are also discussed.

THE NEED

Over the years a decided productivity lag has developed between U.S. shipbuilders and other shipyards around the world. For instance, a few years ago it was shown that U.S.-built container ships typically required 120 man-hours per delivered ton, while the equivalent ship built in West Germany required 90 man-hours per delivered ton. For ore carriers the U.S. required 75 man-hours per delivered ton whereas Japan required 59 man-hours per delivered ton.

Until 1970 the only recourse available to the U.S. Government to keep our Merchant Marine facilities competitive was to provide a subsidy program which reimbursed ship operators and ship builders the difference between the cost of materials and labor in the U.S. and those of competitive foreign countries.

In 1970, however, new laws were enacted which set in motion a large-scale research and development program in cooperation with U.S. shipbuilders and ship operators aimed at reducing costs and to improving productivity rather than merely reimbursing inefficiency.

THE SOLUTION

As a first step toward administering this program for the shipbuilding industry, the U.S. Maritime Administration convened a group of industry experts to identify where the most critical deficiencies existed and to provide guidance as to the best means for resolving them. The recommendations of this Technical Advisory Group resulted in the formulation of a number of MarAd supported research and development activities addressing six major development areas: computer automation, welding technology, surface preparations and coating, materials handling, ship producibility, and general projects.

In an effort toward developing a coordinated thrust in administering the resulting programs for applying automation and computer technology to shipbuilding, the REAPS Program was born. REAPS, an acronym for Research and Engineering for Automation and Productivity in Shipbuilding, is a cooperative program involving the U.S. shipyards and the Maritime Administration in a total system approach designed to identify and take advantage of productivity opportunities through the application of automation technology. Developments associated with this program are keyed to specific applications. Projects are not considered complete and successful until they have been implemented under shipyard production conditions. This implementation phase precludes the possibility of a project failing because of poor implementation of a sound development. It also insures that only those projects with valid objectives will be undertaken.

The REAPS program itself is funded jointly by MarAd and the participating shipyards and is administered by a contractor (IIT Research Institute). Its activities entail three major efforts: (1) Advance planning to recognize future productivity opportunities; (2) Library and information services to apprise the industry of the latest available information on technology; and (3) R&D Program formulation.

The advance planning activity involves the identification of high-cost areas and subsequent target opportunities for new hardware and software research and development efforts.

The library and information services activity involves: (1) the quarterly publication of a Shipbuilding Technology Update Bulletin containing selected up-to-date citations and abstracts on world-wide publications of interest to shipbuilders; (2) maintaining a library of shipbuilding technology information and selected software programs; (3) distributing a library catalog and copies of the Update Bulletin to all major U.S. shipyards and providing a document reprint and software distribution service; and (4) holding an annual REAPS Technical Symposium where industry leaders are invited to discuss new advances in shipbuilding automation.

The R&D program formulation activity entails both project initiation and project monitoring. The advance planning activity identifies opportunities for productivity enhancements. Representatives from the REAPS yards then collectively prioritize these indicated requirements, develop project briefs defining detailed needs, solicit proposals from competent agencies for fulfilling these needs, and determine the best source for their realization.

The resulting development projects are then carried out on a cost-sharing basis with MarAd funds, with monitoring of all progress being pursued under the cognizance of the REAPS program.

ONGOING PROGRAMS

The remainder of this paper will be devoted to detailed discussions of the extant and contemplated computer-related projects within the REAPS Program.

AUTOKON SUPPORT PROGRAM

Background

The AUTOKON Support Program is actually the charter REAPS activity. Its genesis stemmed from actions taken by a U.S. shipbuilding industry advisory group in 1971 in response to a recognized void within the industry in the area of computer-aided shipbuilding. This requirement was most pressing for hull fairing functions and for numerically controlled burning of steel plates.

Accordingly, to resolve this deficiency, the Maritime Administration, acting on the advice of this Technical Advisory Group, purchased U.S. rights to a software system developed by a Norwegian Shipbuilding firm, the Akers Group. This system, known as AUTOKON-71, was in active use in more than 40 European shipyards.

MarAd then sublicensed AUTOKON use rights to U.S. yards. The AUTOKON Support Program, as it is now called, was then established to provide a mechanism for adapting this system to the U.S. shipyard environment.

A detailed discussion of the AUTOKON-71 system itself is contained below. Following that is a discussion of the activities of the AUTOKON Support Program for effecting enhanced productivity through cooperative efforts in adapting the system for U.S. requirements.

AUTOKON features and structure

Overall organization

The overall organization of the AUTOKON-71 system is shown in Figure 1. The system itself is completely modular, thus allowing shipyards to pick and choose among the modules to best serve their individual needs, with the ability to easily substitute alternate programs if they desire.

As shown in the figure, the entire system is tied together through the use of a common database. The relationship of each of the AUTOKON subsystems to this database will be elaborated below. In general, however, all new data generated by the modules of each of the subsystems are accumulated within the database and any subsequent module may reference previously-generated data from the database. Thus it is possible to gradually accumulate the information de-

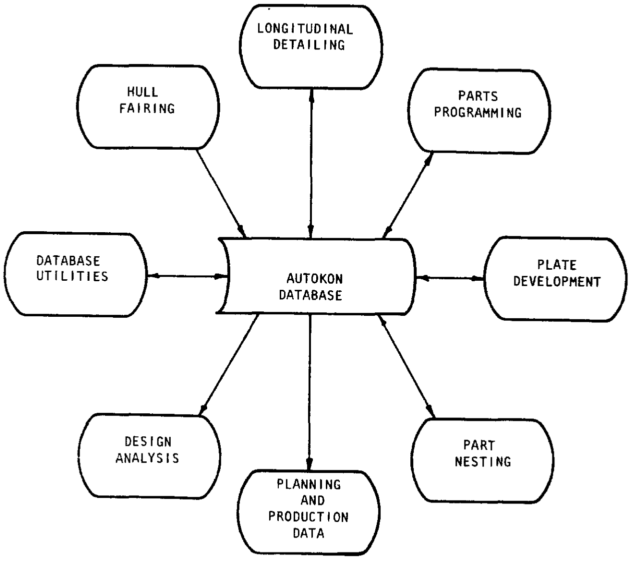

Figure 1—The Autokon-71 system

fining a ship, in effect allowing it to be constructed within the database prior to its actual erection.

In addition to the usual economies in data maintenance and storage costs resulting from the minimization of data plethoration, further benefits are achieved in the design and construction cycle since all personnel using the system have access to identical information for consistency and efficiency.

With two exceptions (Modules ALKON and DUP—see below) each of the modules comprising the various AUTOKON-71 subsystems are applied in a simple straightforward manner involving submission of a minimal amount of data in fixed-field format on preprinted data sheets. Following the commands and information on the input sheets, additional information, as required, is automatically retrieved from the database, appropriate computations are carried out, and results are recorded on the database and output listings, with graphical plots and/or N/C tapes also produced as necessary. The N/C tapes may be input to a drafting table, flame cutter, or alternatively, via a postprocessor, to a Tektronix CRT display or Calcomp drum plotter for quick-look review.

The two exceptions alluded to above are equally simple to apply but incorporate an interpretive command language in lieu of the fixed input format.

The entire system is structured to effectively fit within existing working conditions at a shipyard, with the overlying philosophy assuming that the users of the system are subject knowledgeable but have no background in computer processing.

Except for a handful of assembly-language programs for handling computer-dependent functions and inner-loop subroutines, the entire AUTOKON-71 system is written in Fortran. Thus, the system is almost completely computer-independent, with functionally identical versions operating on Univac 1100, IBM 360/370, Honeywell 6000, and CDC Cyber 70 systems.

A detailed discussion of the AUTOKON-71 database and each of its subsystems follows.

Database management subsystem and associated utilities

The database itself is physically assigned to direct access storage (drum, disc, etc.) and accumulates to the order of two million computer words for a typical ship, such as a large tanker or container ship. Data are stored in an arbitrary number of variable-sized indexed-sequential files each residing in one or more fixed-size physical blocks as required. Every file contains a number of variable-sized logical records (designated as "matrices") each incorporating information of a specified type and having a specific format.

Files are addressed using a six-integer identifier. The meaning associated with each of these six integers is established according to a fixed set of conventions, which for each shipyard, are adapted to best adhere to local procedures and techniques.

The AUTOKON-71 database access and control subsystem is embedded in a module designated as the AUTOBASE module. These AUTOBASE routines, which are completely invisible to the user, provide an efficient access method for operating on the database. Whenever a specific six-integer identifier is referred for storage or retrieval (see Figure 2), a hashing algorithm is applied to the numbers to identify a unique page in the file catalog containing information on that identifier. That one page of the file catalog is then searched sequentially to find the most recent version of the desired file (grandfather versions of all files are optionally retained in the database to allow backup). The matching entry in the file catalog then contains a direct-access pointer to the desired file. The file, in turn, contains a File Table of Contents for accessing the desired matrix.

Thirteen independent utility modules are provided as an aid in administering the database. Nine of these are used to facilitate establishment and modification of the database, and three others for storing and retrieving data directly to and from the database, bypassing the other modules—useful for transferring data from N/C tape images, from a digitizer or to or from another database.

The last utility module, designated as DUP (**D**atabase **U**tility **P**rogram) is a stand-alone system for manipulating the database contents, for creating magnetic tape backup, for copying specified portions of the database onto another database, and for generating an annotated table of contents for the database. Unlike the other modules, DUP is an interpretive system using a set of commands specified free-form on punched cards. Typical commands include: READ, WRITE, DELETE, CONTENTS, COMPRESS, DUPLICATE, etc. Each command is usually followed by one or two parameters describing the data affected.

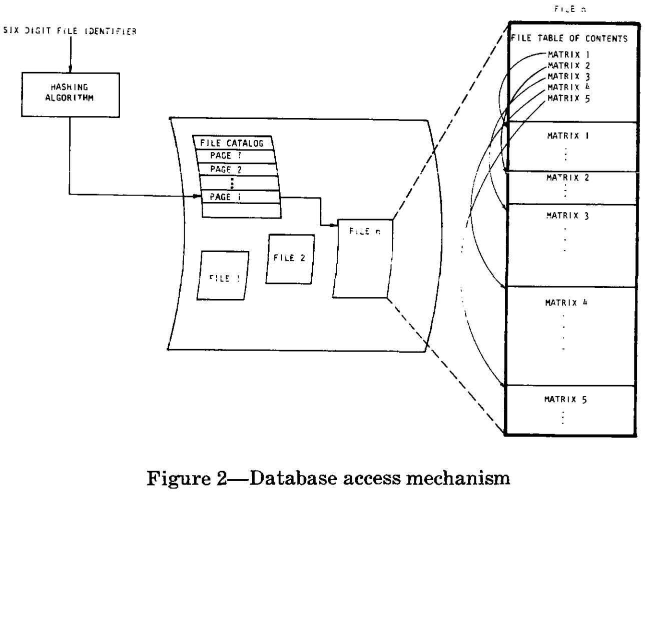

Figure 2—Database access mechanism

Hull fairing subsystem

The AUTOKON-71 hull fairing subsystem is actually comprised of three modules: FAIR for the actual fairing of the ship's lines; DRAW to generate N/C drafting table drawings of the faired lines; and TRABO for **TRA**nsferring the final **BO**dy plan to the AUTOKON database. As shown in Figure 3, the fairing process is carried out using a sequential file for storing the offset information. Because the fairing activity involves an iterative man-machine process, significant economies can be effected by performing the initial fairing runs independent of the database, incorporating only the final faired lines into the database.

The purpose of the FAIR module is to perform the fairing of ship lines and to transform these lines into a numerical form suitable for further computer processing. The basis for performing the fairing process is a preliminary lines drawing in a suitable scale. Normally 200-400 data points for an entire ship are lifted from the lines drawings, the number depending upon the extent of shape incorporated in the hull form.

Input consists of some key curves and selected points on frames, waterlines and/or buttocks. The fairing is performed automatically from the data points selected by the user, and results are presented in printed form and, via the DRAW module, in N/C form for subsequent drawing on an N/C drafting table. Drawings are automatically produced, as desired, for all curves faired.

In use, FAIR may be employed as desired to generate an entire ship or as little as one-fourth of a ship. The different parts of the ship may then be "hooked up" to form the complete ship. As any of these hull representations is satisfactorily developed, it may then be transferred from the working storage used by FAIR into the database for the desired hull and added to whatever previously exists. This body plan transfer is accommodated through the use of the TRABO module.

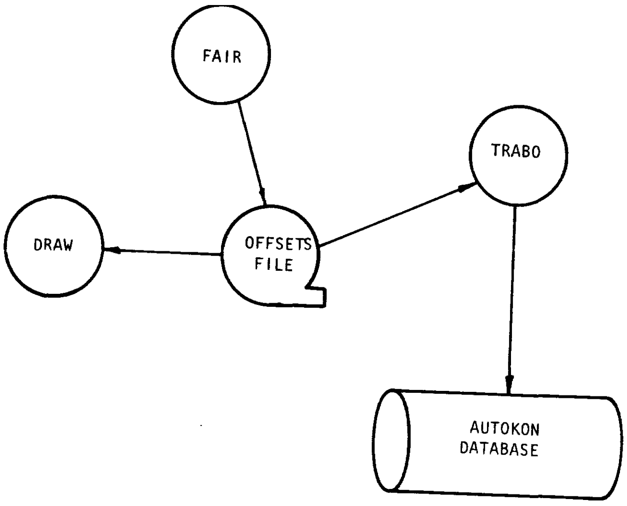

Figure 3—Hull fairing subsystem

Longitudinal detailing subsystem

Once the hull data are incorporated within the database, this subsystem can then be applied to strake the shell by fitting longitudinal curves to the hull surface. Using a module called LANSKI (a Norwegian mnemonic standing for longitudinal details), contours for seams, longitudinals, stringers, bulkheads, decks, etc. can be automatically defined.

Input to the program consists of a few points for each seam and for each longitudinal from its start point and end point, together with a simple identification of desired cutouts and of the first and last transverse frames along the shell to which the cutouts are to be applied (also using INCLUDE or EXCLUDE operators to identify explicit frames where cutouts are to be omitted).

As output, a Table of Details is produced, both in the database and as a tabulated listing, describing how and where the longitudinals, seams, and decks cut through transverse frames, bulkheads, etc. The space angle between two intersecting parts is computed and stored to provide automatic correction of the nominal dimensions for clearance, on height, width, and, if necessary, on the thickness and angle of flange, etc. Plots of the body plan with the longitudinal curves superimposed, and other drawings for checking purposes are produced.

Parts programming subsystem

The subsystem for parts detailing, designated as ALKON (standing for **AL**gorithmic **CON**struction), is by far the most sophisticated element of the AUTOKON-71 system. Input for this module is specified in a very powerful Fortran-like problem-oriented language. While it is primarily a plane geometry definition tool, ALKON boasts of many other powerful features including:

- Fairing of individual curves
- Detailing of complex steel structures
- Production of drawings with augmented text (drafting automation)
- Production of data for N/C control (drafting, flame cutting, milling, etc.)
- Definition and printing of miscellaneous tabular information
- Definition of standard details (parametric descriptions of stringers, scallops, etc.)
- Formalization of design and production practice (accumulation of experience)
- Definition of identification system and data structures

The ALKON language is completely flexible, providing the user with tools to replicate the functions of literally any of the other AUTOKON modules if desired. It should be noted that while the grammar and meaning for every vocabulary word is explicitly defined within the system, the spelling associated with each of these words is not; thus each yard is able to define its own version of the vocabulary, incorporating whatever abbreviations and localized spellings are desired, taking full advantage of local customs and nuances.

One of the most powerful adjuncts of the ALKON language is represented in its ability to allow definition of norms (i.e., subroutines and functions). Norms may be given dynamic names and may be defined and called at any time. Norms are stored in the database just as any other AUTOKON information, are re-entrant, and may be executed recursively.

Since norms are, in effect, extensions of the ALKON language, the capabilities of the ALKON system are virtually limitless. In practical use within a shipyard, norms are applied in a hierarchical manner: Very basic norms are used to define elementary items such as cutouts, holes, etc. Other norms combine them into series of holes, contours with cutouts incorporated, etc. Still other norms can be used to generate complete parts to produce web frames, floors, etc. It is even theoretically possible to write a norm to design an entire ship.

The ALKON processor itself is organized in two passes, translation and processing, which are executed in sequence. All input for a run is translated before the processing pass is activated, with all data transfers between the passes being handled by the AUTOBASE routines.

Input to ALKON is normally on punched cards. This input information is read into the ALKON processor one card at a time by the Translation module. Each line is listed on the line printer and is then translated from the higher-level, external representation of words and numbers into a binary format. At the same time, a few special symbols are interpreted with appropriate actions taken, and a check is made on the formal correctness (syntax) of all the other input code. Misspelled words are rejected, missing parentheses are noted, etc. If complete fields in a statement are missing, a default value is substituted. This default feature makes it possible to write statements in a very simple way for common situations while allowing the same statements to be used in a sophisticated manner for more complex situations. Vocabulary definitions are also accommodated at this point as well as Comment statements which are recognized and immediately discarded.

All the major fixed internal logic for Translator processing is handled through the use of three sets of joblists together with vocabulary tables and decision tables. Through the use of these tables, all other statement types not mentioned above are efficiently translated from the character representation of the input to a binary (inverse Polish) notation and passed on to the Processing Module via a set of database records designated as code blocks. Newly defined norms are also retained as code blocks as are previously-defined norms.

Following completion of translation, control is then passed on to the Processor. Here the code blocks for manuscripts are returned from the database one at a time, and the statements are acted upon. If a call for a norm is encountered, the processing of the manuscript is temporarily suspended while the statements of the called code block are acted upon. If another norm call is encountered, the processing of the present code block is again suspended and the new code block acted upon. This process may be repeated to any depth, the processing of the previous code block being resumed when the processing of the called code block is completed.

When processing of the code block for a manuscript is finished, the next manuscript code block is then retrieved from the database and processed in the same manner. Finally, when there are no more manuscript code blocks, processing is completed and the present ALKON run is terminated.

The ALKON code for a simple part is shown in Figure 4. As previously indicated, the fairing subsystem results in the storage of the ship's lines in the database. The use of simple norms for retrieving this information is illustrated in Figure 5. The norm calls

FETCH TFRAME (89) AT SHELL'

instruct the system to retrieve the file containing the contour defined by the intersection of Transverse Frame 89 with the outer shell of the ship. The norm

FETCH LCON'

then instructs the system to retrieve the specific matrix in the file for the desired lofting contour. This code can then be embedded within a new contour definition, as shown in Figure 6, to define a part made up of this contour.

The Longitudinal Detailing subsystem generates tables of details for all required cutouts and stores them in the database. The ALKON code shown in Figure 7 illustrates how the wire frame norms can then be applied to automatically modify a lofting contour to incorporate these cutouts. The norm

GEN ACON ( )

retrieves the various tables of details, previously stored by the LANSKI module, references the appropriate norms for the cutout definitions and automatically generates the augmented contour incorporating all the desired cutouts.

Plate development subsystem

seams and butts in the database, use of the shell plate development subsystem normally commences. This subsystem is comprised of two AUTOKON-71 modules, aptly designated as SHELL and TEMPLATE.

Shell is used to develop the steel plate required for the outer shell of the ship and TEMPLATE generates the roll sets to be used in forming them. For each desired shell plate, input consists of butt locations (stated as axial distances from transverse frames) and seam identifications together with an indication of which of two alternate expansion methods is desired. The SHELL program retrieves the required hull form and longitudinal curve information from the database and generates 2-axis or 3-axis N/C tapes for cutting and marking the plates. It also generates N/C drawings in various scales to be used for checking, planning, or optical burning. The locations of the rolling lines and any stiffeners are automatically punch marked on the plate, or indicated in the drawing by dashed lines.

The TEMPLATE program uses essentially the same input and generates N/C tapes for plots of roll sets for the shell plates, or the roll sets themselves. Information for three templates is produced for each plate: at the first transverse frame, the last frame and the middle frame. This module may also be used to generate dimensions for the production of 1:1 wooden templates for shaping transverse frames.

Part nesting subsystem

Most parts developed with the parts programming subsystem are not directly cut but rather are stored on the database for subsequent nesting on a rectangular steel plate so that the steel is used efficiently. The AUTOKON-71 NEST module is utilized for this activity. Working with appropriately scaled part drawings, the placement of the parts on the raw plate is determined manually. Input to the NEST module then consists of the part numbers for each of the nested parts, their relative location and orientation (normal or mirror) on the plate, approximate cutting bridge placement, and (forward/backward) cutting sequence for each part. The program automatically retrieves the contour and auxiliary function information from the database for each part specified, and generates the required N/C tape for plotting and flame cutting of the nested format. The plots can be used for checking, planning or optical cutting.

Planning and production data subsystem

This subsystem is embodied in the AUTOKON-71 PRDO (**PRO**duction **DA**ta) module which is used to extract data from the database to provide useful information for planning and production purposes. Output produced includes: (1) burning time and cutting length for nested formats and single parts; and (2) area, volume, and weight information for single parts or, optionally for an aggregate series of parts.

Design analysis subsystem

This subsystem, as incorporated within the AUTOKON-71 system, is collectively designated as the PRELIKON (Norwegian mnemonic for Preliminary Lines) package. It is comprised of 23 modules which are used for both preliminary and final naval architecture calculations and for automatic production of various tables and plots normally required on delivery of the ship.

All computations are performed on an independent database. Initial establishment of this database is achieved with the Hull Definition module or the Hull Variation module, the latter of which can be used to apply minor changes (LCB,CB, or main dimensions) to elements of a library of hull forms.

The AUTOKON-PRELIKON linkage module, which, in effect, retrieves the body plan from the AUTOKON database and maps it into the PRELIKON database, may be used later to allow the modules below to be applied for final calculations.

Modules are also provided for the following computations:

- Hydrostatics
- Load Distribution and Balancing
- Resistance
- Bon Jean Tables and Plots
- Transverse Stability
- Floodable Lengths
- Launching
- Trim Tables and Plots
- Capacity, Sounding, and Ullage Tables
- Grain Stability
- Longitudinal Strength

Program support activities

The AUTOKON Support Program can be defined as a special interest activity being pursued under the auspices of the REAPS Program. As previously stated, the basic purpose for this program is to provide an organized mechanism for maintaining and enhancing the AUTOKON-71 system for optimal use in the U.S. shipbuilding environment. Activity towards this end falls into three categories: Software Support, Information Dissemination, and System Enhancements Requirements and Planning.

For software support, all the expected system support activities are being pursued under this effort. A formal mechanism has been established for reporting system failure information for subsequent resolution by the REAPS Program staff. Periodically, all the accepted fixes are incorporated into the system and a new Standard System is distributed to the participating yards. Tapes and complete update documentation are provided. Implementation assistance is also made available to new system users. A new four-volume AUTOKON Users Manual has been written and made available to participating yards, and training courses have been developed and given.

Proposals for major system capability enhancements are periodically reviewed by the AUTOKON Support Program Technical Representatives, with resultant recommendations made for MarAd funding for those deemed to merit implementation.

PIPE DETAILING SYSTEM

The following describes the results of a preliminary systems design recently carried out by Newport News Shipbuilding and Dry Dock Co. in the first phase of a two-phase effort to design and implement a minimum cost system for pipe detailing. The purpose of this effort was to identify an input station configuration for use in digitizing piping design data that would substantially reduce the cost of preparing input data for various computer-based systems used for the production of pipe manufacturing documents.

Operational overview

Functionally, the desired system must accommodate four major tasks: data input, document production, data revision and updating, and data communication. These tasks are described below in the context of a typical operational sequence.

At the beginning of a typical design session, the designer will retrieve the appropriate piping arrangement plan or preliminary design drawing and mount this document on an X-Y digitizer, along with the command menu list to be used in the input process. Next he must retrieve from a hull structural database (e.g., an AUTOKON database) the necessary structural reference data (transverse frame, deck, bulkhead locations, etc.) such that geometric data for the piping system may be conveniently referenced to these locations. Using these reference locations, the designer will then calibrate the drawing(s) on the digitizer by touching the positions of these structural landmarks with the free cursor. The system is then prepared to accept digitizer input.

The designer then proceeds to input the piping system geometry and details utilizing the digitizer, a keyboard or CRT cursor picks. These picks relate to a CRT display of the current definition of the piping system which is built up during the input process. The CRT display also serves as a check on the designer's work as he proceeds.

Keyboard input of piping geometry may be in the form of coordinates relative to the structural reference locations retrieved from the hull database, absolute coordinates or coordinates relative to other points already defined in the pipe geometry itself.

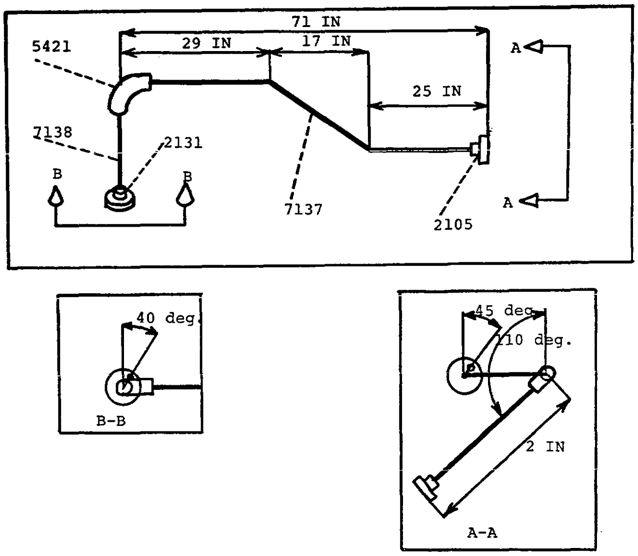
An important feature of the system is the capability to automatically select specific components based on a predefined set of component selection rules applicable to a particular piping system. This feature, for example, will allow the designer to specify a condition generically (e.g., TURN) during the input process. Then, a post processing operation will automatically determine the specific fitting, etc., to be substituted (e.g., a bend or a 90° or 45° elbow) for the generic condition through an analysis of the component selection rules.

Regardless of whether components are explicitly referenced by the designer, or automatically selected as described in the preceding, the system will proceed to automatically determine the required orientation in space of the component based on its local geometry and the geometry of the connected piping. Additionally, error checks are performed on the geometry of bent pipes, to insure that they may be produced by the yard's pipe bending machines, as well as on joints in the piping system to verify the compatibility of members at the joint in terms of diameter, end type, and alignment.

At the completion of an input session, or at any time during the input process, the designer may request the system to produce checking documents. These include a centerline check print (plot), consisting of a single line drawing of piping centerlines drawn to the same scale as the drawing from which the piping geometry was lifted such that it may be overlaid on the original, a piping system data list, and a listing of missing data (see Figure 8). This latter list is required if the designer is working from a preliminary design drawing which will not contain all necessary detail information required to complete the design. In this case, the system notes the locations where information is lacking, but allows the designer to proceed with the input process. Then, at a later date, when the designer has determined which details are to be used for this specific system, he can return to the incomplete system definition to fill in the missing information.

Figure 8 is an example of such a checking document as might be produced by the system. Note that graphical prototypes of the defined fittings are also presented. Also indicated are two sectional views of the system, defined by the user. The user may select views of the system by one of three methods:

1. by identifying several structural reference points which are to be included in a plan, section or elevation view;
2. by identifying a pipe leg which will serve as a view axis or a pair of intersecting legs the normal to which will serve as the view axis;
3. by specifying cross-sections through an existing view (e.g., Figure 8).



ID	TYPE	SIZE	SOURCE

7138	Pipe	3 in x 12.0 in	SN62131

Figure 8—Typical pipe detailing system plotter output

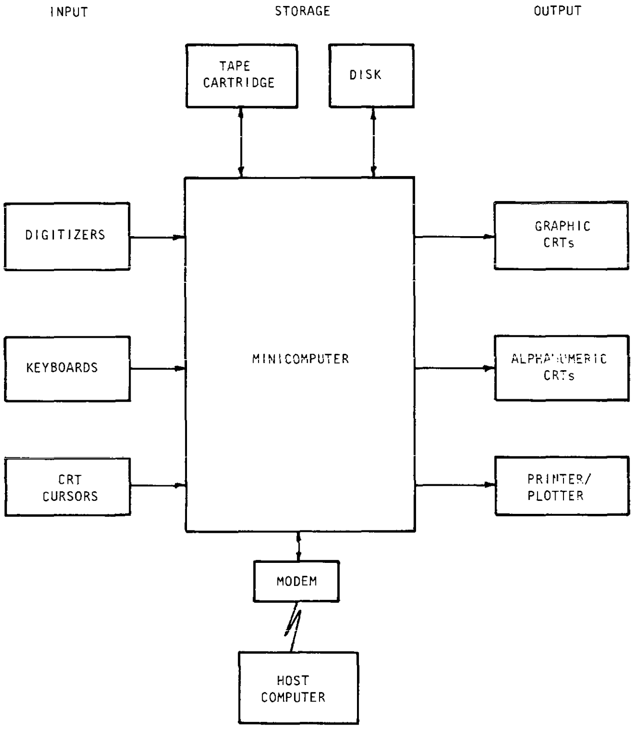

Figure 9—Hardware environment for pipe detailing system

At the conclusion of an input or modification session, the designer may either dump the specific piping system database to magnetic tape for later retrieval and additional detailing work or, if the system is complete, transmit the database to the central database for accessing by engineering analysis, material and production control, and manufacturing document production programs.

System configuration

Figure 9 is a schematic representation of the proposed input terminal configuration. Each such terminal may support from one to four input stations each consisting of a digitizer, a keyboard, an output graphical display device and an output alphanumeric display device (either a teleprinter or character CRT). The box labeled "Printer" may actually consist of one of two alternative configurations; an incremental pen plotter for the production of centerline check prints and a medium speed line or character printer for producing data lists, or a single electrostatic printer/plotter which would satisfy the requirements for both applications. The communications interface and modem will support 1200 baud synchronous communications between the minicomputer and the central site facility, a Honeywell 6080, via a Datanet 355 communications front-end.

All database operations will be implemented within the framework of a vendor-supplied database management program which conforms to the recommendations of the CODASYL committee. A database network structure has been defined for the representation of piping data interrelationships which uses a subset of the CODASYL specifications and which is compatible with several commercially available minicomputer-based DBMS.

The final, or development phase of the work reported here is currently under way at Newport News and is scheduled for completion in early 1978.

SHIPYARD GRAPHICS AND COMMUNICATIONS TERMINAL

The following discussion reports on the results of a design effort carried out by IIT Research Institute to develop a low cost remote terminal configuration for use by shipyard loft departments in processing the input and output of N/C software systems such as AUTOKON and others.

Background

This project was initiated with the intent of developing a terminal design which was modular, for ease in configuring various throughput/cost configuration alternatives, as well as to minimize the cost of each such configuration throughout the range of these capability alternatives.

Functional requirements

The functional requirements of the terminal, developed as a result of interviews with the personnel of various shipyards in the U.S., are as follows:

1. The terminal must provide a Remote Job Entry (RJE) capability for a variety of mainframes via emulation of various remote batch terminal protocols typically associated with these mainframes.
2. It must provide a local facility for reviewing numerical control (N/C) data graphically on a cathode ray tube (CRT) display and on an automatic drafting machine (ADM) in the following modes:
   a) ESSI verification
   b) Drafting

   Additionally, the system must be capable of punching, on paper tape, the final verified ESSI file for transmittal to the burning shop to be used to direct N/C flame cutters.
3. It must provide the necessary data management and storage facilities to support the above-mentioned activities efficiently.
4. It must finally, provide an operating environment in which software tasks associated with the above functions may execute concurrently in servicing one or more users.

Operational environment

The terminal user/operator, as with other remote batch operations, will load the appropriate RJE emulation software into memory from local mass storage and establish communications with the central site facility. Once loaded, the emulator is prepared to accept for transmission a user input deck. The user loads the deck in the card reader and instructs the emulator to transmit the input stream to the central site.

At the central site, the appropriate N/C software system module is invoked and executed and the output of the run queued for transmission back to the originating terminal site. Output from these programs is of two forms: the normal printed output (or Print File) which will be directed to the terminal's line printer, and the resultant ESSI code describing the geometry of the part, plan, etc., produced by the run. This file will be treated by the central site as a Punch File and addressed to the terminals' punching device. In practice, however, this file will be automatically written to the terminal's local mass storage device and catalogued under a file name consisting of the unique run identification information assigned by the central site.

Upon reception of these files, the user may then referring to the run I.D. appearing on this printed output, initiate a graphics session at the CRT console and call out the appropriate "Punch File" for graphics processing.

The graphics processing system will allow the user to plot the ESSI data on the CRT for a quick check of the data or produce an ADM drawing of the data by simply specifying the desired output device. If the user of the CRT is not the originator of the run, this terminal operator may simply produce a hardcopy of the CRT check plot on the optional hardcopy device for delivery, along with the printed output listing, to the run's originator for review. After review of the run results, the loftsman or designer who initiated the run may request the operator to either plot the catalogued Punch File on the ADM, if the results are satisfactory, or purge the file if an additional run will be required. A punch tape of the file will also be requested if the file is to be used by the N/C burning shop.

System description

Figure 10 represents a typical configuration of the terminal being described. One of the more interesting features of the system is the block labeled "Table Control." This is a microprocessor-based control unit containing all the required logic for linear and circular arc interpolation and the generation of slope and acceleration control required by the head drive electronics of the ADM itself. This capability relieves the system processor of the requirement of computing and outputting incremental positioning data for each step of the ADM's resolution (i.e., 0.001").

The controller can be interfaced to the system processor via standard EIA serial interfacing, further simplifying the overall terminal configuration.

The CRT device is of the storage tube variety and is also interfaced to the system via an asynchronous EIA RS 232 interface. It will operate nominally at 9600 baud. It is equipped with a thumbwheel cursor for use in the graphics processing software for digital coordinate input.

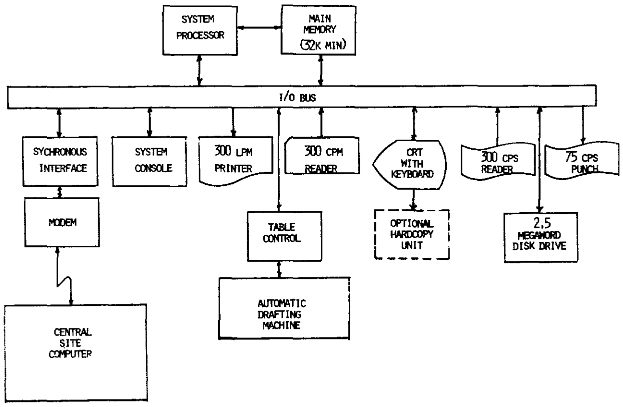

Figure 10—Typical RJE/graphics terminal configuration

The system console may alternatively be a character CRT display or teleprinter device.

Graphics software

As mentioned previously, two distinct modes of operation of the graphics processing system are available. The first, or ESSI verification, mode of operation in addition to producing plots of geometry described by the ESSI data, also checks the ESSI auxiliary function codes (e.g., center torch on/off, rapid traverse on/off, left/right kerf width compensation on/off, etc.) for consistency. In this mode, auxiliary function code annotation is added to the geometry display/plot and errors reported (e.g., both center torch and rapid traverse on concurrently) on the user console.

The second, or drafting mode, ignores all but the center torch auxiliary functions which serve as the pen up/down commands. This mode is of particular value in reviewing ESSI output from the N/C software modules which are not directly concerned with flame cutting. These would include, for example, the AUTOKON FAIR and LANSKI (see the discussion of AUTOKON in this paper) modules which output ESSI representations of hull lines (e.g., bodyplan, buttocks, waterlines, shell plate seams, etc.) and longitudinal structure traces. For these applications, the user may make use of the graphics processor's windowing (or zoom) capabilities to good advantage to examine more closely potential problem areas requiring greater visual definition. Also implemented in the graphics system software are 3-dimensional display and transformation routines to support future applications in the design area.

Capabilities summary

A modular, multi-user RJE/Graphics terminal system for shipyard use has been designed. The system's capabilities (summarized in Figure 11) include RJE communications, for a variety of main-frames, which may be executed concurrently with one or more graphics processing sessions or with various utility programs operating in background mode. The graphics processing software allows interactive view modification at a CRT or a simple batch type mode of operation applicable to both CRT and ADM.

N/C FRAME BENDING MACHINE

The following describes a development effort carried out by Case Western Reserve University which has resulted in the production of a prototype, fully automated frame bending machine.

TABLE I—FRAME BENDER CONTROL ALGORITHM

1. OPERATOR INSERTS BEAM INTO FRAME BENDER
2. OPERATOR CLAMPS TRANSDUCER AT END OF BEAM
3. INPUT THE DESIRED BEAM SHAPE
   A. ESSI model of circular arcs and straight line segments (can be piecewise linear)
   B. From AUTOKON paper tape, teletypewriter, or disk file
   C. ASCII or EIA character codes
4. INPUT THE BEND PARAMETERS
   A. Work length minimum and maximum
   B. Initial unbent length at end of beam
   C. Clamping mode
   D. Tolerances for feed distances and bend angles
5. CALIBRATE TRANSDUCERS WITH A/D CONVERTERS
6. SET UP IDEAL MATHEMATICAL MODEL OF BEAM
   A. Work points are preferred at junctions of ESSI elements
   B. The last work section may overlap the second last one
   C. The tangent vector at each work point is determined from the ESSI model
   D. A table summarizing ideal model of beam can be printed
7. EACH WORK SECTION IS PROCESSED AS FOLLOWS:
   A. Feed beam and adjust moving head to position new work section between the fixed and moving heads
   B. Update model of actual beam to reflect feeding
   C. If necessary, move transducer to new point on beam, find new reference point on model of actual beam, and find corresponding point on ideal model
   D. Calculate (X, Y) aim coordinates for transducer reference point from ideal model
   E. Bend to Y coordinate of aim point, release, and measure springback
   F. Until bend angle tolerance is satisfied (but never more than 2 iterations), recalculate required "overbend" based on springback just observed, bend to new Y coordinate, release, and measure springback
   G. Update model of actual beam to reflect bending of this work section
   H. Feed to X coordinate of original aim point
8. WHEN ENTIRE BEAM IS FINISHED, OPTIONALLY PRINT A TABLE SUMMARIZING THE MODEL OF THE ACTUAL BEAM
9. OPTIONALLY PRINT A TABLE COMPARING THE IDEAL MODEL WITH THE MODEL OF THE ACTUAL BEAM

Background

Historically, frame bending in the shipyard has been carried out by one of two methods: hot slabbing, which requires the shape to be furnaced until the material becomes plastic and then forced against a full-sized template through use of a hydraulic ram, or three-point cold form bending, in which the operator of the three-point machine iteratively applies a force on the shape between two fixed support points until the desired curvature has been produced.

Each of these techniques has substantial drawbacks. Both require the production of full-sized templates. The hot slabbing process requires a furnace facility

Figure 11—Shipyard graphics terminal capabilities summary

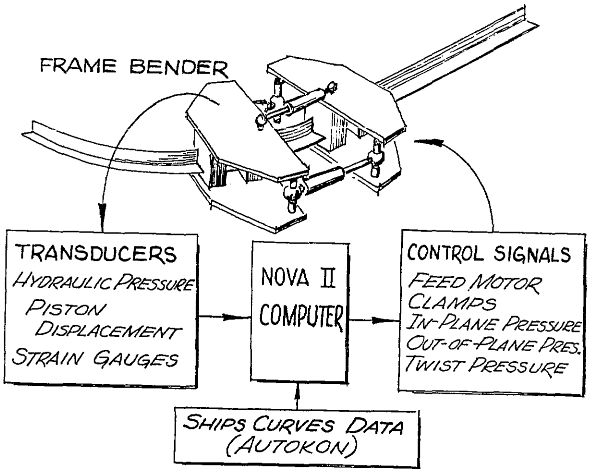

Figure 12—Control loop for automatic frame bender

and is very labor intensive. And the cold bending is slow, requires a skilled machine operator and, most significantly, produces out-of-plane bending, buckling and twisting (i.e., the plane of deformation of the shape and the plane in which the bending moment is applied may not coincide).

The CWRU frame bender represents a unique solution to these problems. The prototype itself is a 1/6 scale version of a full scale device which can accommodate interchangeable dies, automatic clamping, automatic feeding and provision for operation in either a completely autonomous, computer-controlled mode or by manual control.

Mode of operation

Figure 12, reproduced from Reference 2, depicts the control loop involved in directing the machine. Feedback signals from the transducer group are fed through a multiplexed 12-bit A/D converter to the computer (a 32k Nova 2/10). Based on the current and desired frame contour (acquired from the ship structural database, e.g., AUTOKON) the computer calculates the necessary bending to be applied and outputs this data, via a D/A converter, to control hydraulic valves on the machine. This process is an iterative one in which short segments of the frame, called work sections, are processed sequentially. For each work section a target or "aim" point is computed such that cumulative error is minimized. The work section is then bent, taking into consideration the approximate springback of the frame, in an attempt to position a reference point near the original end of the frame on the aim point. If the two points do not coincide after bending and springback, the work section is again bent on the basis of the springback measured after the last bending operation and the deviation of the reference point from the aim point. Throughout this process, for frames with non-symmetrical cross-section, hard wired logic maintains the appropriate in-plane bending through control of a servo valve.

Three separate mathematical representations of the frame are maintained by the minicomputer during the bending process. The first is the ESSI (i.e., N/C contour) model of the frame as retrieved from the AUTOKON database. The "ideal" model is derived from this ESSI model prior to the initiation of bending by segmenting the ESSI elements into work sections (see Figure 13) according to a set of segmentation rules, and computing vectors tangent to the ESSI model data at all work points for alignment of the frame. Finally, the actual model, developed during the bending process, represents the true shape of the frame based on actual curvatures applied and work section lengths fed. From this model, a table of discrepancies can be produced relating the final actual to desired shape.

FUTURE PROGRAMS

Consistent with a broadening of the technical scope of, and shipyard participation in the REAPS Program, is a shift in emphasis in the program's R&D efforts to the development of programs or systems which do not rely on any of the several individual N/C software or other production-oriented systems for applicability. Some examples of projects to be undertaken in the near future are listed below.

1. Structural Detailing System—for definition of stiffener intersection details including N/C descriptions of end-cuts for subsequent use by N/C fabrication equipment.
2. A Low Cost Parts Definition System—for quickly entering or modifying existing part geometries in an interactive mode through use of a minicomputer-based digitizer system.
3. Sheet Metal Template Generation System—for use in developing sheet metal ducting details and subsequent template preparation.
4. Structural Assembly Aids System—for producing parts explosion type drawings of structural units to assist assembly crews in fabricating structural units quickly and accurately.

Such developments it is felt will now and in the future provide U.S. shipbuilders with cost-effective technological problem solutions which will serve to enhance shipbuilding productivity.

Computer analysis and evaluation of marine structures

by DONALD LIU and MATIAS E. WOJNAROWSKI
American Bureau of Shipping
New York, New York

ABSTRACT

The marine industry in general and the American Bureau of Shipping in particular have turned to the extensive use of computers for the solution of the problems encountered in the design, analysis and construction of ships and other marine structures. Mathematical solution techniques have been available for some time, but the complexity of the necessary calculations precluded their use. The advent of electronic digital computers with their powerful, constantly expanding "number-crunching" capabilities has bridged this gap, leading to the application and further expansion of available techniques.

The most useful and usable tool is the finite element method, which has found widespread use and has been extensively applied for structural, dynamic and thermal analyses of marine structures, ranging from entire vessels to local structural details. Descriptions and examples of such analyses are given in the paper.

Other facets of computer versatility applicable to and used by the industry include conversational programs, naval architecture programs, computer graphics and information retrieval. These subjects are presented and discussed in the paper.

Looking ahead, future trends of computer applications in the industry are mentioned.

INTRODUCTION

The American Bureau of Shipping (ABS) is a ship classification society which performs the primary service of certifying the soundness and seaworthiness of merchant ships and other marine engineering structures. ABS establishes standards known as "Rules"[1] for the design, construction, and periodic survey of vessels. By applying these internationally accepted "Rules", ABS classes ships, that is, assures that ships are fit for their intended service. Classification provides assurance to owners, purchasers, shippers, underwriters, and other interested parties that a particular vessel possesses the structural and mechanical capability for safe performance.

Realizing the power of the computer and its application as a valuable engineering tool for vessel classification services and such fields as naval architecture and structural engineering, the American Bureau of Shipping has been in the forefront of the development and usage of computer programs in the marine industry. As a service organization to the industry, ABS has also adopted a policy of making known to interested parties the methods it employs in computer-related activities. This paper is a small contribution toward that goal.

The complexity of engineering problems encountered in the marine industry has led to extensive and ever-expanding computer usage.[2] In addition to the conventional static and dynamic problems of design, the problems encountered in assessing marine structural response are compounded by the unpredictable nature of sea, and sometimes cargo, loads. Sea conditions represented by wave heights, wave lengths and wind speeds are measured and the information is compiled statistically. Structural design is based on sea conditions with a probability of occurrence of 10^{-8}, which corresponds to an event occurring once during an assumed ship service life of approximately 25 years (20 years at sea). Special phenomena associated with the dynamic interaction of waves and ships at sea must be taken into account. Springing, for example, is a vibration of the complete vessel induced by the wave frequency in conjunction with the ship's elastic properties. Other areas of concern are local vibrations, which may be induced by waves or action of the propeller and drive shafts. Other loading conditions include those due to thermal effects, sloshing of liquid in cargo tanks and sea ice.

Mathematical techniques, such as matrix methods, finite element methods and statistics, have been available for a long time. It has taken the advent of electronic digital computers to make possible the full utilization and implementation of these techniques into an efficient engineering approach to the solution of the numerous problems associated with the design, construction and analysis of ships and other marine structures.

FINITE ELEMENT METHODS

The finite element technique is a relatively new and very useful method for stress analysis of structural continua. The method relies strongly on the matrix formulation of structural analysis introduced mainly as a result of the increasing use of computers. There has been a concurrent and rapid development of electronic computers, matrix methods and finite element techniques.

In the finite element method, a solid continuum is subdivided into an assemblage of discrete elements of finite dimensions.[3] In effect, the real system or structure is modeled by a simplified, idealized system for which a solution is available. The idealized model is then analyzed by one or more of the available methods of analysis.

The finite element technique has a sound theoretical basis within the framework of the classical theory. It may be interpreted as a close relative to the well-known Ritz method, in which the displacement field in a continuum is usually described by means of a sum of preselected functions, each multiplied by a constant. The constants are determined by means of the condition of minimum potential energy.

While in the classical Ritz procedure one set of functions describes the displacement field in the entire continuum, the finite element method assumes individual displacement fields for each of the elements. The internal displacements in the elements are uniquely defined in terms of the nodal point values, and the entire displacement field is assumed to consist of a large number of piecewise continuous fields, each covering the extent of one element. The conditions of equilibrium of the nodes may be shown to yield the displacement field corresponding to minimum potential energy for the selected displacement pattern. As in the Ritz procedure, the solution will generally be approximate, but the method converges toward the correct solution.

Many new developments and refinements are constantly being added to the existing finite element programs. One of the most promising of these extensions, extremely useful in the analysis of complex structures, is the substructuring capability. Substructures are assemblages of basic elements (beams, plates, etc.) which serve as building blocks for the representation of larger, more complex structures. Substructuring decreases the amount of input data required to generate the structure, particularly for repetitive structural arrangements. It also decreases the number of unknowns encountered in the solution of the problem, with a corresponding reduction in computer requirements.

An improved substructuring concept involves the use of the "reduced substructure" technique,[4] in which kinematic constraints are applied on the boundary so as to reduce the number of interaction freedoms. This insures displacement compatibility along the boundaries between adjacent substructures and/or elements.

Some examples of the numerous finite element applications in the marine industry are given in the following sections.

STRUCTURAL ANALYSIS

Discretization is an essential part of the structural analysis problem.[5] In general, discretization introduces approximations into the analysis; for example, a finite element idealization generally involves approximations both of the geometric form of the structure and of the displacements which it develops. The degree of refinement which is employed in the finite element mesh should be based on the analysis requirements, i.e., a fine mesh is needed in regions where the structural behavior is most complex. Moreover, the mesh must be particularly fine if the primary objective of the analysis is stress distribution rather than deflection, because the derivatives of the displacements are represented less accurately than are the displacements themselves when applying the more commonly used displacement method.

The finite element method has been extensively applied to all types of marine structures. The first applications were for the analysis of supertankers (large tankers with deadweight tonnage above 200,000 dwt), as a result of their rapidly increasing size and associated changes in ship configuration.[2] Classification society rules based on previous design and experience were not adequate for these new ships, and considerable structural damage was sustained by some of the earlier supertankers. Computerized structural analyses have provided the means to overcome Rule limitations and to provide the required structural integrity and design efficiency.

Other marine structures such as containerships, ore or bulk carriers, liquefied natural gas (LNG) carriers, submarine structures, surface effect ships, hydrofoils, ice breakers, drilling rigs (fixed and floating), offshore platforms, etc., have been extensively analyzed by computerized methods.

Some examples of these analyses by means of the ABS/DAISY (**D**isplacement **A**utomated **I**ntegrated **SY**stem) program[6] are shown in Figures 1 through 4.

Figure 1 shows the displacements of the deck and the lateral expansion of the front hatches of a container vessel in oblique waves, subject to combined vertical, lateral and torsional loads.[7] Figure 2 shows the extent of a three-dimensional model of an LNG carrier.[8] Figure 3 shows a typical transverse web frame of an oil tanker, its idealization by finite elements, calculated displacements and corresponding stress contours. Figure 4 shows the various design improvements of a shell longitudinal connection to a horizontal oiltight bulkhead girder in a supertanker.[9]

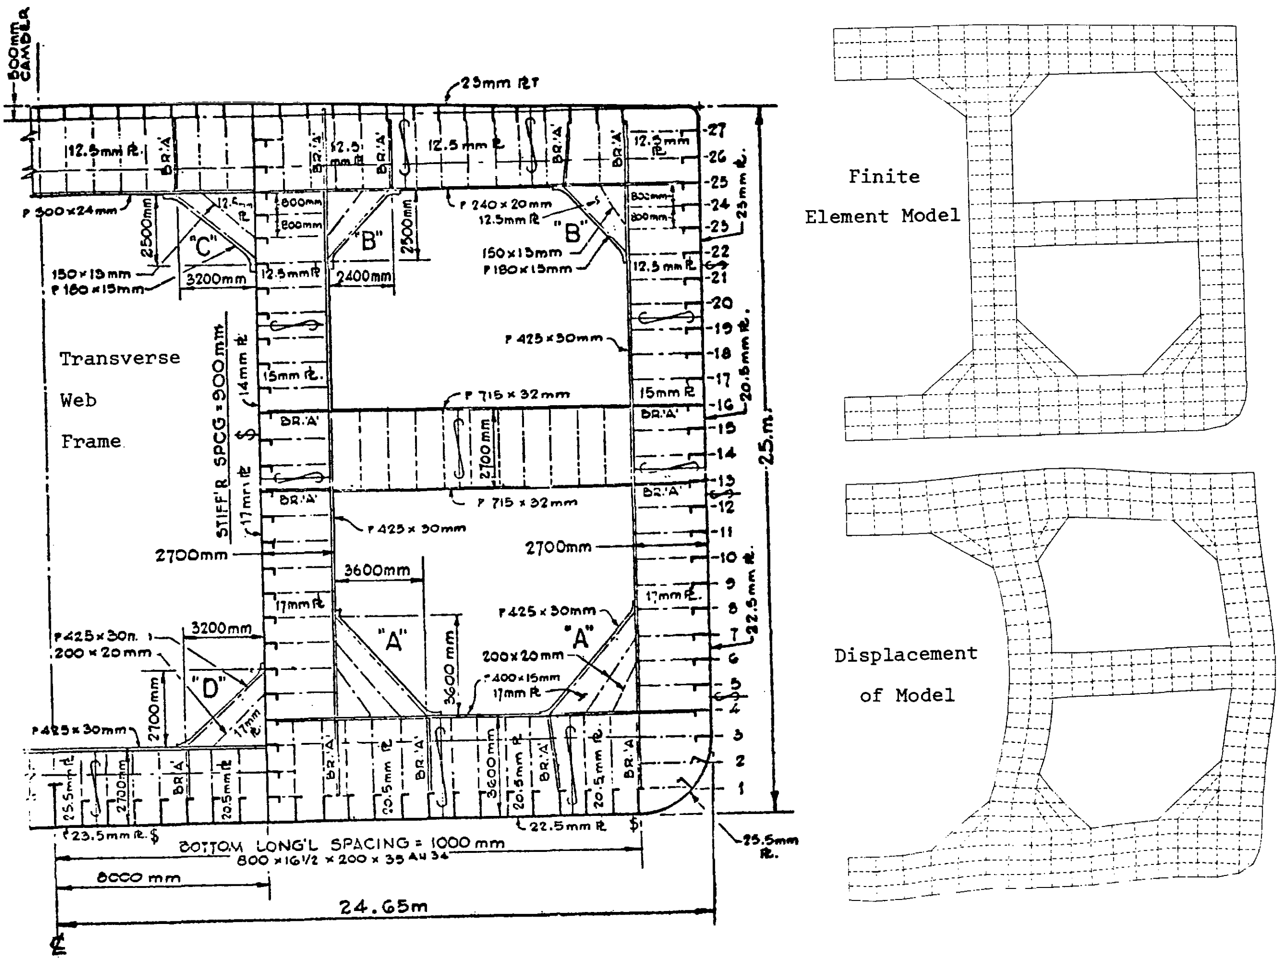

Figure 3—Two-dimensional web frame analysis

STRUCTURAL DYNAMICS

Generally speaking, the concepts of structural dynamics are not new; both mode-superposition procedures and direct time-integration analyses of the equations of motion were well understood many decades ago.[5] However, the finite element method provides a unified approach to discretization which can be applied to completely arbitrary and highly complex structures, and the modern digital computer makes possible the routine solution of the resulting equations of motion, which may involve hundreds or thousands of degrees of freedom evaluated at hundreds of time intervals during the dynamic response. Thus, these new tools make it possible to meet current structural dynamic analysis needs in fields such as the design of offshore oil drilling platforms for wave, wind and earthquake loads, the design of supertankers and other ships for wave loads and other hydrodynamic forces, etc.

Some examples of the application of computerized dynamic analysis are shown in Figures 5 and 6.

Figure 5 shows the idealization of an entire cargo ship for the study of vibrations and slam response by means of the SHVRS (Ship-Hull-Vibration Response System) program.[10] Figure 6 shows an isometric view of the model used for the vibration analysis of a supertanker.[11] The model consists of one-half of the entire vessel, and was plotted with the aid of the SAP IV (Structural Analysis Program) plotting routines.[12] Figure 7 shows the wave-induced, springing and combined bending stresses at the midship section of a Great Lakes ore carrier as a function of the wave frequency. This was calculated and plotted with the aid of dynamic analysis programs being developed at the American Bureau of Shipping.

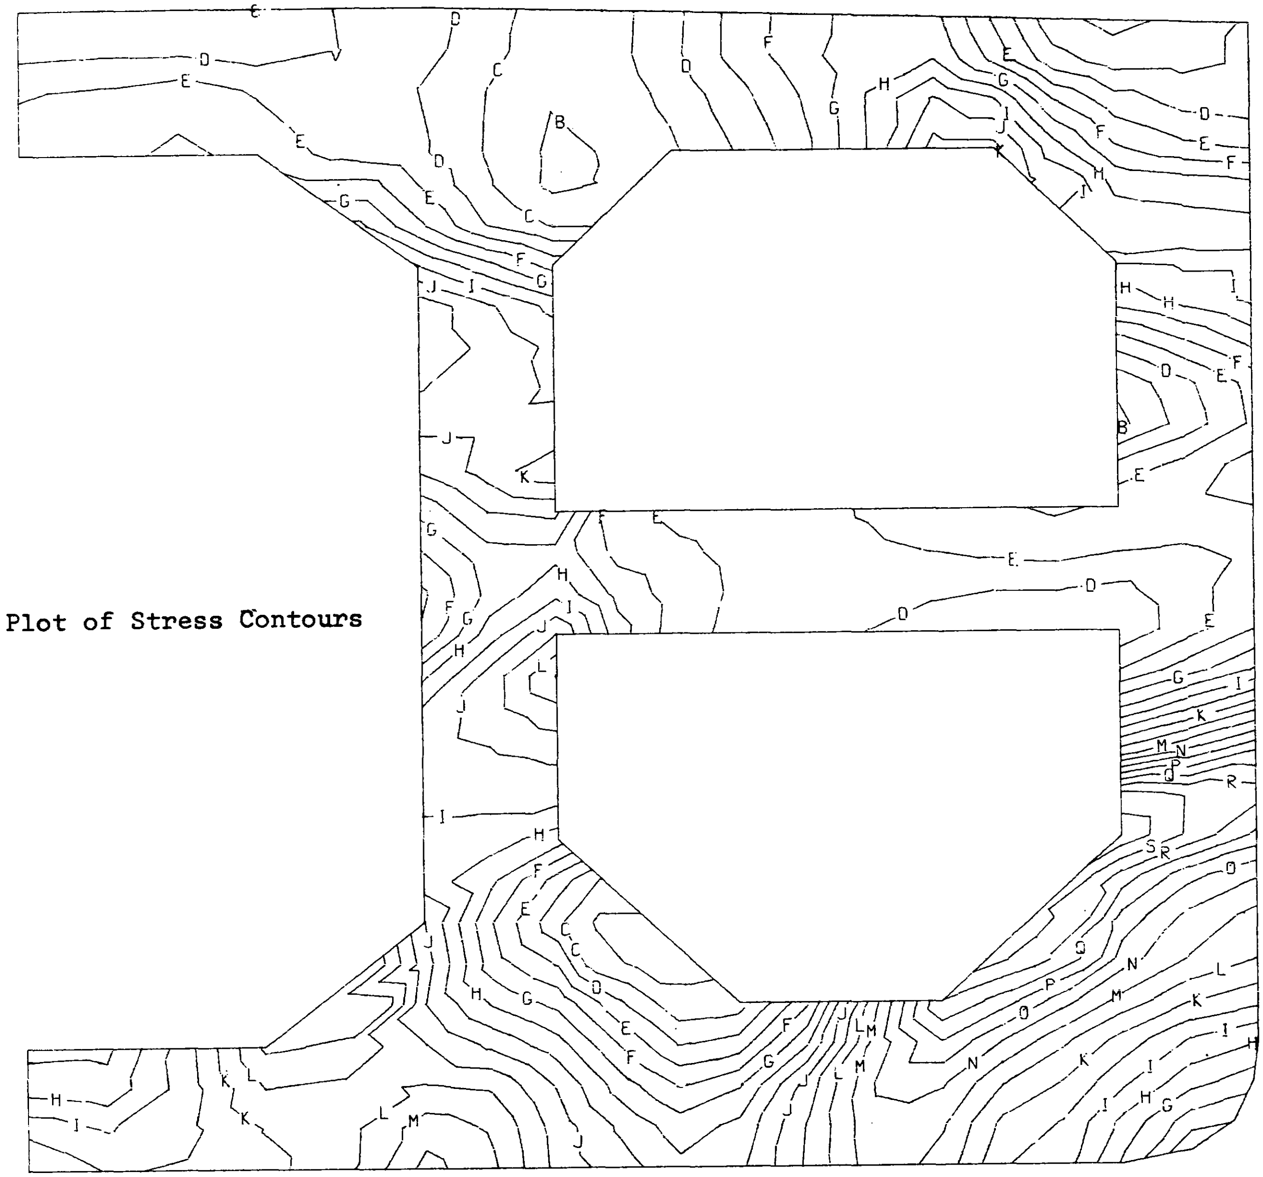

Figure 3 (continued)

THERMAL ANALYSIS

Thermal stresses and deformations are produced by changes in temperature distribution, and high temperatures influence the mechanical properties of a material to a great extent.[13] Ship structural members and machinery parts are often subjected to various kinds of heat treatment, producing thermal stresses which may result in residual deformation. Temperature differentials of cargo and surroundings, as for example in the high temperature range of hot asphalt (300° F.) or in the very low temperature range of LNG (−260° F.) produce high thermal stresses and deformations which must be considered in the overall design and analysis of a vessel. The magnitude of thermal stresses developed in a hull structure is governed by the restraints provided by surrounding structure and by the non-uniform temperature differences in the hull due to the ship's internal and external environment.

The finite element method is a powerful tool to obtain thermal stress distributions and deformation patterns. Some examples of its application are shown in Figures 8 and 9. Figure 8 shows thermal loads and calculated stresses on a typical transverse web frame of an asphalt tanker carrying cargo at temperatures of up to

NAVAL ARCHITECTURE PROGRAMS

Numerous computer programs have been developed over the years to perform various naval architecture calculations such as hull girder shear and bending moment, section modulus, hydrostatic stability and hull characteristics. These calculations all require a description of the hull geometry, usually in the form of offset data. Perhaps the most widely used and comprehensive hull characteristics program is SHCP (Ship Hull Characteristics Program).[16] This program develops both intact and damage stability characteristics for ship forms by conventional methods. Hull girder shear and bending moments can also be calculated. Computer-generated plots can also be produced, such as Figure 10, showing hydrostatic curves, and Figure 11, showing the transverse sections of the hull outline of a vessel.

In addition to comprehensive computer codes such as SHCP, special purpose programs for calculating grain stability, tank ullage, and section modulus are also available to naval architects. As a description of the hull form is a requirement for all of the above calculations, establishment of a common data base for the hull surface geometry is highly desirable.

Computer programs based on the classical naval architecture approach to stability of ship hulls are not easily adaptable to offshore drilling rigs such as the semi-submersible and self-elevating types. These rigs are generally composed of assemblages of tubular sections and/or geometric shapes having planar surfaces. Use of conventional offset data to describe their unusual shapes can be difficult and complicated. To handle drilling rigs, stability computer programs have been developed to perform intact and damage stability calculations for mobile drilling rigs. To overcome difficulties in describing the unusual and multi-connected shapes of these rigs, a typical program such as the ABS-developed DRILRIG[17] contains a library of solid element shapes (cylinders, tetrahedrons, hexahedrons, hemispheres, etc.) which are readily defined with a minimum of data. The user selects the shapes and assembles them so as to represent the compartmentation and geometric configuration of the rig. Stability calculations are then performed by conventional methods.

CONVERSATIONAL PROGRAMS

Conversational programs, which provide for back-and-forth communication between the engineer and the computer, have been successfully applied to obtain ship scantlings (structural properties, such as plate thicknesses and beam sizes) based on classification society rules.

Such a typical computer approach to ship design is the ABS/RULESCANT (**RULE SCANT**lings) systems of time-sharing programs that determine scantlings satisfying the ABS Rule requirements for midship sections of oil, ore or bulk carriers.[18] The input typed by the user at a time-sharing terminal consists of the basic configuration of the vessel, the plate and stiffener sizes and the location and arrangement of structural members. A data base (file) of all the processed ship information is created for use by the many output subprograms which can be individually selected for execution by the user at the terminal.

One of the programs is used to check scantlings of the midship section. The program determines the Rule-required plate thicknesses and stiffener and hull girder section moduli. It also calculates the weight per unit length, and the allowable shear stress and shear force. The formulas used by the program in determining the Rule requirements are also listed, as a matter of information to the user. After viewing the results, the user can dynamically change any of the input, including the given values of the plating and

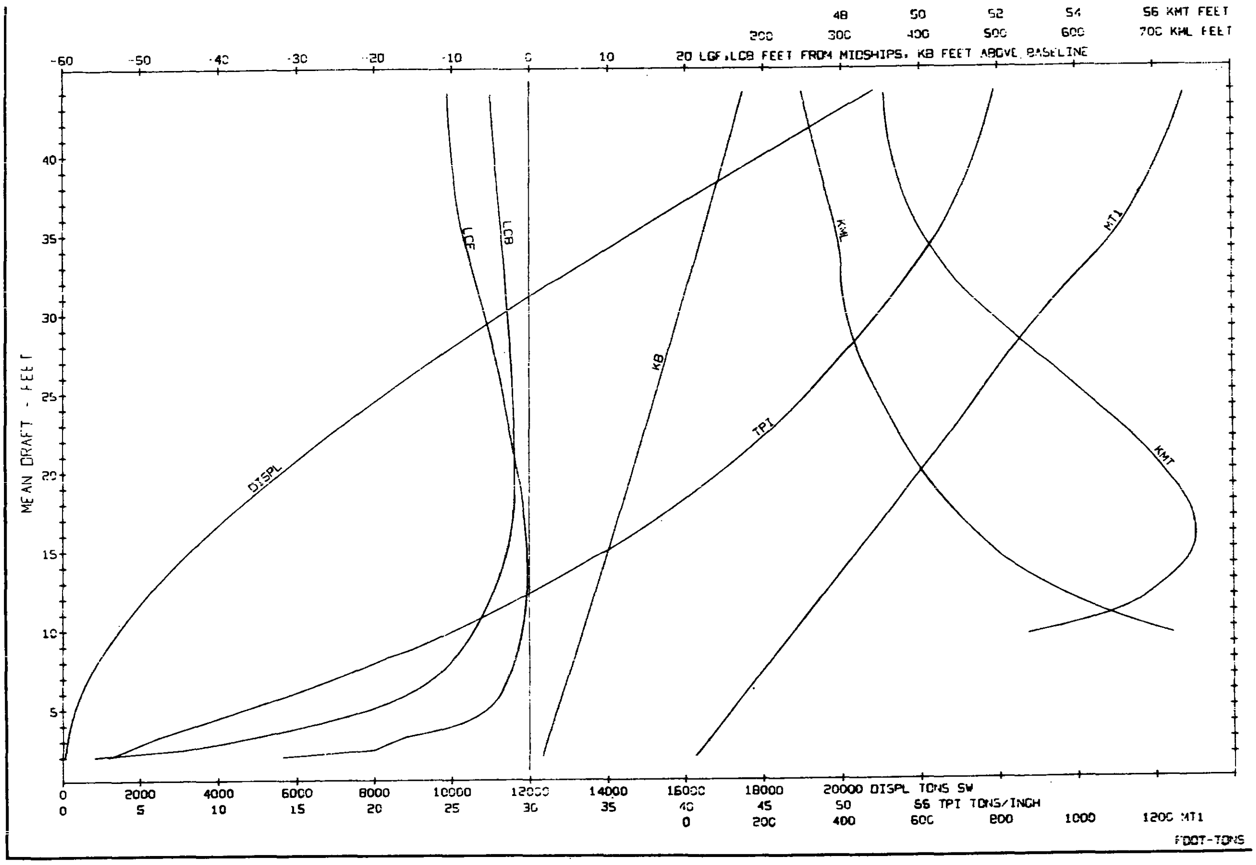

Figure 10—Computer plot of hydrostatic curves

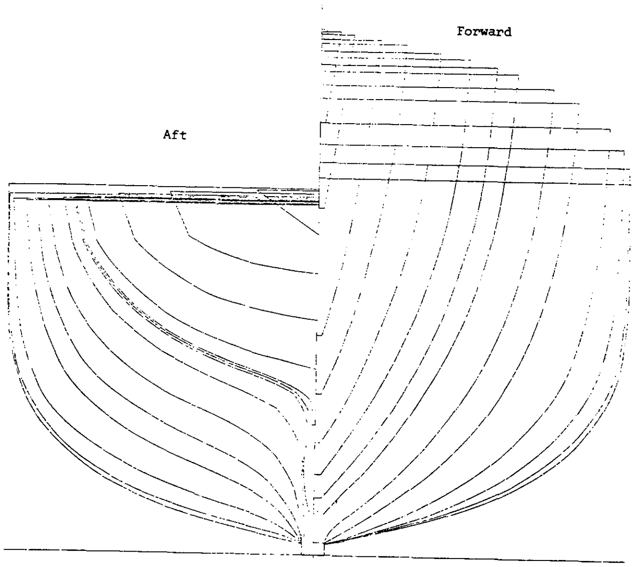

Figure 11—Body plan—Transverse sections of hull outline

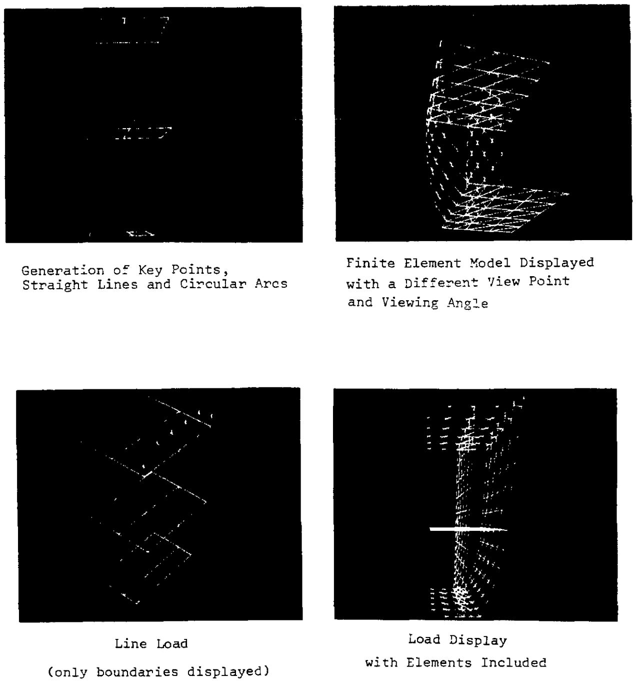
stiffener sizes. Then he can rerun the program while at the terminal and obtain answers within minutes of altering the input.

There is also a preliminary design subprogram, which requires input of only a basic definition of the midship geometry. The program then determines the minimum Rule requirements for the midship section, which can be used for preliminary design purposes.

Many more sections of the Rules will be integrated into a computerized system similar to ABS/RULESCANT.

COMPUTER GRAPHICS

With the improvement of the general purpose structural programs to analyze large and complex structures economically, the need for efficient methods of checking input data and reviewing output results becomes more pressing.[19] The field of computer graphics satisfies this need by producing visualizations of the structural



Generation of Key Points, Straight Lines and Circular Arcs

Finite Element Model Displayed with a Different View Point and Viewing Angle

Line Load (only boundaries displayed)

Load Display with Elements Included

Figure 12—Graphical displays of ship segment

models and stress patterns. The inherent advantages and disadvantages of the two basic methods of computer graphics, passive and interactive, dictate the usefulness and areas of application of each method.

Passive graphic systems include plotters (flatbed, drum, and electrostatic) and microfilm recorders. The nature of these devices precludes user interaction, and therefore they are best suited to applications where a user has time to review the resultant plots before making any changes or going on to the next step. The most popular applications include plots of the geometric model (input) and deflected shapes and stress contours (output). Since turnaround requirements for these applications can usually be measured in hours, the normal operating procedure is to run these jobs in the batch mode on large computer systems and produce tapes which can subsequently run on the plotters.

Most of the large finite element programs have plotting capabilities as part of the basic program or as separate add-on modules. In addition, there are many general purpose plotting programs that can use the output files generated by most finite element programs, although in some cases interface programs must be written. Input geometrical plots (two- and three-dimensional perspective views) and a wide variety of output plots (deflected shapes, force and moment diagrams, stress contours) form the most generally available plot features.

The basic advantage of the passive system is that large amounts of data can be processed economically. The plotter is the only additional equipment needed, and the actual computer runs necessary to generate the plots can be run in the batch mode, with minimal impact on a large computer system. The obvious disadvantage is the lack of interaction. Incremental mode plotters are relatively slow (detailed plots can take many hours), but electrostatic plotters can produce hard copies at rates comparable to most reproducing machines.

Interactive graphics systems consist of display consoles, means of entering and editing data (usually cathode ray tubes, tablets, keyboard devices), and a computer system to maintain the data files and perform the calculations needed to produce the plots.

Interactive systems find their greatest use in design work. The designer is able to communicate with the computer, see the results, and make the necessary changes. The earlier systems required either a totally dedicated medium-sized-computer or a large portion (partition) of the resources of a large computer. In recent years, the availability of time-sharing systems and powerful minicomputers has relaxed these requirements.

The GIFTS (Graphics-oriented Interactive Finite Element Time-Sharing Package) system,[20] designed primarily for ship structures, is one widely used interactive package. The entire system accesses a Unified Data Base (UDB) which stores all pertinent data on a set of random access files. Each individual module can access and operate on the UDB. After the entire model has been verified, part of the UDB forms the input to a general purpose analysis program such as DAISY, NASTRAN (NAsa STRuctural ANalysis),[21] or SAP IV. The output from the analysis program is then incorporated into the UDB and additional modules can display results.

Some of the displays obtained during the various phases of the analysis of a vessel are shown in Figure 12.

INFORMATION RETRIEVAL SYSTEMS

The service experience of vessels at sea provides a wealth of data to evaluate ships. Information on occurrences of structural and mechanical damage and failures must be collected and statistically analyzed. Subsequent feedback of this information will enable shipbuilders and designers to incorporate this knowledge into future improvements in design, construction and analysis techniques. The only means to efficiently handle the vast amounts of data involved is through information handling systems.

A comprehensive computerized system for information storage, correlation and retrieval has been implemented at ABS. This system, known as ABSIRS (American Bureau of Shipping Information Retrieval System)[22] handles data concerning shipowners, shipbuilders, ship characteristics, service histories and other pertinent data relevant to merchant vessels of the world. ABS uses its vast stores of information and worldwide telecommunication facilities to provide easy and rapid accessibility to the industry.

The ABSIRS system consists of seven files, whose functions can be summarized as follows:

Master File is the nucleus of ABSIRS. It contains all the data in the published RECORD of the American Bureau of Shipping,[23] a ship registry that contains pertinent characteristics of more than 42,000 vessels—virtually all sizeable vessels in existence—including the more than 13,000 vessels that have been classed by ABS.

Technical Notes File contains service data limited to statistical compilations and correlations of damages or casualties in vessels classed with ABS since 1965. Hull or machinery failures that are considered significant are entered in the file, i.e., those failures that may eventually show a recurring problem and thereby prompt Rules changes or revisions in existing construction techniques. The File contains a brief description of hull damages according to type (buckling, welding, cracks, corrosion, etc.).

Construction File stores additional information on vessels of ABS classification, including particulars on characteristics of hull construction and materials and machinery items and associated components.

Dead File stores data on ships that have ended service life. The recorded data passes from the Master File to the Dead File, insuring a preservation of the vessel's history.

On-Order File carries data on vessels in excess of 1,000 gross tons that are either being constructed or are under contract to be built in shipyards around the world.

Owners File is a record of the names and addresses of owners, agents, and operators of ABS-classed vessels appearing in the RECORD of the American Bureau of Shipping.

Shipbuilding and Drydock File lists the names, locations, capacities, and descriptions of shipbuilding, drydock, and repair facilities available throughout the world.

Each file can be searched separately and there is a multi-file capability that allows the information within each file to be cross-correlated with data in any other file or files. Inquiries may be based upon any category stored in the computer, and many report formats are available to suit the user's needs.

CONCLUSIONS

Computer usage in the marine industry is extensive, diversified and expanding. It combines the use of mathematical techniques with the latest technical facilities of computers, software, hardware and communication with the user.

The developments of computer analysis in the industry point to the following future trends:

1. More intelligent use of the computer as an engineering tool will result in more economical analysis methods. For example, advanced techniques such as substructuring will find increased applications in the design and analysis of ship structures.
2. Increased use of computer graphics display terminals will facilitate the automatic generation and verification of the large amounts of data necessary to create an extensive finite element model.
3. Engineering analysis programs will acquire a more interdisciplinary character. For example, the hydrodynamic forces acting on a ship will be calculated by the same computer program that determines the resulting structural response.
4. More interactive programs emphasizing user-computer interaction will result in a greater variety of applications among a wider spectrum of users.

Evolution of automation in terminal air traffic control

by HOWARD R. McGLAUFLIN
Federal Aviation Administration
Burlington, Massachusetts

ABSTRACT

The Evolution of Automation In Terminal Air Traffic Control was written to provide the reader with an overview of the why, when and how of the needs of air traffic controllers in the terminal. This paper compares systems and a decision to award contracts. This paper contains a description of the subsystems used at ARTS III facilities and its capability for expansion. Attachments to this paper show a radar display, an ARTS III display, a system design and a work flow-through design, basically how it works.

The intention of this paper is to provide an overview of the evolutionary process of system automation in the Terminal Air Traffic Control environment, and provide a look at the basic flow of data through the existing system.

To do his job in the 1920's, the controller had only to wave a green or red flag; in the 1930's he operated a radio in a control tower; in the 1940's he had to learn to operate a radar set; and now he must start learning to communicate through a computer.

The need for some degree of automation to assist controllers in Terminal Air Traffic Control has been apparent for some time. Air Traffic volume has been increasing and is forecasted to increase so that many terminals will be taxed to capacity. Delays at the busiest airports are frequent, and all too often, lengthy.

The formal initiation of plans to develop an automated system for terminal traffic control occurred in March 1961, when the Project Task Force was established. The result was the Project Beacon Report, which was submitted to the FAA (Federal Aviation Administration) and then to President Kennedy in September of 1961. One significant recommendation of this report was, "utilization of general purpose digital computers to provide controllers with aircraft position information."[1]

Subsequently, the FAA's System Design Team was established to fulfill the requirements of the Project Beacon Report; a functional specification for an experimental model of an automated radar terminal system that could be used for appraisal of the concepts in a field environment was developed. In 1963, the FAA awarded a contract to Univac to provide the computers, software, and system integration efforts for the establishment of this model known as Advanced Radar Tracking System I, in the Atlanta, Georgia, terminal. After field testing, this system was implemented and has been in use since 1966. Basically, Advanced Radar Tracking System I, utilizes a general purpose digital computer together with video digitizers and displays to increase the radar and beacon video on a controller's console. It does so by the display of alphanumeric aircraft identity and altitude information which is automatically associated with the proper video returns.

The next activity involving terminal air traffic control was the implementation of an automation system in the New York Common Instrument Flight Rule Room. This room was implemented in 1968, located at Kennedy Airport in New York City, and permits the individual airspaces over Kennedy, LaGuardia, and Newark Airports to be combined into a single operation by utilization of computer assistance. This system is called Advanced Radar Tracking System IA, "this system differs from the Advanced Radar Tracking System I in that it uses two separate, non-collocated radar and beacon inputs."[2]

In 1969, the FAA arranged for implementation and demonstration of a terminal automation system suitable for medium traffic load in Knoxville, Tennessee. The purpose was to demonstrate that a small, stored program computer offers more flexibility and capability than special purpose calculating devices, which had been devised for the detection and display functions at smaller installations. After these hardware implementations were carried out, in December of 1969, a committee was organized by the Department of Transportation (commonly called the 1980 Committee) Air Traffic Control Advisory Committee whose duty it was to project air traffic requirements until the 1980 and 1990 time frame. This Committee report was released and is now being used as guidelines for automation development and enhancement. One major recommendation of the 1980 committee's report affecting terminal automation was, "The addition of more capability to the terminal automation system in order to provide such functions as command and control sequencing, conflict detection, and collision avoidance, and other functions which can increase safety or maximize terminal system aircraft acceptance rate."[3]

Based on experience gained from the operation of ARTS I and IA, as well as continuing analysis of the present and projected air traffic situation, the FAA developed a design for an improved air traffic control system. The Advanced Radar Tracking System III, ARTS III, was designed to simplify the acquisition and maintenance of radar identification, display beacon derived altitude data, simplify intrafacility and interfacility coordination procedures and reduce the communications workload. (See Attachment #1) The result is a more efficient utilization of terminal airspace and air traffic control personnel and an enhanced safety system. The ARTS III system is now being implemented at 62 major air terminals, and at the FAA Academy in Oklahoma. It is intended to be a first step for many in terminal automation of air traffic control and to provide an automation basis on which to build. In order to provide the capability for growth of system functions at the same pace with increased requirements and resultant developments, ARTS III was additionally designed to be built with a modular expandable concept. Because software is, of its own nature, modular expandable when using the executive program/sub-program hierarchy, and also dependent on the hardware modularity, the primary design considerations were related to the hardware. Being an add-on system, basically, the major sub-systems were added to the existing terminal area equipment: Data Acquisition Subsystem (DAS), Data Processing System (DPS), Data Entry and Display Subsystem (DEDS).

The following is a description of the three subsystems used in the ARTS III system:

(1) The ARTS III DAS, which will accept inputs from a variety of airport surveillance radars and beacon interrogators which consist of the azimuth, range and timing group, the beacon reply group, and the azimuth pulse generator. The azimuth, range and timing group generates all the basic timing pulses for use by the DAS. The beacon reply group detects and interprets the beacon video signals; the azimuth pulse generator, physically mounted to the radar pedestal, converts radar antenna position to digital position data.

(2) The DPS consists of the data processor (IOP) and its peripheral equipment, as well as the operational computer program. (See Attachment #3) The IOP receives digitalized beacon target report messages from the DAS. It also receives flight plan data from a computer in the enroute center via the ICA. The IOP also receives controller-initiated messages from the DEDS. The IOP provides the system with a capability for arithmetic computation, logical decision making, data processing, and overall system coordination. Operation of the IOP is controlled by a stored program located in the memory bank with each major processing task organized into a sub-program. The IOP then employs an executive control sub-program that without performing any processing tasks itself, serves to control the execution as needed, rather than in fixed sequence. The task selected depends upon an assigned priority scheme that adapts to changes in the system processing load and permits the processor to respond to simultaneous external demands. Some tasks are executed on the basis of a fixed time interval, while others depend upon the completion of prerequisite processing of external events. The IOP provides control of overall communications between the DAS, the DEDS, and the peripheral equipment via high speed digital input/output channels.

The basic DPS includes peripheral equipment commonly found in a data processing application:

(1) A magnetic tape unit provides permanent storage for the computer programs, and is used to load the programs into computer memory. In addition, selected data obtained during system operation may be recorded on magnetic tape for future processing and analysis.

(2) An input/output console containing a low speed printer, typewriter and keyboard, and paper tape facilities is provided for controller communications with the IOP. This console is used off-line to enter variable parameters required by the system and is used as a back-up device to load programs when the magnetic tape unit is unavailable. It also provides on-line printout capabilities for various sub-programs. The hard copy may provide alarm, recording on requested functions. Alarm printouts result from program-detected malfunctions in hardware and errors in input.

(3) The DEDS consists of a common equipment assembly, display consoles, and data entry sets. The DEDS provide the man-machine interface between the air traffic controllers and the automation equipment.

Since the ARTS III system has been in operation at Chicago O'Hare Field since May of 1971, many questions have arisen and one point has been made very clear, "the automation applications made to date in the air traffic control system do not seem to have increased the capacity and productivity of the system, even though there are some indications of increased safety and relief in the workload of the controller."[4]

This paper has attempted to provide an overview of the evolutionary process of system automation in the Terminal Air Traffic Control environment.

ABSTRACT

The Marine Air Traffic Control and Landing System (MATCALS), being implemented by the Naval Electronic Systems Command, provides advanced capabilities for fully automatic all-weather landing. Using radar-derived aircraft position reports, a ground computer provides appropriate guidance commands, which are transmitted to the aircraft's autopilot, and used to fly the aircraft automatically to touchdown.

Due to severe system requirements of one-half minute landing intervals, and six aircraft simultaneously on final approach, a unique combination of display presentation and operator interaction techniques must be used. These support ground operators who as controllers are responsible for initialization of each landing sequence, monitoring its progress, and aborting the sequence if an unsafe condition develops.

A display concept has been developed for MATCALS with the goal of reducing the controller's workload and increasing his effectiveness. The display is used as a single working surface for both output and input functions. A dynamic, graphical display format presentation, with alphanumeric annotation, and alert information is displayed for the operator in multiple colors. More than 150 system controls are organized on the same display as a highly structured hierarchy of virtual control buttons grouped into menus. The operator is prompted through all data entry and control sequences. All operator entry is made by using a "Rand" type data tablet.

MATCALS OVERVIEW

A simplified block diagram of MATCALS is shown in Figure 1. MATCALS is organized into three main system segments: the Air Traffic Control Segment, the All-Weather Landing Segment, and the Control and Central Segment.

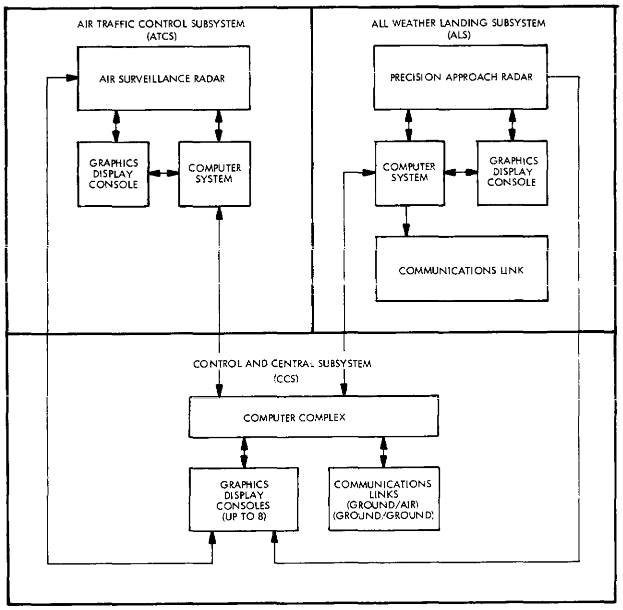

Figure 1—MATCALS system overview

The system normally operates from the Control and Central Segment which receives information from the two other segments. The Air Traffic Control Segment provides automated surveillance and traffic control within 60 miles of the airfield. Specifically, MATCALS provides for surveillance, identification, tracking, sequencing, vectoring, and inter-facility coordination for all approach, departure and overflight operations within the terminal area.

The MATCALS Landing Segment provides for fully manual to fully automatic landings. The sensor for

* The comments made herein are those solely of the authors since they pertain to early research and development and do not necessarily represent exact Government or technical requirements of the United States Marine Corps and the Naval Electronic Systems Command.

the landing segment is the AN/TPN-22 radar system shown in Figure 2. This precision approach radar provides the necessary positional reports with sufficient accuracy for automatic landings.

Three modes of landing are available to an aircraft. In Mode 1, ground derived steering commands are transmitted over a data link and directly introduced into the aircraft autopilot.

Under Model I, the system is able to transmit course deviations to any cross pointer equipped aircraft via a variety of data links. Specific up-links which have been implemented include pseudo-ILS signals receivable on standard airborne ILS equipment and side-band coded signals on a UHF voice channel. Pseudo-MLS signals receivable on the planned standard MLS airborne subsystems will be implemented later.[1]

In Mode III, ground derived approach course deviations are displayed to the landing controller who verbally transmits the landing correction commands to the pilot. The Landing Segment also provides for maintaining inter-aircraft separation minimums, monitors the approaching aircraft for acceptable positioning within defined boundaries, and provides for automatically aborting unsafe landing sequences.

CONTROLLER DISPLAY DESIGN OBJECTIVES

Emphasis has been placed on the selection of the computer graphics display formats and the type of operator interaction mechanisms which will support the MATCALS Landing System display requirements.

The display system must provide for the monitoring and control of up to six simultaneously landing aircraft. Inherent in the concept is the facility for controllers to assume responsibility for additional aircraft control in the event of failure of other display consoles. The overall objective is reduction of controller's workload and increase of landing safety in a multiple landing aircraft environment. A number of assumptions were made and desirable features were identified concerning characteristics of operator abilities, the varying difficulty of the operator's task during downgraded conditions due to hardware failures and reduced manning support, and the operational mission of the MATCALS production system.

It is first assumed that the console users in general will have little or no computer training. It is therefore unrealistic to impose any unnatural input techniques or display format output techniques. The operator/computer interface has to be as natural as possible and tailored to his conception of the landing operation—not just to simplify computer requirements. Ideally, representation of data or conditions should be done pictorially using a situation display type of abstraction. Auxiliary information may be presented alphanumerically to reinforce the pictorial representation. This auxiliary data assists the operator with his evaluation of the present operational situation. It is felt that graphical presentations lend themselves to rapid qualitative operator evaluation of global relationships of the data, while alphanumeric data presentations amplify and quantify the details of the landing situation. Both types of presentation (viewed as hierarchy of information) are necessary, and are most desirable if presented simultaneously on the same display surface.

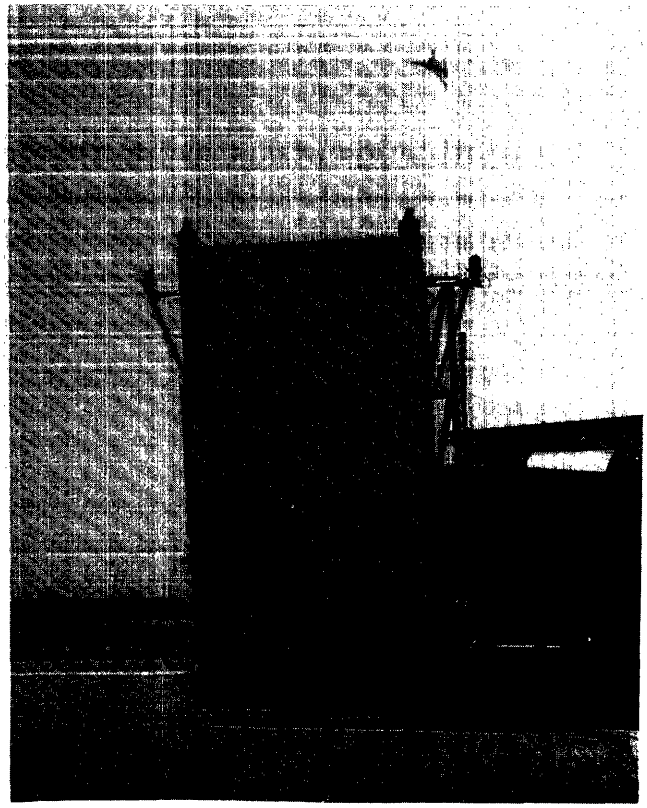

Figure 2—AN/TPN-22 precision approach radar system

The parallel presentation of pictorial (graphical) and tabular (alphanumeric) information simplifies not only the learning of the system but reduces the reaction time during critical and alert periods of system operation. The operator should not be required to divert his eyes to other presentation panels in order to make decisions, instead he should have available on a single display surface all pertinent information within his field of view. This allows him to assess the situation and make a corrective decision.

The complexity of the display format must be kept at a minimum. The state of the landing mission environment is presented as directly as possible. Information should be non-redundantly presented to the operator to assist and not hinder his evaluation of the situation.

All input mechanisms should be as direct as possible. Operator input should not be alphanumeric in nature (which is harder to understand being another level of abstraction). The MATCALS operational environment cannot tolerate lengthy input sequences such as from a physical A/N or function keyboard. Inputs instead should be implemented by operator selection of commands and controls from a list of alternatives presented on the display. This list must contain the complete set of controls for system operation. The range of his possible input responses to the output data may be limited by the computer system to those which are correct for that instance of time. The computer therefore guides the operator through entry sequences and prompts him as necessary for correct sequences of data entry. Menu groups of virtual control buttons are organized as a hierarchy into a tree. The operator progresses through the branches of the tree for all control and data entry functions. At any point in time, the interaction sequence is clear to the operator. In addition, the interaction method of implementation should be flexible to system enhancements.

Both output and input functions are performed through a single display working surface. All input controls are immediately adjacent to the output information from which a control decision must be made. Also, input controls are immediately available for operator actions. This varies from the conventional approach in that it eliminates additional hardware control panels and switches which add to the system complexity. The operator does not have to divert his attention from the single working surface display to search and locate other hardware controls.

Finally, the display must be responsive to operator requests. This requirement is satisfied by a careful design of both the hardware and software system. The level of responsiveness may vary, however, with the operator's evaluation of the complexity and importance of the requested service. As an example, the execution of a command to abort a landing sequence (a wave-off) should be immediately serviced and feedback acknowledging the action returned to the operator in a fraction of a second. Conversely, the request for a change of the display scale range may be delayed for several seconds with little operator dissatisfaction.

SYSTEM CONFIGURATION

Figure 3 is a simplified block diagram of the MATCALS System at Patuxent River, Maryland showing major hardware devices. The system is configured around a Univac AN/UYK-7 general purpose computer with 48K words of memory (32 bit words, 1.5 μs cycle time). The AN/UYK-7 is a medium scale, single accumulator machine which has floating point hardware and four independent data channels. Software for the AN/UYK-7 computer was developed in the CMS-2 language operating under an executive configured from the Common Program.

The central computer receives aircraft position from the precision approach radar, an ITT Gilfillan AN/TPN-22 radar with a nominal coverage of 10 miles in range, 46° in azimuth, and 8° in elevation. The radar system itself contains a minicomputer and provides stand-alone capability for Modes II and III landings in the event of a failure of the central system.

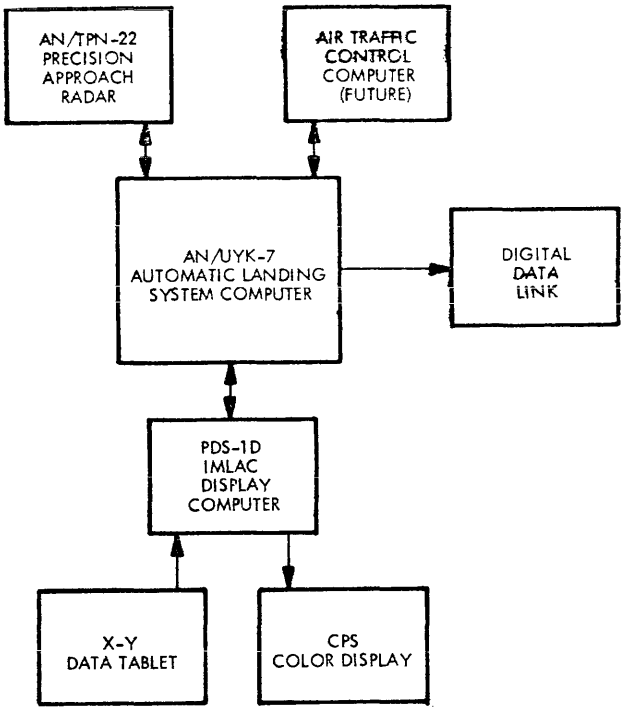

Figure 3—MATCALS landing system test bed configuration

The AN/UYK-7 computer calculates the flight path corrections and transmits the results to the aircraft via the digital data link. These corrections take the form of pitch and bank commands which are fed directly to the aircraft's control surfaces.

The IMLAC display computer with its associated CPS-8001 color slave display console and Computek data tablet constitutes the primary interface between the operator and the landing system. The IMLAC computer is a single accumulator machine with 16 bit words, 16K memory, 1.8 μs cycle time. The data tablet is utilized as the main interaction device. Unlike the conventional trackball, joystick, and lightpen, constant monitoring of the device by the computer cursor tracking calculation is unnecessary. There is no loss of track problem as with light pens, no wrap around problem as with trackballs, and no slow positioning as with trackballs and joysticks. Both functions of positioning and selection are provided by the stylus and tablet combination.

The division of responsibility between the central landing computer and the remote display computer was designed to

(1) reduce loading on a saturated AN/UYK-7 computer

(2) minimize the message transfer rate between the AN/UYK-7 and IMLAC computers
(3) provide for functionally partitioning display/interaction tasks from the landing guidance computer to allow easy extension for future multiple display support.

DISPLAY DESIGN

Design features

Based on the design objectives of the previous section, techniques were introduced which reduced the complexity of the display, assisted the operator in his interaction with the system, eliminated keyboard entries, and increased operator acceptance of the display format. These features were added without any degradation to the basic system requirements. The operational requirements for the MATCALS mission state that up to six aircraft may be simultaneously on final approach. The design therefore, has been predicated on a combination of display output and input techniques to allow the monitoring of the maximum number of aircraft by one operator, and a desired attainment of the control of six Mode I landing aircraft by a single operator.

Although it is doubtful that the single operator situation is desirable (with probably one operator for each two aircraft on a final approach being optimum), it is still mandatory that an operator have cognizance of all other aircraft on approach for safety reasons. The relationships of the aircraft under his control with those of other controllers must be continually monitored. In addition, it may also be postulated that due to hardware failures of other display consoles (and computer sections), or insufficient console manning resources, it is necessary that each operator can assume responsibility for more aircraft than is usual. This type of inherited fail-safe protection is a spin-off of the six aircraft status display requirement. The design of the MATCALS landing display format was therefore made with the assumption that data for all six aircraft on final approach be simultaneously presented, and that any individual operator can assume control of any or all aircraft.

Obviously this specification places an inordinate burden on the operator if conventional display and hardware techniques are utilized. Figure 4a depicts a conventional display which is used in the landing of a single aircraft. One could imagine the complexity of the hardware control panel if it were expanded to allow the landing of six aircraft. A system of this complexity would deluge the operator with controls, displays, and possible operational input combinations and confusing input sequences. On the other hand, Figure 4b shows the display hardware used in the MATCALS system to land six aircraft with just the single display surface and the tablet.

Display format design philosophy

The simpler hardware is possible due to the implementation of techniques wherein the computer organizes the type and format of data graphically or tabularly presented to the operator. The operator executes all data entry and request sequences to display auxiliary information, monitors the operation of the radar and computer hardware and software, analyzes and observes landing sequences, and is notified of any abnormal alert or danger conditions.

Four distinct types of information are presented on the display CRT face (Figure 5):

Graphical—Presentations with amplifying alphanumeric information
Tabular Parameter Data
Alerts and Status Information
"Virtual" Pushbutton Menus

Up to now, situation data of radar video presentations have been the conventional and common method of information presentation in aircraft control and aircraft landing display systems. To clarify the data on the screen, graphical and pictorial information has been added in some cases, often annotated by limited amounts of alphanumeric information (such as tracking data blocks for air traffic control systems).

The display format implemented for the MATCALS effort extends these concepts. In addition to graphical information, critical landing system parameters are presented grouped as tabular listings of alphanumeric data. Alert messages of hardware or software malfunctions and/or landing system safety irregularities are presented as necessary along with system status information as requested by the operator. Instead of hundreds of hardware control buttons continually being allocated space on a panel, the computer dynamically presents "virtual" control button panels which are displayed on the face of the CRT only when they are necessary and removes the panels when their use is no longer required. For example, it is necessary to have the controls which initialize various parameters to define an impending landing sequence (such as entering aircraft type and aircraft tail number) only at specific time intervals during the landing sequence. At other times these controls are extraneous. The display to be implemented as part of MATCALS utilizes this technique of control panel variability to simplify input operations and to reduce display format complexity.

The MATCALS Display presents all system status and controls in a single basic display format to the operator. Extending this concept to overlay the display graphical situation data with background air-search radar or precision approach radar video is practical using time compression display techniques. Whereas older conventional displays commonly used round CRT's, the MATCALS display organization, using multiple output data types, calls for a rectangular display

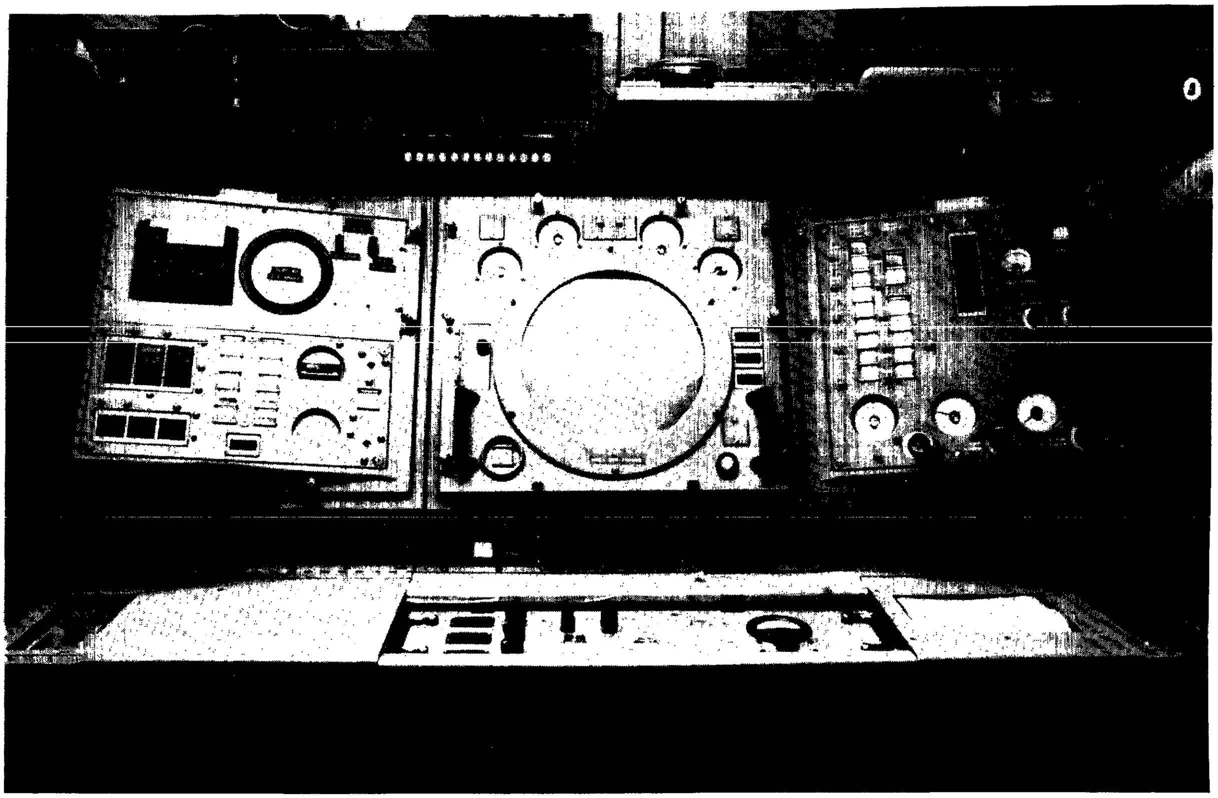

Figure 4—Evolution of landing controller operational consoles

Figure 5—Display format areas

format (21 inches is sufficient). The use of a round CRT compromises the optimum positioning of the tabular parameter, alert messages, status data, and virtual control buttons. Air traffic control displays which use round CRT's often place short tabular preview lists in portions of the situation surveillance area—and thereby obscure and mask possibly important data.

CODING MODALITIES

A number of coding approaches are being utilized in the MATCALS display format and interaction sequence. The modalities of color, intensity, line type (dot-dash), shape, blinking, and sound have been used to increase the range of coding dimensions, simplify the display format, and attract attention to specific information on the screen (Figure 6).

Burdick[2] has published the number of identifiable coding levels associated with these modalities:

Modality	*Coding Levels*
Color	3-10
Intensity	2-4
Shape (abstract)	8-16
Flicker (Blinking)	2-4
Line Type (dot, dash)	3-4

These modalities allow additional data to be displayed and absorbed by each operator so as to minimize the number of consoles and operators.

Color

The most intriguing modality, color is provided by the use of a slave beam penetration tube display, connected to the IMLAC. Assignment of display entities to the displayed four colors is as follows:

GREEN	*All background information,* parameter tables, time, wind, axes and labels, status, and control pushbutton menus.
YELLOW	*Aircraft and higher priority entities,* wave-off buttons (turns red when confirm is required), acquisition gate.
ORANGE	*Entities higher in importance than above,* aircraft symbols and tracking alphanumeric data blocks, glideslope vector.
RED	*Alert or Danger Indicators,* wave-off button confirmation, alert messages, symbols of aircraft in unsafe situations.

	Color Slave Monitor	Color Slave Monitor & Imlac Monochrome Display		
Item	Color	Intensity	Line Type	Blink/Flicker
Background	GRN			
A/C Parameter Table		Med		
Axes		Low		
Input Menus		Med		
System Parameter Readouts		Low		
Wave Off Buttons	YEL	Med		
Glide Slope	ORN			
AZ-EL Glide Slope		Low		
Aircraft		Med		
Acquisition Gate	YEL	Med	Dash	
Alerts	RED	High		High/Low
Wave Off Confirm Button	RED	High		

Figure 6—Coding modalities

It is recognized that color increases the effectiveness and information content of a display. Search time, selection accuracy, discrimination and counting of classes is minimized by the use of color coding. Color is also used in MATCALS to direct attention to portions of the displayed information base. The increased operator speed and accuracy due to the increased information content, realism and recognition is mandatory for MATCALS.

Intensity

Three intensity levels are being used:

HIGH	Alerts, wave-off confirm (used to draw attention)
LOW	Axes, and other background information (lowers the tendency of the display to be cluttered by low priority data)
NORMAL	all other data

Shape

The aircraft symbols are encoded as six uniquely shaped symbols (triangle, square, circle, half circle, diamond, and inverted triangle). These symbols are displayed on the Az-El surveillance area portion to indicate relative position, and displayed on the wave-off button and parameter list entry rows to allow rapid correlation and association of information by the operator.

Flicker

A combination of color, sound, and flicker was used to present alert messages. Blinking of messages annoys the operator. Red, while attention gathering, forces the operator to divert his eyes even after the message has been sensed. Inspired by Kubrick,[3] the display of a new alert message is initially red with a rapid flicker accompanied by a low pitch buzz sound. It then automatically changes to a silent, steady state red. When the operator first acknowledges the message, the color changes to a less annoying green. Subsequent acknowledgment deletes the message from view. Acknowledgment is accomplished by merely pointing to the message with the tablet pen.

VIRTUAL BUTTON CONCEPT

The graphical equivalent of hardware control buttons is presented on the face of the display. The operator may point to these "virtual" control buttons and the corresponding control function will be executed through the computer software.

For the MATCALS Display Console, a "Rand" X-Y data input tablet is used as the primary input device. The operator holds a stylus over a tablet surface horizontally mounted below and in front of the display CRT. This stylus can be randomly pointed to any position on the tablet surface. The computer system may read the X-Y position of the stylus over the pad (even when the operator holds the stylus some distance above the surface) and generates a cursor symbol (a small cross) on the face of the display. As the stylus is moved, the cursor on the display tracks the operator's hand-held stylus position on the pad as a feedback mechanism. A micro switch in the tip of the stylus is activated when the pen is pressed to the surface of the tablet. Therefore a button "push" is executed by the operator moving the pen to position his cursor over the "virtual" button he desires to push, and depressing the stylus. The operation is analogous to "pushing" a hardware button. This input strategy is very natural and the operator becomes immediately accustomed to its use.

HIERARCHICAL ORGANIZATION OF COMMANDS

The MATCALS Display organizes the operator's data input and system controlling actions into cohesive and logical multileveled groups. Each group consists of a number of menus of displayed virtual control buttons.

The hierarchical ordering of button menus allows the manipulation of commands and information requests. The command groups are ordered into a tree structure of usage and inter-relations. The user traverses branches of the tree (commands) as he progresses through the structure. This model attempts to describe the control relationships identical to the user's conceptual understanding and to guide him through his interaction with the control structure. Normally only classes of important control are displayed. When the user selects a class of commands, the detailed control types of sub-menu commands appears. When the user completes his interaction and use of these commands, he may return back to the higher levels of control types and command classes. The lower level is then automatically removed from the screen. We therefore have dynamic display and removal of command pushbuttons depending upon their syntactic requirement during an entry sequence. Extraneous and unnecessary controls are not continually displayed. A particular button menu is displayed only when its requirement is logically necessary. Any tendency toward a complex, cluttered, and confusing control panel presentation is avoided. The user can always quickly return to a higher command level even before making an actual entry at that level by pushing a "RETURN" button (which is always present). He may also directly return to the top level of the command class menu of virtual buttons when desired. All controller interactions with the system are checked for errors and provide feedback as to the entered quantity or function.

Interaction description

Figure 7 shows a primitive controlling initialization sequence to define an impending landing sequence. When he pushes the button "Select Landing Sequence," a new set of buttons appears. The operator may manually define the glideslope (and be taken down another branch where he enters a numerical value), enter the radar acquisition position, or (as is shown) select the desired Landing Mode. When this is pushed, the menu list allows him to select modes I, II, or III. As there is no computer communication with the landing aircraft in mode III, there is no need to enter a data link address and he is returned to level B and allowed to continue his data entry. If I or II is selected, he is allowed (at D) to enter an octal data link address. If he wishes to do so, a graphical numerical keyboard appears. In sequence, he may point to the desired keyboard buttons and the entered numerical value is accumulated. When he is satisfied with the value, he enters it by pushing the return button.

If no entries are made at a particular level, previously defined default values are assumed and used by the system.

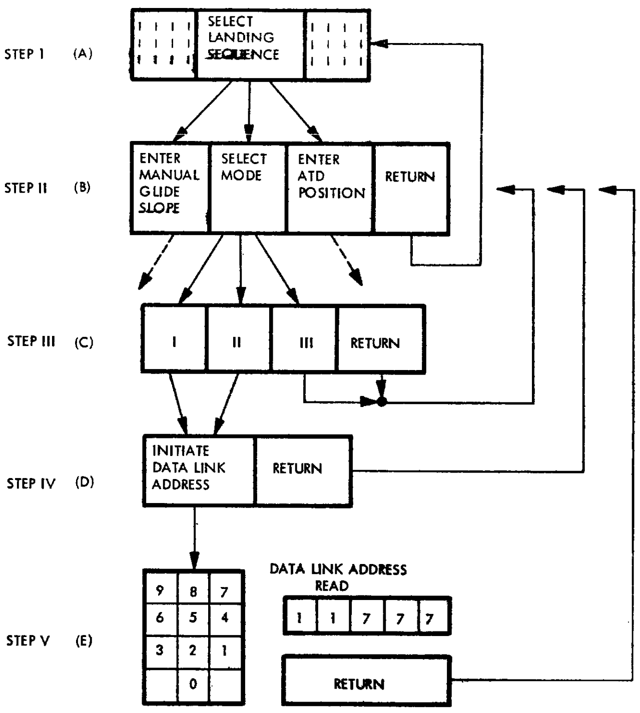

Figure 7—Hierarchical command selection sequence

This approach to computer input takes full advantage of the graphic display and of the human eye's ability to scan rapidly a single menu of commands. The entry rate is higher than by using a multi-function keyboard or array of hardware pushbuttons. The slowness associated with these hardware devices is due to the finite search time required to find the desired button and diversion time of the operator's eyes away from the primary display surface. The user does not have to recall a specific input control response (as with a keyboard) as all allowable responses are displayed. All displayed system status information necessary to make a decision is adjacent to the selection area.

Two different approaches to the ordering of levels must be mentioned. Generally, for initialization of a number of parameters a sequential multileveled ordering is optimum (a tall tree). Each group has a few selection buttons in each level menu. This forces the user to step through all the control initialization options to enter either the required data or to acknowledge that the system default value may be assumed (when he elects to go on in the hierarchy sequence without a data entry). This insures that an operator decision was made on all critical system parameters.

However, for modification of previously entered data, the scheme above would be frustrating to the user if he had to go through all parameters to get to the one he wished to modify. So instead, a shallower short tree of fewer levels is used for this case. However, each level has many buttons in each menu to allow the selection of the entity to be modified in a parallel fashion from a large list.

MATCALS utilizes two distinct multi-level trees:

a. Wave-Off Initiation Buttons
b. System Control and Parameter Input Buttons

The entire tree data structure is shown in Figure 8.

The System Control and Parameter Input Tree is the most complex example of hierarchical interaction with up to 6 levels of menus. Typically, the operator is lower than the third level only for brief times. The controls are grouped into six distinct classes:

a. Landing Channel Definition (aircraft initialization)
b. Landing Procedure Initialization
c. Landing Mode Selection
d. Radar Track Acquisition
e. Systems Controls (data recording and simulation)
f. Display Controls (range scale and other display format selection)

Within these classes are the levels of sets of virtual button menus that control the system or are used to enter system data. There are 2-6 buttons in each menu set. At many stages of data entry, general purpose menus are presented in the general scratch pad area to perform:

a. The entry of numerical values (using a virtual graphical keyboard)
b. The selection of an aircraft track number
c. The selection of a general purpose index

These general purpose menus may be thought of as interaction subroutines which may be used in any place in the control/data entry hierarchy. These graphical interaction subroutines appear only when required.

The use of hierarchically organized dynamic command panel menus in the MATCALS display system provides:

a. insured accessibility to information—fast update, reduced delay time, and improved spatial accessibility (no longer the need to search for that one correct button in a haphazard fashion).
b. increased reliability from the use of software to implement these complex control relations instead of the multi-wire/hardware switch approach.
c. increased flexibility—easier to adapt to required changes in types of controls.
d. increased utilization and efficiency of the control actions—improved vigilance of the observer—increased data input rate for untrained operators.
e. Commands may be tailored to the system understanding and educational level of the user/opera-

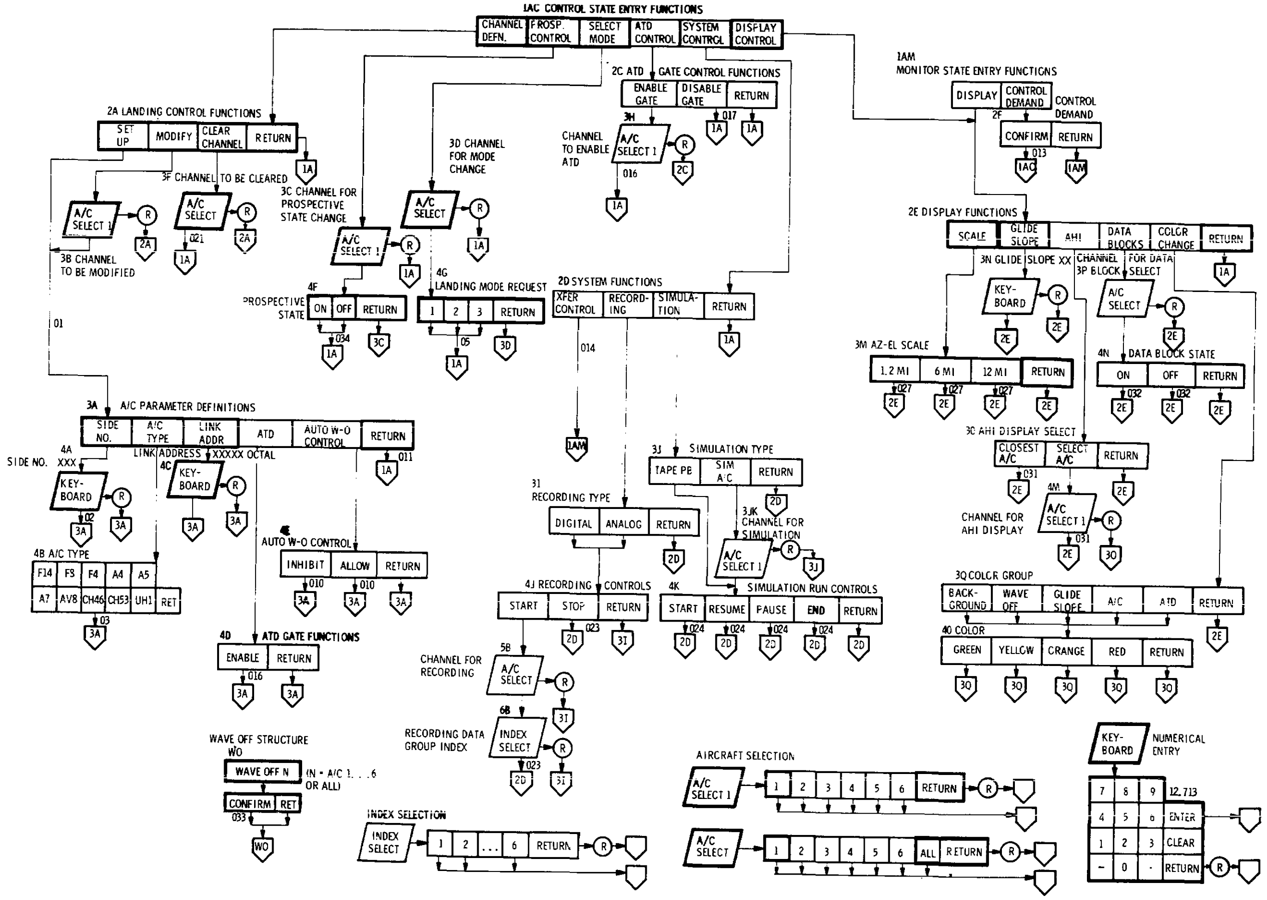

Figure 8—MATCALS interaction tree

tor. The commands are organized to allow the operator to teach himself the man/machine interaction.

Human factors considerations

Some quantitative research has been made on hierarchical dynamic controls using displays. Uber[4] has published that a maximal response time to this type of request is 0.5 seconds, which is one of the reasons for the high level of intelligence utilized in the MATCALS local display processor. Uber has also analyzed the optimal number of menu selection buttons per level. With a typical scan time of 0.5 seconds per entry, and selection time of 2 seconds per entry, the menu length is 7.7 entries. Experimental and trained users can have practical menu lengths of 10 to 40. Because of the possible background of the MATCALS user, a maximum menu length of 6 buttons has been selected.

DISPLAY FORMAT

Introduction

The display is divided into the following general areas: (Figure 5)

—Az-El Display
—Aircraft Parameter Table
—Wave-off Buttons
—Alert Message Area
—Interactive Control Buttons
—Width-Height Display

The Az-El area is the primary observation area. Glideslope angle and centerline, acquisition gate positioning, aircraft positions (6), and associated tracking data blocks are graphically represented. Three scales are selectable. Wind and time of day information is also presented. Aircraft positions on the display are rapidly updated to show relative motion of the aircraft.

The aircraft parameter area is a tabular alphanumeric listing of detailed information associated with each aircraft. Its use is considered secondary to the Az-El area, and more of a reference to less often needed data. The necessity for each type of data to be displayed for each aircraft will be evaluated during actual landings.

Wave-off buttons are continually displayed so they may be immediately accessible to the operator. Alert messages are presented in the lower corner of the Az-El area where they are immediately noticed.

The menu of hierarchical interactive virtual pushbuttons is presented on a row adjacent to the Az-El area for easy reference.

A Width-Height display (WHI) is presented at the right of the lower portion of the display. It is of fixed scale, and only one aircraft is shown. The WHI is primarily used for only the terminal portions of a landing sequence near touchdown.

Detailed description

A detailed description of the major display format areas as shown in Figure 9 is given in the following paragraphs.

Aircraft parameter table

Each aircraft is allocated one line in the aircraft parameter table located across the top of the screen. Each line of data is identified by the aircraft index and the associated symbol to be plotted on the Az-El and WHI displays. The aircraft parameter table contains alphanumeric data associated with each aircraft, including static parameters describing the particular aircraft and dynamic values related to the aircraft's position and movement. The static quantities remain fixed throughout a track while the dynamically varying data is updated every half second. Static quantities are side number of the aircraft, aircraft type (A7, F4, etc.), communication channel address, landing mode (I, II or III), and glideslope angle.

Dynamic quantities displayed alphanumerically are pitch and bank angle commands being transmitted to the aircraft (Mode I), sink rate (fast/sec), speed (knots), range (tenths of miles), height (feet), height error from the desired glideslope (feet), azimuth position (feet) and time-to-touchdown (in seconds). Corresponding parameters for each aircraft are arranged in columns and are appropriately labeled.

Wave off area

A row of wave off initiation buttons is placed immediately below the parameter table. This position puts the wave off area in close proximity to both the parameter table and the Az-El portion of the display. The wave off area is maintained separate from other interaction functions to allow continual and immediate availability to the operator. To speed up the wave off process, each aircraft is provided with a separate button, identified by the correlated aircraft index and symbol. When a wave off button is selected the operator is then required either to confirm that a wave off is to be generated or cancel the wave off request. Confirmation of a wave off request is required to lessen the probability of accidental pushing of a wave off button.

Az-El display

The Az-El display is centrally located and occupies the major portion of the display area. Aircraft height versus range is presented in the upper half of the Az-El display area and lateral position versus range in the lower half.

Provision has been made for a selection of three scales. Twelve mile, six mile and 1.2 mile ranges are selectable with a corresponding change in the vertical and lateral scales. Logarithmic or expanded linear scales are desirable alternatives that will be considered for future implementation. Axes are labeled for ease in estimation of aircraft positional relationships and the touchdown position is offset from the edge of the display to allow tracking for a short distance after touchdown.

A unique identifying symbol is used to plot each aircraft's position. The symbol is also shown in the parameter table to correlate the tabular and graphical presentations. In addition, a tracking alphanumeric data block is displayed adjacent to each aircraft position, connected to the aircraft symbol by a short leader. The aircraft index, side number, landing mode, simulated target tag, range, velocity and vertical and lateral glideslope errors can be read directly from Az-El display without consulting the parameter tables.

The time-of-day, wind speed and heading, displayed glideslope angle, and runway heading are listed in unused portions of the Az-El display area. The time is updated every second and is an indication to the operator that the control computer is active. High priority alert and warning messages appear in the lower left corner of the azimuth display.

Interaction and monitor area

The lower portion of the screen, approximately one fourth of the total area, contains the interaction functions. All operator/system interactions except wave off initiation and positioning the acquisition gate directly on the Az-El display are accomplished in this part of the display.

The function selection menus consist of several sensitive buttons that can be selected by positioning the tablet pen within the button boundaries. The display processor reads the pen position and determines what action is to be taken. A message accom-

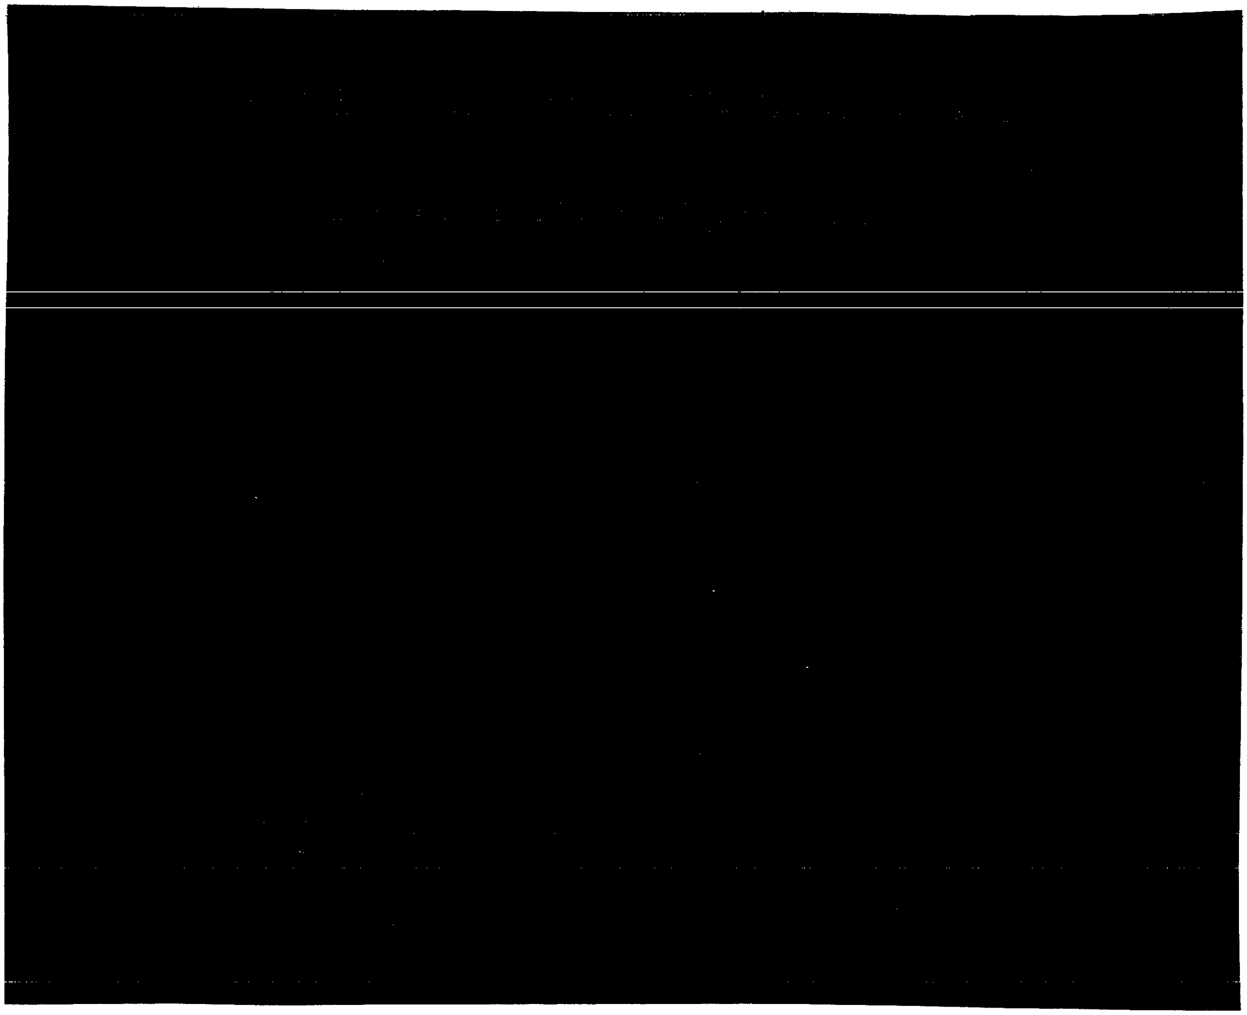

Figure 9—Display format

panies each menu to help direct and cue the operator's actions. Each button is labeled indicating its associated function.

When input of numerical data is required, a ten digit numeric keyboard appears in the interaction area with additional keys for minus sign and decimal point. The data is entered by sequentially pushing the appropriate buttons with the tablet pen. The accumulated digits are displayed as they are entered by the operator. Buttons are provided to allow the operator to clear the accumulator and begin again, enter the value if all digits are correct, or return with no data entry being made. When the numeric keyboard is no longer necessary in a data entry sequence, it is removed from the screen.

The rightmost lower portion of the display is used for the Width-Height Indicator (WHI) display to be used in conjunction with the normal Az-El display. Vertical and lateral glideslope errors can be plotted for any one of the aircraft shown on the Az-El display. The WHI has a higher resolution scale (±200 ft.) than the Az-El display and is used to determine more accurately the aircraft position close to touchdown. The system automatically selects the aircraft closest to touchdown for display unless this selection is overridden by the operator. The symbol correlated with the index number for the aircraft is used to plot the aircraft position on the WHI.

MULTILEVEL SOFTWARE DEVELOPMENT

Implementation of the display software was conducted in a top-down manner using the chief programmer team management philosophy and the guidelines of structured programming.[5] The system was developed in evolutionary stages with the first stage testing the high risk area of intercomputer communications and the central computer's operating system. In the first stage of the display program, skeleton modules ran under a primitive executive. As the implementation progressed, increasingly complex functional aspects of each module were developed.

The most important benefits of this approach were the early visibility of a working program, early assessment of the hierarchical interaction concept, simplified testing and integration with the risk reduction of integration problems, and elimination of the "90% complete" syndrome. Code review and the use of a program librarian were not significantly successful. The program team did achieve the ability to review each other's system designs and description with freedom from insulting each other's egos.

SUMMARY

The approach taken in this display design has led to an operational system which meets the objectives set forth in the introduction. Operators have complete control of the All-Weather Automatic Landing System from a single display console which presents an uncluttered view of the landing situation. The system is easily learned, operated, and requires no knowledge of computer systems. The hierarchical interaction strategy for data entry and system control has been proven to be both accurate and fast. Measurements taken on operator performance have determined that a 0.7 second per button selection rate can be maintained with the hierarchical interaction technique. The operator entry of all initialization data required for an automatic landing sequence (some seventeen virtual button selections) is accomplished in only twelve seconds. The operator is aware at all times of the permissible controls which are active and what possible actions he may take. Favorable comments have been received from a number of experienced landing system controllers, who feel the interaction and display concepts will increase operational safety.

ACKNOWLEDGMENTS

This effort was supported under Contract N00228-75-C-4544 with Mr. John Mulhern of the Naval Electronic Systems Engineering Center, Vallejo, providing many helpful technical suggestions. Discussion with Mr. Richard Wilz, NAVELEXSYSCMD, Washington, and Mr. Ken Potyen, NESTED, Patuxent River, Maryland, were also valuable during the development of the display system.

Implementation of the computer programs was accomplished by George Firkins, Susan Rubin, Lowell McMahan, Leo Hoffman and Al Crown. Project support was provided by R. L. Goodman and R. L. Johnson.

Libraries and the implications of computer technology

by MURRAY TUROFF and MARION SPECTOR
New Jersey Institute of Technology
Newark, New Jersey

ABSTRACT

This paper examines the potential impact of computer and information technology on the role and mission of the library. In an indirect, but no less significant sense it also considers the impact of the library on the technology. The specific concerns focus on the library as a mechanism for making computer and information technology directly available to the public. The paper also reviews a pilot project being conducted by the New Jersey Institute of Technology involving the Newark and Millburn public libraries in New Jersey.

INTRODUCTION

As of January, 1976 a number of powerful calculators have been installed in the Newark and Millburn Public Libraries as well as the library of the New Jersey Institute of Technology. The Newark Public Library serves an urban community which reflects the diversity of population and the multiplicity of problems facing most major urban areas in the country. In addition, the Newark library is the official state regional library for the northern New Jersey area and as such offers a number of unique collections pertinent to this mission. The Millburn Public Library reflects an upper middle-class suburban community. A majority of the high school students go to college and the working adult population is largely businessmen or professionals. The NJIT library services a scientific and technically oriented university community of about 5,000 students. It is largely a commuter-oriented institution for northern New Jersey and the Metropolitan New York area. A significant proportion of the students are from blue collar families and a very active program for the disadvantaged has attracted a good number of these students into the engineering and technical programs.

None of the above mentioned libraries have had any previous experience with computer or information technology. They have not utilized the marvels of computerized reference services, data bases, automated cataloging, etc. Although a calculator might seem a limited aspect of computer technology, in the environments under consideration the introduction of these devices represents a major shift of perspective along with a rethinking of roles, missions, and objectives.

Principally, this equipment is for the explicit use of patrons for any purpose they wish. The primary goal, as stated in public flyer, is making directly available to the public via the public library various computer and information services. This is not to say librarians do not use the machines. In fact, the machines installed are in the five hundred dollar range and considerably more convenient then the machines that existed solely for internal use.

No project of this type exists because of any one rationale. The members of the project team, users, librarians, sponsors, manufacturers may very well perceive this project differently. The implications are perhaps best understood by viewing a number of alternative rationales that are or could be representative of the parties involved.

SOCIAL CONCERN

Approximately two years ago one of the members of the project team was in a Washington, D.C. department store and happened to observe a salesman driving away some young children who wanted to play with the calculators on display. Evidently he did not perceive them as likely customers. To those of us who have envisioned computer technology as accessible to the public such an occurrence is personally disturbing. However, disturbances of this type have a way of generating reflection.

It seems that for many years the view of many professionals was that the all-encompassing computer 'utility', because of economics of scale, would be the mechanism for bringing computer power to the people. While hardware costs have demonstrated their economics of scale, software and communications will remain a bottleneck for quite sometime. Even while this orientation toward the grand large scale system continues for a vast number of prophets in the field, it has turned out that for the people 'it is the little things that count'.* The calculator is the first major item of

* Attributable by the authors to Richard Wilcox.

computer and information technology to fall in the hands of the public on any wide-scale basis.

Perhaps the events arising out of the selection process that occurs in a competitive market place are hinting that it is not large scale but the small scale we should be looking at for delivery mechanisms. There have been in the past few years a growing number of such small scale-efforts—Resource One in the San Francisco area for example.[1] The majority of endeavors appear to be the volunteer efforts of concerned professionals and community groups. Unfortunately, because of the nature of these activities many of them lack documentation and very little evaluation is accomplished. While many of the individuals behind some of these programs might scoff, we feel they have suffered from a lack of institutionalization. What is sacrificed, of course, is the opportunity for permanency and wide scale transferability.

With these considerations in mind our choice was to start at the bottom, utilizing a variety of calculators with performance and associated price above the level the average person could afford. It was also a conscious choice to institutionalize the effort—but why the library? In one real sense it is like the explanation of why people climb mountains: they are there. The library is an institution that is available to the public, its personnel are familiar with serving the public, and it is relatively neutral with respect to political, social, ethnic, and organizational polarizations. From the point-of-view of a person who is interested in delivering computer technology to the public the library is the convenient place to do it.

Why one wants to put advanced technology in the hands of the public is probably a question each individual should answer for himself. However, one view is that it may be increasingly difficult to exercise the privileges of an intelligent citizenry in a democratic society without an understanding of the capabilities and limitations of the technology which is beginning to monitor, regulate, and perhaps control aspects of that society.[2] The key issue seems to be: "Will the utilization of this technology by society be such that each citizen must have a right of access and availability in order to function as a part of the society?" Suppose today we took a group within our society and denied them use of the telephone? One could easily list a set of severe consequences for such a group.

LIBRARY MISSIONS

The average person probably equates the usual library with vast arrays of printed material such as books or other physical images like films, records, etc. The more appropriate view for our purpose is to consider the library as an institution for allowing people to utilize information. Utilization implies not only storage and retrieval, but creation, organization, and manipulation as well. The use of the technology to allow patrons to be able to directly perform these latter operations implies a host of information services that have not previously been possible:

- Allow the library to support transient information needs of its user community.

  Individuals able to develop their own personal data files and text files on electronic storage media such as floppy disks—to manipulate, update, and edit these as need be.

- Provide mechanisms for patrons to exchange information.

  Essentially the community electronic bulletin boards and the computerized conferencing[3] with discussions going on of any topics of interest to the users of the library.

- Establish the Library as a Learning Resource Center.

  A place where individuals of ages 5 to 85 can go to take advantage of the educational options offered by the technology.

The possibilities stretch from rather straightforward electronic bulletin boards, text processing, discussion systems and CAI implemental on microprocessor oriented intelligent terminals with floppy disks or digital cassettes to more future oriented visions as those expressed eloquently by such individuals as Kagan and Nelson.[4]

In essence the key ingredient is the concept of easily dealing with "variable" information. Information subject to change and modification on a frequent but unpredictable basis.

The choice of the library and its institutional characteristics has led us to another premise in our design of this effort. Most libraries have been reasonably successful in the performance of their mission because the services they provide have no short term dependency on other organizations in the delivery process. Short of the dramatic act of closing a library, most sponsoring institutions do not (at least not yet) instruct libraries to sell books to raise money, whereas colleges can be told to cut down enrollments, offer less courses etc. With this in mind a choice has been made to focus on equipment which is self-sufficient, and not dependent on outside computer power. This is not to say that if we install at some point, an intelligent terminal or word processor, it will not have the dual-use capability of being able to talk to a computer. In fact, any reasonably sized organization buying word processing equipment that cannot be upgraded for this, has not looked to the immediate future.

EDUCATIONAL ASPECTS

Although there are public schools which offer experience with computer technology, they present a distorted perspective of the extent to which technology is actually being taught to the public. There are many outstanding programs in largely upper middle-class communities or in communities in proximity to a university. These efforts represent only a fraction of the pupil population. For example, in the near future, it is unlikely the Newark New Jersey school system would be able to replicate the six thousand dollars worth of calculator equipment available in the Newark Public Library within each of its schools. Even if it did, the equipment would not then necessarily be available to other specialized educational programs without added staff costs to open school facilities after school-hours.

In the case of a public library, one must consider a diversity of user needs for computer technology that must be met. They run the gamut from advanced research to recreation. The objective of expanding computer technology depends, as well, on the nature of the user population. In the case of this study, equipment for the Newark Public Library (a lower-income area library) may not be appropriate for Millburn (an upper-middle income area library).[5] Similarly, one would allow for more sophisticated equipment to be included in the library at NJIT, a technical college library. The sample of this study was especially chosen to represent two socio-economic communities as well as a technical college community. It will thus be possible to evaluate differences between the groups from the point-of-view of the appropriateness of the new equipment. The principal question to be answered is whether this advanced media equipment represents any improvement over past services.

The library has traditionally been the place where individuals go to learn on their own. It serves as an important place where users can pursue their own information needs. Librarians continue their efforts to encourage users to consider learning as a life-long process. Therefore, an objective of this study is to investigate if the library cannot serve as an improved educational agency. In addition to introducing computer technology to the public, this service of the library could be used efficiently in the educational process.[6]

It is clear that the adult population particularly from thirty on up has not been adequately serviced by traditional educational programs. Many adults no longer have the opportunity to attend school. For those that do, there are many problems associated with returning to college or even to graduate school. Imagine a practicing engineer in a class of engineering students becoming aware that he knows less than some of the young students! Technical areas of instruction, particularly where updating is concerned, are ideally suited to CAI (Computer Assisted Instructional Systems) made available on a self-service basis in libraries. One of the earliest lessons to be learned by those involved in designing operational Management Information Systems is if you want senior managers to use these systems and do not have enough terminals for every office, you put it on wheels so the manager can take it into his office and not publicly demonstrate to younger employees the mistakes he is making in learning the system.

NJIT has developed a number of specialized educational programs to provide opportunities for disadvantaged students to enter technical fields. These programs have partially blurred the distinctions between course materials offered in the high school and in special first year programs at the university. They have entailed tutoring efforts, summer sessions and weekend classes for high school students, special classes for high school teachers, as well as the development of instructional materials for the use of high school teachers.

Educational institutions involved in the programs for the disadvantaged, could pool their resources, and invest in Learning Resource Centers located in libraries. From an educational standpoint the availability of computer technology able to support drill and practice as well as the updating of basic knowledge, would greatly alleviate the coordination difficulties that result from offering remedial services in public schools, universities, and adult programs.

This pilot project will emphasize guidance and instruction in the use of computer technology to teachers. Their willingness to use the media made available is essential to the success of this program. Their perception of the role of educational technology is of the utmost importance.[7] It will determine the length of time they are willing to spend developing specific educational lesson plans for the equipment. They will be encouraged to take advantage of the calculators to design stimulating assignments for children. In mathematics, children could easily handle more challenging problems such as computing a growth curve to fit the daily growth of a classroom avocado plant. This computation would normally be too laborious without the use of a calculator.

From the point-of-view of educational theory, there appears to be a shift from concern with teaching to a concern with learning. Whereas, teaching provides a framework for learning, teacher-centered learning does not develop independence in the learner. Teaching is done to the individual, not by the individual.

Educational technology may be an effective technique for students to acquire skills independent of the teacher.

A question to be explored is what types of individualized learning experiences students can handle in different grade levels as a result of educational technology? Also, computer technology is especially important for providing work at varying rates for students at the extremes (faster or slower) than the average classroom. It is expected the library could serve as an adjunct to the teacher for these students. For example, this study will use drill and practice techniques as one effort for those needing remedial mathematics. Applying the psychology of learning to practical teaching problems, the student is presented with individualized instruction in arithmetic.[8] Actively involved with his own performance of arithmetic problems, the correct answers via computer print-out serve as an incentive in the learning of repetitive tasks. It is no longer necessary to wait to have a test scored. As far as assisting the classroom, drill takes up considerable time. Drill and practice take time away from teacher-contact with students that could be used in better ways.

Generally schools and libraries have co-existed as separate units. An objective of this study is to determine professional (librarians and teachers) roles in the use of educational technology. It is possible that teachers will be more receptive to educational technology when it is in the library. They may not sense the equipment as a threat to the teaching force.

Many teachers have been dubious regarding the importance of the new material and have not taken it seriously. This study will utilize survey instruments as well as interviews to evaluate the attitudes of teachers and librarians.[9–10] They will also be working with the media specialist in the selection and utilization of materials. Results from questionnaires will serve as an up-to-date monitoring system to determine which tools are serving advantageously and which are falling short of expected outcomes. The results will be used as a basis for future priorities, deciding the long-range goals of this program.

PROFESSIONAL CONSIDERATIONS

The concept of technology assessment has emerged in recent years as an issue of primary concern to society.[11] Most assessment studies have been executed as paper and pencil efforts. It has yet to be realized that there exists a need for assessment by experimentation. From one view this effort could be considered a 'live' technology assessment. A major goal in this assessment effort is to gain insight into the unexpected consequences of technology. We expect to observe results we could never have predicted. A few unanswered questions in this area are:

(1) For what purposes will the technology be used by the public and what are the benefits or limitations?

(2) Will the library schools have to train educational librarians (will SLA add a new component to its membership)?

(3) Is the technology designed to really meet the requirements of this mission?

(4) While we have in Information and Computer Science had some success in designing to deliver "Information," do we know how to design to deliver "Information Technology"?

Even at the calculator level the variability in human interface for machines of similar capabilities is quite significant. In terms of advanced machines, the layout of the keyboard and the associated instruction manuals appear to be either for the sophisticated user or the individual who *must* learn to use the machine. The developments in this area have been so rapid that few of the companies appear to have made any evaluation efforts in terms of market assessment or product development. This may change as the market saturates.

Another aspect of the assessment issue is the observation that Congress seems to be dragging the National Science Foundation, kicking and screaming, towards a program called 'Science for the Citizen'. No one at this point seems to be sure what that program might encompass. One would hope the delivery of advanced technology would be a key aspect. It is quite clear that organizations such as the National Association for the Public Assessment of Technology would tend to support a view that the public should have a right of access to information and information technology if it is to have an equal voice with those institutions that can afford these benefits.

Technology has moved so rapidly it always appears that implications for the training of professionals in these fields takes place as a reactive process as opposed to an anticipatory one. For example, the vast majority of development and design activity in the professional community represented by ASIS has dealt with the technical means of retrieving data for the user but not the processes of allowing users to create, store, manipulate and update data.

We can foresee that as a result of programs designed to improve the availability of technology for the public, there will be a further blurring of the divisions between Computer Science, Information Science, Library Science and the Social Sciences related to educational processes.

ISSUES AND PROBLEMS

This paper has raised a number of issues and problems. Whether it be at the limited level of the calculators, or the more sophisticated equipment we hope to incorporate later, the following is a summary of issues that must be examined, evaluated and resolved before one can expect any wide scale implementation of programs of this type.

Community acceptance

There are a great many individuals with unimpeachable credentials whose current reaction to computer and information technology is to avoid it like the plague.

One can point to the existence of this antagonistic attitude represented even on our own faculty. Perhaps more serious a concern is the feeling that the technology is an influence in widening the gap between the disadvantaged and the rest of society. Apparently some community organizations have taken positions that they do not want calculators allowed in public schools because it will degrade the child's learning of basic math. Also, some experiments with the availability of CAI systems, have indicated that a child having difficulty in relating socially to other children may further withdraw.

This latter phenomenon is also behind some success stories with Management Information Systems. Given an organizational environment that has severe restrictions on human communication, an MIS system that is designed to be very reactive at a terminal, can easily become an unconscious surrogate for human communications—the computer becomes someone who will listen, obey and respond.

One key element in the library approach is the volunteer nature of the effort. The use of the calculators is a self-made choice by the individual. This may lessen possible friction involved if these were imposed directly into an educational program. We are trying to maximize the availability of material on games and puzzles which represent an unconscious form of learning, and the existence in the program of the 'Computer-Tutor' and the small 'Quiz Kid' means the teacher can encourage those children who need basic drill and practice to engage in such. The more advanced machines for either business or scientific use can only be mastered if the individual knows or attempts to learn the basic applied math concepts that are presumed in their design. Also we have undertaken to instruct those teachers who want to learn as to the types of lessons that could be assigned in math and science areas that would not be convenient without these machines—e.g., curve fitting to plant growth data. Since we are not set up to have a full-time educational staff available, the procedures encourage people to help one another to learn. Initial eyeballing of what is taking place appears to indicate that children are most often learning and doing on a machine in groups of two or three rather than one alone. Maybe our concept of a CAI workstation, with one child working alone at a terminal, bears re-examination.

CAI design

The CAI area can be characterized today by two diametrically opposite approaches: One is the large system with a great many hours of effort put into developing a single lesson by specialists trained in the intricacies of the system. This could be represented by the PLATO system and the TUTOR language at the University of Illinois. An alternative approach is the PILOT CAI language which represents ten simple commands that can be taught in about one hour and allow any teacher to prepare straightforward lessons to be used by students. Interestingly, the PILOT has been implemented on the DATAPOINT Intelligent Terminal, and can be implemented on any of the similar devices made by such companies as DEC, WANG, etc. The PILOT language can also be taught to sixth graders on up and utilized to allow students to design lessons for other students which represents another intriguing learning approach, particularly for the student designing the lesson.

Basically, these two approaches can be distinguished by: one, canned lessons prepared by specialists and two, tailored lessons modified or created by the individual teacher and the students. The latter is implementable on stand-alone devices costing today about twelve thousand dollars. One can infer from other parts of this paper that we feel this latter small scale approach belongs in public libraries as part of a Learning Resource Center concept.

Some other rather obvious issues we have already discussed are:

Institutional Cooperation—Ultimately the problems of cooperation of educational and library institutions have to be faced, not only at the funding and administrative level, but at the training level of professionals employed by these institutions as well as the research and evaluation efforts associated with these endeavors.

Recreation and Learning—It is really not clear that we understand these processes or their relationships and potentials within the context of the technology we have been describing. The little calculator has already raised issues about possible dis-benefits to the student without accurate evaluation to support any of a multitude of views. The calculator is only the tip of the iceberg with respect to the potential technology.

Equipment Design—Current equipment design is far from satisfactory for the purpose of general public use. This is even more true as we move up the ladder to intelligent terminal capabilities. Also, instructional material supplied by manufacturers is usually written with the assumption the user *has* to learn the machines. Security of the equipment is another aspect that has only received minor attention from some manufacturers.

Problems with Change—Both librarians and educators can suffer from the same psychological resistance as other adults reluctant to reorient or engage in updating their knowledge and rethinking basic goals of their endeavors. As a whole, we have been very fortunate with the individuals involved in this project. However it does take time and patience to bring about an understanding of an endeavor of this type as it is not established practice for libraries. Also, a number of libraries that have made available simple hand-held calculators, in the twenty dollar range, have had to drop the programs because of maintenance and loss problems. Most public libraries do not usually have the background to judge the machines required and to evaluate their capabilities. It has been our approach to provide the expertise to utilize advanced equipment that is not competitive with what the average person can afford. This then provides the library patron a service that is potentially attractive in terms of what he or she may need to accomplish.

APPENDIX—SCENARIOS

One way to place the goals of this program into concrete terms is to list some specific scenarios which show the various uses to which this technology located in the library can be put.

A high school student uses a calculator to do some calculations on physics homework.

A housewife uses a calculator to balance the family checking account and evaluate the impact on the planned budget.

A professional (engineer, accountant, etc.) comes to the library to utilize a more powerful calculator than he or she could normally afford.

Many teachers at local schools can restructure their homework assignments in the math and sciences to reflect the availability of calculators at the library.

A secretary and/or treasurer of a local club, organization, community group walks into the library carrying his data file on membership and finances in the form of a small digital storage device—e.g., digital cassette, minitape, floppy disk, etc. He or she goes and sits down at an intelligent terminal that has been set up as a text editing and composing device and performs the updating on recent changes in addresses, membership, dues, expenses, etc. He or she then prints out a summary and duplicates copies for the membership.

A student utilizes this same storage media and terminal to compose and edit term papers over a period of time.

A new form of book called the 'interactive book' has become very popular. With this book stored on a digital storage medium, the reader can play the role of one of the characters so that as he reads he can make choices at strategic moments in the plot which result in different plot resolutions.

Even the librarian can utilize the word processing equipment to prepare various reference lists with continuous updating capability.

A young couple walks into a library and asks for the digital cassette holding the advertisements of babysitters available in the neighborhood: a teenager walks in to add his name and description to the same cassette.

A teenager requests the cassette or floppy disc advertising part-time help available for cleaning, gardening, snow clearing, etc., so he can add his name and capabilities to it.

A citizen requests the cassette devoted to discussing a new and provocative book so he may review what other people have said and add some of his own comments.

A teenager requests the cassette of an anonymous discussion of dating problems by teenagers. An adult requests the cassette dealing with marital problems.

A group of local businessmen or procurement officers have a cassette on which they are exchanging notes on the performance of various supplies, equipment and suppliers.

A cassette is being used by people in the community to discuss their views on various local issues, say a rezoning item. A copy is sent once a week to the government group involved.

Various cassettes have been prepared and are maintained by various local government and community groups to provide information on services, volunteer work available or needed, etc.

A psychologist is utilizing cassettes in the library as a form of random group therapy sessions.

A social worker has organized and monitors a number of problem oriented conferences among people having similar difficulties.

A class discussion cassette has been established with a local teacher to augment the regular class hours and provide more opportunity for free discussion. This is a particularly popular facility for use in adult education courses.

A group of stamp collectors utilize a cassette to bid on stamp trades.

A group of professionals in a common area of endeavor utilize a cassette to exchange information on recent papers and findings in their field.

A teacher delivers to the librarian a floppy disk containing a CAI lesson she has prepared for use by her class.

The expanding role of on-line interactive searching

by VIVIAN S. SESSIONS
The City University of New York
New York, NY

ABSTRACT

On-line interactive searching represents the newest thrust in information retrieval. The combined technologies make available to librarians and other information professionals large volumes of bibliographic data which reside in computers as remote as thousands of miles from the terminals using them. Presently the individual data bases that furnish the examples of actual usage (ERIC, NTIS, Psych Abstracts, etc.), are accessed primarily via Lockheed, SDC, Medline, and the SUNY Bio-Medical Network. Although it is difficult to give a definitive statement on the proportionate economic contribution of this kind of information retrieval to the entire computer economy, estimates of numbers of characters of information on-line (25-50 billions), indicate a significant dollar involvement. It is in this framework that bibliographically-oriented members of the computer community urge their non-bibliographic colleagues to understand information retrieval and to heed its requirements for further development.

Of all the library and information center usages of computers, the one that concerns this paper is on-line interactive information retrieval. It is retrieval in the sense of finding references to documents relevant to a particular problem in data files that are comprised of bibliographic records. Not all such data files can be used either interactively and/or on line, but those that do not qualify on both counts are excluded from this discussion in order for us to zero in on the I.R. mode that is today most visible in terms of public discussion, in terms of growth, and in terms of challenges to the computing community.

A typical form of on-line interactive retrieval would be the situation in which an information professional uses a terminal with dial-up capabilities to log into, say, Lockheed Information Systems in California via a communications network. S/he indicates a particular data base (the Educational Resources Information Center (ERIC) is a good although over-used example), and then proceeds to process such a query as the one recently done at the Center for the Advancement of Library-Information Science at the City University of New York. This particular query was for references to materials on collective bargaining in higher education. The CRT quickly indicated that the particular way in which the query was asked would yield 367 references in the ERIC data base. The terminal operator asked to have a few displayed, and when all of them seemed on target to the requestor who was sitting by, a message was sent to have the entire number printed out on the high speed printer in California. In a few days the information arrived in New York.

As this was one of the less expensive data bases, and very little computer time was needed to develop a strategy, the total bill was about $40 for the combined use of the data base, the communications network, and the high speed printer—mostly the latter, with 367 citations @ 10¢ per citation printed. This cost excludes, of course, the original investment in the terminal and the time of the information scientist who served as the interface between the requestor and the system. Since the requestor was satisfied with 367 references, there was no attempt to query the file with alternative strategies, thereby keeping the connect time, the most important cost item, at a minimum.

Characteristic of the kinds of systems under discussion in this paper is the fact that the data bases are loaded on computers that are remote from the terminals accessing them—remote not just in the sense of being in a different part of the same building as the terminals, but remote as measured in hundreds or thousands of miles, and housed in different organizations. Even the creators of the data bases (The National Technical Information Service, American Psychological Association, to name a few), once they send their regularly scheduled up-dates to Lockheed or SDC, then access their own files over the same kinds of terminals and via the same kinds of communications networks as the users of their data bases. (Some specialized exceptions do not affect the general situations.)

Remote on-line information retrieval only became a publicly available resource in libraries and information centers in 1972, with a limited number of files. By 1974 Lockheed and SDC had developed their respective capabilities to the point that the Information Industry Association awarded them jointly the Product-of-the-Year award in 1975. In the year since the award they have made considerable advances in the terms of services and customers. Together these two private corporations now account for two-thirds of the kinds of bibliographic data now available for on-line remote searching in the U.S., the other third being provided by public systems, the files of the National Library of Medicine and those of the SUNY Bio-Medical Network. Although there are large overlaps in the data bases handled by these four systems, they can be considered as being independent contributors to the computer economy, for reasons that will be pointed out shortly.

The fact that some of the Lockheed and SDC data bases are government-created and some are private in origin, such as the Institute for Scientific Information (ISI), is of significance to the user only inasmuch as the privately created data bases are more expensive; methodologies for using them differ to the extent that every data base has its own characteristics as to coverage, access points, and hard copy aids to users. And all these are constantly changing.

In the decade before the remote on-line interactive developments, many librarians were already involved in information retrieval. If they worked for organizations with the resources necessary to mount their own bibliographic information systems, they could directly participate in the vanguard of their profession. However, these opportunities were limited to librarians in large corporations and government agencies; the public and university librarians were out of it except for those few places that had contact with information dissemination centers.

Now, however, direct participation in the information retrieval process is possible to anybody having access to a terminal with dial-up capabilities, access to a purchase order of a few thousand dollars, and access to some training (more is obviously preferable). Although many information professionals may be forced by institutional reasons or personal inclination to continue depending on intermediate search centers, the desire to be independently on-line to immense storehouses of bibliographic data is less a matter of wishful thinking and more a matter of persuading internal management of the desirability of such action. The advantages to the individual information professional for upgrading his/her skills aside, the advantages to the organization are enormous. The more its own professional information staff knows about information retrieval, the more that organization is going to profit from it.

"On-line" and "interactive" are usually stressed rather than the "remoteness" of the data bases in present-day discussions of information retrieval. All three are intertwined. It is the on-line capability that brings remote access to life, and it is the interactive characteristic that really separates on-line from batch searching. Without the interaction, information retrieval on-line offers little advantage in search strategy to the batch mode.

The interaction now possible on the standard on-line information retrieval system is not as conversational as the term implies, but has divided itself into systems—type interactions (such as the user being told that the host system is on line, or that the operator has made a syntactical error), and interaction wherein the user knows immediately (computer-time immediately) how many document references would be retrieved in the NTIS system by using the search terms being investigated. For instance, how many "hits" by using the search term "service industries", how many would be found by the term "innovation", and how many by the combination of the two in an AND strategy? It quickly developed in this search that the results would be insufficient unless "service industries" was broadened to include "services" in general in an OR relationship.

To illustrate another interactive feature in the very versatile NTIS file, the information professional looking for material on "information theory" might do well to use the EXPAND command, which would then put on the CRT all the descriptors in which "information theory" is only the first part of a multi-word descriptor. This could result in a decision to either broaden or narrow the search, the latter being done by asking only for "information theory, band widths", if that is more appropriate. The EXPAND capability is particularly important in systems that either have no printed thesauri, or in situations in which the user has no immediate access to the thesaurus.

One of the most powerful features of interaction has already been mentioned in connection with the ERIC search earlier: the ability to display a few citations to see if they are on target, thereby enabling the searcher to decide whether to continue modifying the strategy, or to work with what has been retrieved, and order a print-out. If the searcher is using a terminal with a printer attachment, or a printing terminal, the only decision left is whether the results are either sufficiently short or sufficiently urgent to have them printed out on the spot, or to leave them to the high-speed printer and the mail. These few examples of the effects of interaction on search strategy merely scratch the surface.

The intricacies already mentioned of searching interactively, and many other fine points extending the possibilities, are starting to be taught to the librarians or other information professionals in a variety of formats. This is quite different from library automation, which concerns itself with circulation control, catalogue card production (now handled in volume through the Ohio College Library Center) and related administrative tasks. While such uses of the computer contribute heavily both to the smooth functioning of the library and to the computer economy, it is information retrieval which responds to the expectations of the information user community.

Although the ERIC search on collective bargaining mentioned as an example seems to meet those expectations completely, it worked out so well only because of specific conditions that existed. All the tricks of computer technology would have been to no avail if there had not existed a data file in which there was a high probability of the information existing, if the information professional did not know of the existence of the file and how best to access it, if she had not had a purchase agreement with Lockheed and an appropriate terminal at her command.

If these facts seem elementary, it will surprise the computer community to report that great numbers of people with some knowledge of computing call our office without either knowing or being willing to learn these basic facts. And these callers are not limited to those whose knowledge of computing is purely peripheral. A gamut of callers assume that because they have access to the University's central computer facility they therefore have access to either ERIC or the other files on the Lockheed, SDC, Battelle, Medline, N.Y. Times, or other systems. It is an unpleasant job to convince them that their research allocation of $400 will not contribute one dollar to the cost of using any of the bibliographic data bases that are available in the interactive, on line mode that they are starting to hear so much about.

This type of problem occurs most often with seekers of information who are neither library nor computer professionals, although even with those groups some confusion exists. The real problem with the computer professionals, however, is that although they understand the concept of files and differing conditions through which they may be accessed, they often have little understanding of how bibliographic files are created; this makes it difficult to carry on a meaningful discussion on how to use them for information retrieval, whether on-line or in batch. Too many graduate computer scientists confuse the experimental work being done in automatic content analysis with the real world in which the analysis is done by human beings, and where data bases are created using descriptors, or subject terms, from a controlled vocabulary usually called a thesaurus.

And everybody is confused by the constant change in what is possible. Each data base has its own characteristics, which influence the way it can be accessed either at all or most effectively—however these characteristics change so rapidly that a file which one day can only be accessed by descriptor may, shortly after, be searchable for any word in the abstract (COMPENDEX is the most recent example). Also, new data bases are being added so frequently that a query which a few weeks ago might have been relevant to only one data base should now be considered from the point of view of, say, Dissertation Abstracts.

It is no more reasonable for me to expect computer scientists to keep up with every change in information retrieval than it would be for you to expect me to be completely *au courant* in the hardware. What I do ask in this area is that the computer professional be sufficiently educated about the conditions of on-line interactive retrieval so that he can play a positive role in the further development of this important sector of the computer economy. The exact nature of the role may vary all the way from not being a hindrance to affirmatively helping solve some of the problems in computing that affect many usages besides I.R.

The "not a hindrance" part of this request has two categories, the first of which is not to play pro in I.R. if your computer expertise is in other areas and, two, not to downgrade I.R. by giving it low priorities in terminal availability, budget for external computing, and training opportunities. Information professionals involved in on-line retrieval deserve terminals that are at least the equal of those assigned to the programmers in the organization. They have enough problems dealing with the intellectual problem of I.R. without in addition having to fight the equipment.

Both the "no hindrance" and the much more active involvement in on-line I.R. to be mentioned shortly are really problems that transcend a particular computer installation, and therefore belong in the domain of the entire computer economy as represented in the Conference. Any one manager has his/her own budget to optimize, his/her organizational hierarchy which determines priorities apart from any personal interest in I.R., and assorted additional internal computing problems that take immediate precedence over an operation that is on-line to an external system. The economic contributions of I.R. in any mode, and especially in the on-line interactive mode, are to the industry as a whole, and that is the reason for their being presented in a conference that represents the industry as a whole.

It would be easier to make the point if it were possible to make some claims for I.R. in terms of its proportionate value to the industry. What proportion of CPU time in the country is devoted to I.R.? What proportion of equipment costs, mainframe and peripherals? What is the proportionate use of programmers systems, analysts, data communications experts? Unfortunately, these questions are impossible to answer, even if put in absolute rather than proportionate figures.

Trying to arrive at some other measures for evaluating the role of on-line interactive information retrieval in the computer economy, some interesting estimates of absolute figures did emerge. The Lockheed Information System has eight billion characters of information on-line 14 hours a day (they start before dawn New

York time in order to accommodate European users). SDC contributes a like number of characters of information, and the bio-medical information systems (the National Library of Medicine and the SUNY Bio-Medical Network) a little over another eight billion together. These four systems are, therefore, making between 24 and 25 billion characters of information available currently in the interactive mode, most of them being used in the U.S. in locations remote to the residency of the data bases. Martha Williams of ASIDIC estimated recently that one million searches a year were being done on those four systems.

Since the figures as to sizes of the on-line systems were estimates of current availability obtained by informal telephone calls to appropriate people rather than from official reports, the same informality (combined with other conversations) persuades this writer that by the time this paper is actually presented, closer to 50 billion characters will be available for on-line interactive searching in the U.S.—especially if one takes into account the information systems available through Battelle, The Information Bank (N.Y. Times), the various ones now just coming up, and the normal growth in the size of files already in existence, as well as the expansion in amount of information in those files that can be searched interactively. There are also many international systems (the International Labour Organization, the World Health Organization, the U.N. Environment Centre, etc.) that seem on the horizon for direct access by U.S. information professionals, that will either contribute to the fifty billion figure or enlarge it.

The point to using characters of information as a measure of size is first its availability, and second its meaning to the computing community in what this means to the economy in terms of systems and programming support, hardware investment, and CPU utilization.

This approach does not solve the problem of how large information retrieval is proportionately to all other uses of the computer, including those for library administration, but it does indicate a contribution sufficiently large to make the point that the needs of information retrieval should be seriously considered in future developments of the industry. The size of information retrieval should also spur all information professionals, whether library trained or with other backgrounds, into demanding more than mere "no hindrance" policies mentioned earlier.

The most obvious need is for more education, education in which the computer professionals and the information professionals cooperate. Even with the development of such courses as those that have been offered in the City University's Professional Development Program for Library-Information Science, too few people have faced the problem of really bridging the gap between computer science and its bibliographic information systems implementation. Courses in programming only begin to bridge the gap; they must be supplemented by courses in how to measure the effectiveness of various kinds of programming. In the on-line remote environment, data communications can scarcely be ignored or confined to sociological discussion. The examples can be multiplied; the point is that educational efforts must be made by all segments represented by AFIPS because they are all involved in information retrieval.

A second "must" lies in the area of data storage. The closets are becoming filled, and will be more so when there are significant breakthroughs in input methods. The possible argument that information personnel already has at its command the very large amounts of bibliographic data already mentioned is not valid, if one starts to point out the large gaps in the bibliographic coverage of the literature, particularly in the social sciences. The systems need large capacity, and the librarians will have to learn to work with those larger capacities.

A third "must" lies in the area of referral vs. bibliographic services. There is too large a duplication of the latter—the overlap in data bases between SDC and Lockheed, for example, may be anti-monopolistic, but it uses capacity that might better service society's total communication needs by the provision of more referrals from file to file. As the number of files on-line grows, so will the necessity to refer even the expert to the correct file, and to instruct him/her properly in how to convert a question from one system to another (assuming that total file compatibility is an ideal rather than a complete reality).

A fourth "must", at least to this writer, is for a more imaginative use of terminals in information retrieval. We now have two possible ways of using the terminal on-line: letting the information roll off the screen or, if available, transferring it to a printing device. Some exploration might well be made of the divided screen, so that information (perhaps on strategy) can be kept in view while the materials to be scanned are rolling off the screen. The technology is presently used in another type of information system, and its application to I.R. use merits some study. Perhaps several screens, with or without divisions, will be needed to make full use of large volumes of material being on-line at once.

The topic of this session: "Enhancing Library Services Through Computer Technology" could have been interpreted as supplying the specifics for on-line interactive searching. However, those details are findable to the kinds of librarians and information center professionals who are likely to attend this meeting. This occasion should be used instead to broaden the strokes, to enlarge the possibilities, to engage the cooperation of the entire industry. It is my earnest hope that this has happened.

Applications of Computer Science

Developing application oriented computer architectures on general purpose microprogrammable machines

by TOMLINSON GENE RAUSCHER
NCR
Cambridge, Ohio

and

ASHOK KUMAR AGRAWALA
University of Maryland
College Park, Maryland

ABSTRACT

Surveying contemporary commercially available computers reveals a general incongruity between computer architectures and the problems the computers are being used to solve. Surveying the commercial applications of microprogramming reveals that microprogramming remains largely an alternative technique for manufacturer implementation of basic machine language instruction sets. With the large number of contemporary general purpose microprogrammable computers (especially minicomputers), the advantages of microprogramming are available to ordinary users for solving specific problems. From a pragmatic view, the architecture of a computer is defined by the microprograms resident in its control store. Changing the microprograms in a computer's control store therefore redefines its architecture. Architectures may be defined for specific problems by changing the microprogram in control store for each problem. As problems are represented by higher level language programs, compilers can *automatically* generate a microprogram for each higher level language program. The generated microprogram, when loaded into control store prior to program execution, defines an architecture that efficiently supports program characteristics. The advantage of this scheme is that it utilizes the power of microprogramming for each user's specific problem without forcing the user to comprehend the implementation complexities of a particular microprogrammable machine. This paper investigates several techniques for architecture redefinition via microprogramming.

INTRODUCTION

Motivation

Problem solving with the assistance of a modern general purpose digital computer generally involves a sequence of processes.

(1) The programmer writes a program to effect his algorithm in some higher level programming language.
(2) The analysis phase of a compiler for the programming language transforms the program into some intermediate language representation.
(3) The synthesis phase of the compiler transforms the intermediate representation into a machine language program.
(4) A microprogrammed interpreter (i.e., an emulator) directs the interpretation of the machine language program by the machine hardware to produce results.

This problem solving process may be considered to be a series of transformations on various representations of an algorithm to solve a particular problem. Most of the representations have been studied in some detail, and as a result there are well-known algorithm representations, higher level languages, and intermediate language representations. Similarly, most of the transformation processes have been studied in some detail, and as a result there are well-known programming techniques, formal language analysis techniques, semantic analysis and code generation techniques, and hardware transformation units. In contrast, the design of machine language instruction sets and the microinstructions that interpret them have been given relatively little consideration.

> Some things have not altered, or only slightly, so, like the Model T, they have remained invariant, upright, slow, inefficient and immune to the winds of progressive technological improvement. . . . I am referring to the basic form and rigid format of our instruction sets.[1]

The instruction sets of many contemporary computers were designed with hardware realization as the foremost constraint. Little attention has been given to the types of operations the computers will perform. As a result, machine language representation of program constructs are often awkward, and the efficiency of machine code for programs is seldom high. "The majority of the . . . required work is involved with placating the computer, while a relatively small portion of the work is actually applied to the job."[1] "In this regard it is interesting to note that . . . most of the instructions executed, even in scientific applications, are used for "housekeeping' details."[2]

Microprogramming was formulated more than twenty years ago as a systematic alternative to the usual somewhat *ad hoc* procedure for designing the control section of a digital computer. Although microprogramming has been used commercially for more than ten years, it generally remains a technique for the implementation of basic machine language instruction sets. Recent developments, such as the availability of fast writable control stores, have sparked investigation into other applications, however, these are mainly special purpose and not immediately generalizable.[3]

The advantages of microprogramming have been mainly engineering aspects: low cost, flexibility, and ease of development and maintenance. Because microprograms interpret instruction sets, microprogramming can be applied to general purpose problem solving to overcome inefficient machine languages.

Environment

Problems to be solved will be represented in procedure oriented higher level programming languages. For the higher level language there is a compiler consisting of two parts:

(1) an analysis phase which transforms the higher level language program into an intermediate language representation and,
(2) a synthesis phase which transforms the intermediate language representation into machine language.

Since a majority of optimization techniques are machine independent, the first compilation phase performs all the machine independent optimizations (such as folding, eliminating redundant operations, moving invariant operations, reducing strength of operations, and eliminating dead variables and assignment operations) before it produces the final intermediate representation of the higher level language program. A general purpose dynamically microprogrammable computer interprets the compiler generated machine code to produce results. "Dynamically microprogrammable" means that the computer has a fast writable control store (much faster than main memory) that can be loaded under program control. Once compiled and debugged, programs will be executed repeatedly. Figure 1 summarizes the problem environment.

Problem definition

Basically, the problem is that computers understand, i.e., perform, machine oriented instructions, and as a result problems expressed in higher level languages must be transformed into machine language programs. The resulting machine language representations of programs are almost always inefficient, and hence the process of computer assisted problem solving in the environment discussed is inefficient. The genesis of this problem has been observed in the constraint of contemporary computer instruction sets to machine oriented operations rather than problem oriented operations:

> When engineers begin to seek more efficient encodings for commonly used sequences of instructions, progress toward the modern computer may begin.[4]

It has been observed that contemporary machines use inefficient machine languages to represent algorithms. More generally, the architectures of computers do not efficiently support programs being run. By computer architecture we mean the attributes of a computer as seen by the programmer, i.e., the conceptual structure and the functional behavior. The conceptual structure comprises such considerations as the memory hierarchy (registers, main memory, external store, etc. and their logical connections), the representation of data and instruction sets, and addressing schemes. The functional behavior is determined by the machine language instruction set, the instruction interpretation process, and the instruction execution process. The architecture of a computer is to be distinguished from its implementation which includes the entire set of machine registers (including the various memories), the physical connections among the machine registers, the mapping of the conceptual structure onto the physical structure, and the implementation of machine language instructions. The efficiency of solving a particular problem on a computer depends primarily on the degree to which the architecture of the computer supports the problem primitives. The primitives of major concern in expressing a problem are the data structures inherent in the problem, the operations (transformations) that manipulate the data structures, and the flow of control or sequencing among the operations. These primitives are employed in the formation of a program which represents an algorithm to solve the problem. Since there is a wide range of problems and algorithms (programs) for solving them, each problem would be handled most efficiently by a computer whose architecture supports the primitives of the algorithm that solves the problem. To realize a variety of algorithms efficiently, it is therefore necessary to define architectures for the different problems.

With a given control store size, the factors of concern that measure the performance of a machine in executing a program are the time required to execute the program and the main memory space required to store the program. While time and space are also functions of the machine realization (e.g., the technology from which the memories are fabricated), here we are interested only in the architectural changes that affect the time and space required to execute a program.

The problem under study may be summarized as follows:

Given a higher level language program and a dynamically microprogrammable computer with a fixed size control store, design an architecture (including the instruction set into which the program can be translated) that (when interpreted by the machine) minimizes the execution time and main memory requirements for the program.

Related work

A design approach that is presently being popularized commercially is language directed computer architecture. As early as 1967, McKeeman noted the absurdity of expecting modern digital computers (which are designed to be very fast automatic desk calculators) to be suitable hosts for supporting such diverse applications as operating systems and compilers.[4] In the Burroughs B1700 computer,[5] there is a novel "S-Language" for each higher level language. The S-Languages are interpreted by microprograms that reside in main memory or in a faster writable control store. While language directed computer architecture shows considerable improvement over the traditional single machine language architecture, there is still considerable disparity between language directed instruction sets and ideal instruction sets for programs.

Microprogramming has been used to improve the performance of programs in several application areas.[3] Inserting microprograms into control store to support a class of problems results in application or environment oriented architectures. The success of this approach depends on the size of the application area. Good results may be obtained for small, well defined application areas.

The approach developed subsequently is an extension of the language directed and environment directed approaches that does not rely on characteristics of particular languages or characteristics of particular environments.

APPROACH

Implementing problem oriented architectures via microprogramming

Within the given environment there are alternative approaches to implementing performance improvement by redefining computer architecture for individual problems. Of concern are the flexibility of the implementation and the binding time of the redefinition.

Since it is necessary to define an architecture for each problem, one approach to implementing architecture definition is to design for each problem a special purpose machine based on the structure of the algorithm and its intrinsic data structures. This approach has been used by Shay[6] in designing machines whose algorithms exhibit natural parallelism. Such an implementation, however, yields a special purpose machine for each class of similarly structured problems. The expense in building a special purpose machine can generally be justified only in dedicated situations, such as real time radar signal processing.

From a pragmatic view, the architecture of a general purpose computer (especially the machine language instruction set) is defined by microprograms resident in the control store and the associated implementation which the microprograms control. The microprograms interpret the machine language instruction set and thus define the instruction format, the instruction set, the instruction interpretation process, and the addressing schemes. Since microprograms control the referencing of machine registers, the microprograms also determine the conceptual structure of a computer's architecture. Changing the microprograms in the control store of a machine therefore redefines the architecture of a computer. Since the problem environment under consideration specified dynamically microprogrammable computers (to reflect capabilities of a large number of contemporary machines), changing the microprogram is a simple task.

Dynamic redefinition

Defining architectures for specific problems requires changing the microprogram in control store for each problem. As problems are represented by higher level language programs that are analyzed by compilers, it is natural to have the compiler generate microprograms.

The approach then is to replace the code generation phase of a compiler by a procedure that performs the following operations:

(1) generates a microprogram that defines an architecture for efficiently supporting the higher level language program being compiled (this includes interpreting the machine language programs of the architecture) and
(2) generates the machine language program for the defined architecture that represents the higher level language program being compiled.

To execute the compiled program, the generated microprogram and machine language program are dynamically loaded into control store and main memory to redefine the architecture of the general purpose host machine. This approach is called dynamic problem oriented redefinition of computer architecture via microprogramming.

Because control store is such a limited resource, translating each higher level language program directly into microcode is not feasible; there would be too many microinstructions for the control store to hold. The compiler, therefore, must still generate a "machine language" program that, when interpreted, effects the algorithm. This means that there is an almost infinite variety of "machine languages".

Effect of control store availability

Since control store is a limited resource, the performance of the procedure that generates microprograms depends on the amount of available control store. Usually control store is small compared to main memory, so the number of generated microinstructions cannot be large. This means that the number of special instructions is small and that most program operations are represented by instructions in a basic machine language.

The instruction sets of the large majority of contemporary computers are redundant in that many operations can be implemented by several different sequences of machine language instructions. As an early example of redundancy in instruction sets, one research group found that "from the programming point of view, little flexibility would be lost if the set of instructions on the CDC-3600 were reduced to less than ½ or ¼ of the instruction options now available."[2] Similar remarks apply to almost all contemporary computers.

Since machine language instruction sets are so redundant, an obvious way to obtain more control store for use in architecture redefinition is to remove the microprograms that interpret superfluous machine instructions. A machine instruction is superfluous if none of the operations in the program need be implemented using that instruction. While this method can provide more control store, it has disadvantages. Upon removal of some machine language instructions, the instruction set, though still complete, may be very inefficient. That is, it may require several machine language instructions to implement an operation that formerly required just a few machine language instructions. The instruction set may not be well rounded, i.e., some operations could be easily implemented while others would be implemented inefficiently.

A better approach would be to design a "kernel" machine language which is simple, complete, balanced, and does not have trivial redundancy. Operations in the kernel machine language should include operations for flow of control constructs, arithmetic and logical operations to manipulate the primitive data types, I/O operations, etc. The actual language of course depends on the environment in which programs will run, e.g., for simple business applications there is little need for data types like real and complex or for data structures like sets and lists. Even within a single computer system it is feasible to have a variety of kernel languages for application to a variety of problem types. The microprogrammed implementation of kernel machine language instruction sets uses only a small portion of control store. It is not minimal but reasonable in its implementation of program operations.

METHODS FOR DEFINING NEW INSTRUCTION SETS

Instruction sequence method

Many researchers have observed that instructions in the static representation of a program fall into natural sequences.[2,7] That is, having seen an instruction at a certain location in the program, some instructions are more likely to follow it than other instructions. Contemporary machine languages generally do not take advantage of this dependence. When considering particular programs to be run on a computer, the observation about dependence between pairs of machine language instructions can be extended to operations in intermediate language programs. It is characteristic of programs to use the same sequence of operations at many points. This observation is the basis for the sequence method of defining new "machine language" instructions.

The sequence method analyzes the intermediate language representation of a program to find all sequences of instructions and the number of times each sequence appears. The method then compares the microprogrammed implementation of each sequence to its machine language implementation. The microprogrammed implementation of a sequence will show improvement over the machine language implementation because it represents a sequence by a single operation code instead of many operation codes. The sequences that yield the most savings are selected as new "machine language" instructions.

As a result of developing new instructions that replace several instructions, the sequence method will also reduce program execution time. The improvement does not usually approach optimality because the method does not take into account the interaction of sequences, especially the dependence between sequences and their subsequences. As the sequence length increases, the number of occurrences of different sequences decreases. Thus there is a tradeoff in implementing sequences of different lengths as new instructions. While representing each occurrence of a long sequence by a new instruction reduces memory size (and execution time) more than replacing its constituent short sequences does, it may be advantageous to use the available control store to interpret instructions that represent short sequences because they appear more frequently in the intermediate language program.

Program structure method

The intermediate language representation of a higher level language program has been used as input to the architecture redefinition process. This static description of the program does not directly provide information about the run time behavior of the program. To minimize execution time, however, the architecture redefinition process requires knowledge of the run time behavior.

One way of learning about the run time behavior of a program is to execute it many times with several representative data sets. By monitoring these executions, information about the run time behavior may be gathered for analysis. An alternative method is to estimate the dynamic behavior using knowledge of input data and statistical techniques. The program structure method for defining new instructions assumes knowledge about the execution behavior of a program. More specifically it assumes knowledge of the frequency of execution of program blocks, i.e., sequences of operations that are executed sequentially with no branching or selection. (Thus if the first operation in a block is executed, all the operations will be executed.)

For each block, the program structure method compares the execution times of the microprogrammed implementation and the machine language implementation. The microprogrammed implementation will require less execution time than the machine language implementation because few instructions need to be fetched and decoded. The method then multiplies the difference by the number of times the block will be executed.

The blocks that yield the most total execution time improvement are selected as new "machine language" instructions.

Some empirical evidence has been reported to support the efficacy of this method. In one study, Knuth "found that less than four percent of a program generally accounts for more than half of its running time."[8] Given that forty percent of the time involved in performing machine language instructions is devoted to fetching and decoding the instructions, Knuth's findings imply that this architecture redefinition method can easily reduce execution time by twenty percent.

A combined method for architecture redefinition

The two methods presented for defining applications oriented architectures may be criticized for using only some of the available information. The sequence approach defines instructions that appear globally throughout a program, however, it does not consider program behavior at execution time. The structure approach defines operations that are local to a part of the program, however, it does not consider the operations that constitute the blocks throughout the program. For these reasons we consider a combined approach.

As in the sequence method, the combined method first finds the different instruction sequences, the places they appear in the program, and the differences between the execution times of the microprogrammed implementation and the machine language implementation. For each sequence, the combined method then multiplies this savings by the expected frequency of execution of the sequence. For all occurrences of a sequence throughout a program, these products (savings times execution frequency) are added. The resulting sums represent for each sequence the total execution time saving when the program is run. Those sequences with the highest savings can then be microprogrammed as new "machine language" instructions.

Defining new architectures in this way reduces program execution time for two reasons. First, fewer "machine language" instructions need to be fetched from main memory and decoded because several operations have been represented by a single new operation code. Second, the microprograms that interpret the new instructions may be optimized. The amount of space required to store the program will also be reduced because several sequences of machine language instructions are replaced by single new instructions.

EXAMPLE IMPLEMENTATION

Environment

An example implementation has been developed to demonstrate the practicability of problem oriented redefinition of computer architecture by microprogramming. The implementation consists of:

(1) the analysis phase of a compiler for a higher level structured programming language,
(2) a procedure that takes the output of the analysis phase and generates microprograms that define an architecture to support the higher level language program being compiled and also generates machine language instructions to represent the higher level language program, and
(3) a simulator that interprets the microinstructions of the host machine.

The higher level language chosen for the implementation was ULP,[9] a language that is simple in structure and general in scope, yet maintains the philosophy of structured programming. The simulator was developed for the Digital Equipment Corporation PDP-11/05 (See Figure 2) with some minor differences. The most important difference was the assumption of a writable rather than a read only control store. This machine was chosen because good documentation was available on the microinstruction format and the machine language emulator, the microprogram level architecture was fairly simple and general (if somewhat inefficient for general purpose use), and the machine size epitomizes situations where architecture redefinition would be beneficial. The simulator simulates microinstructions that interpret machine language instructions. The architecture redefinition program takes the intermediate language representation of a higher level language program generated by the ULP compiler and performs the combined procedure using a kernel language as described previously.

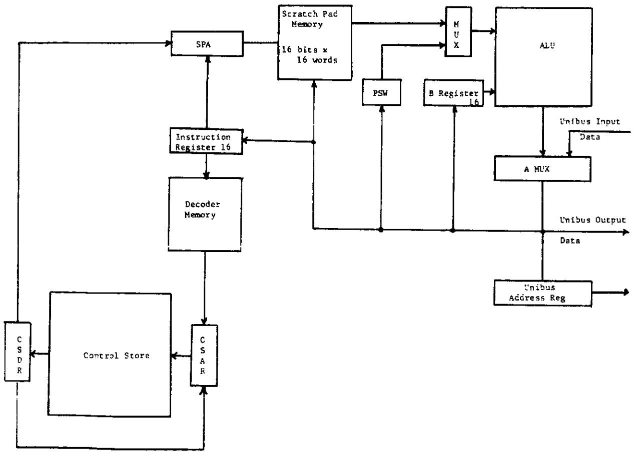

Figure 2—Organization of the PDP-11/05

With the ULP language and compiler, the architecture redefinition program, and the PDP-11/05 simulator it is easy to compare the performance of a program as executed on the PDP-11 architecture to the performance of the program as executed on the redefined architecture.

Simulation results

For the simulations, two ULP programs were selected. The first program is a part of a programming system developed to design telephone exchanges, and the second program computes operator precedence relations for an input grammar. Each program was simulated nine times on each of two different input data sets, for a total of thirty-six simulation runs. Of the nine simulations for a program on one set of data, the first represented the standard PDP-11 architecture interpreted by the PDP-11/05 emulator. The remaining eight simulations represented the kernel and redefined architectures (generated by the architecture redefinition program) using control store sizes ranging from 64 to 512 words in increments of 64 words. Each simulation recorded the execution time, the number of machine language instructions executed, and the number of microinstructions executed.

As illustrated in Figure 3, execution time for the simulated programs decreased as the amount of available control store increased. Especially important are the decreases in execution time of the redefined architecture using 256 control store words compared to the PDP-11 architecture (which also uses 256 words of control store). The execution time improvement of more than twenty-five percent may be somewhat modest because small data sets were used to keep simulation times reasonable (less than ten minutes on a UNIVAC 1108). In retrospect, larger (and more typical) data sets would have resulted in the programs spending more of their time in frequently executed program loops. As these loops contained new instructions, significant additional time savings would accrue.

Figure 4 illustrates the effect of the new instruction set on program execution. It shows that the number of executed "machine language" instructions on the new architecture was less than half of the number of machine language instructions executed by the PDP-11.

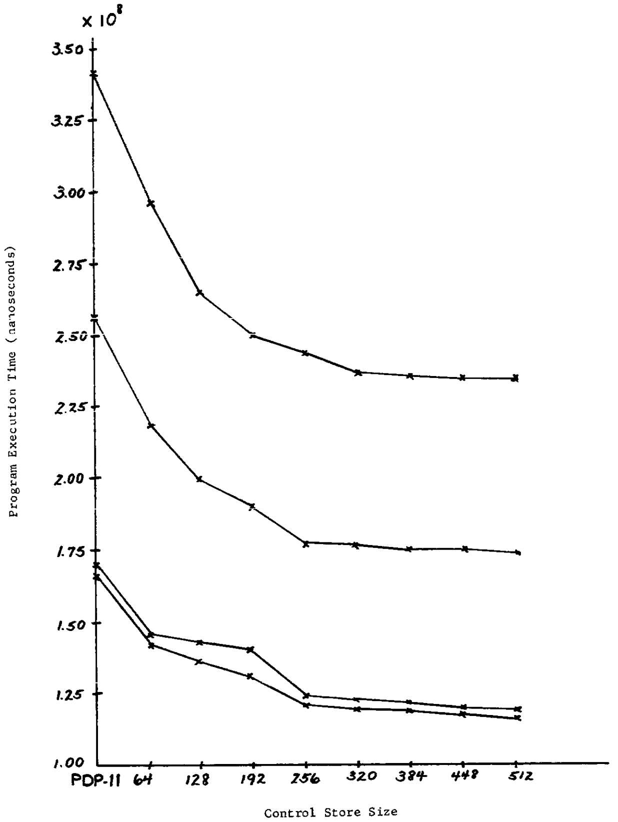

Figure 3—Program execution time vs. control store size for simulated programs

The defined architectures were indeed oriented toward the particular applications.

SUMMARY

The purpose of this paper was to investigate techniques involved in defining architectures to support different problems solved on general purpose computers. In the selected approach microprograms are generated by a compiler and loaded into the control store of a computer thus redefining the machine architecture for the particular problem program.

The first technique for designing new instruction sets was motivated by the observation that instruction executions exhibit repeated sequences of operations. The sequence approach searches through the intermediate language representation of a program and represents commonly occurring sequences as new machine instructions. The second technique was motivated by the observation that different program parts are executed with different frequencies. From the dynamic behavior, the program structure approach represents the most frequently occurring program blocks as new instructions. The architecture redefinition procedure developed to solve the problem combined the techniques used in the sequence and program structure methods.

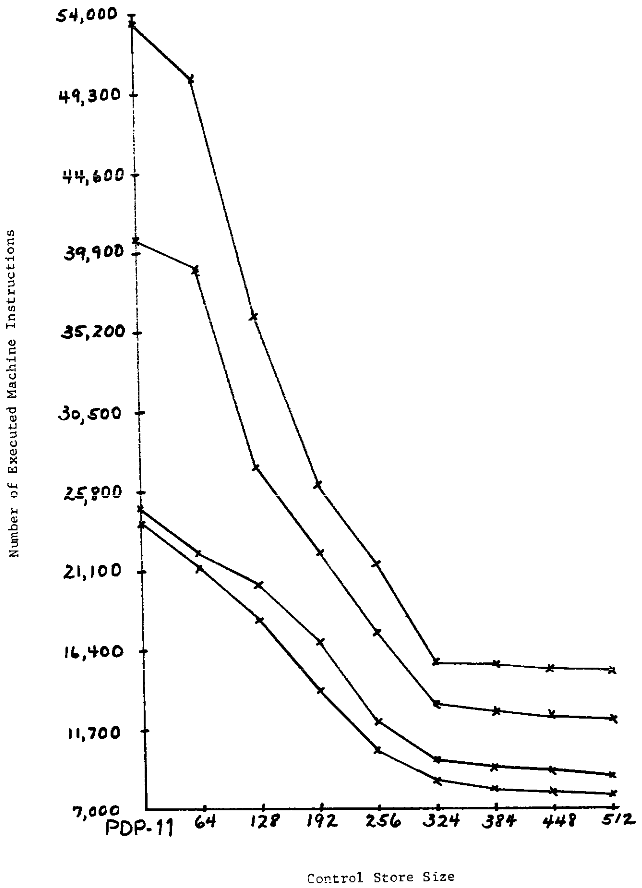

Figure 4—Number of executed machine instructions vs. control store size for simulated programs

An example implementation using this procedure was developed. Simulations provided empirical verification of the procedure in improving performance by defining architecture oriented toward particular applications.

A pipeline polish string computer*

by GERARD G. BAILLE and JEAN P. SCHOELLKOPF
Computer Architecture Group
Grenoble University, France

ABSTRACT

This paper describes a new computer organization which allows the pipeline execution of a polish-string code. The central characteristic of the proposed organization is a FI-FO queue, that holds values just accessed by an Access Station, until they are used as operands by an Execution Station for an arithmetic or logical operation. Operands are taken out of the queue by means of two pointers whose modifications are managed by a Control Station. This new computer organization is capable of high performance, since access to variables and execution of operations are performed in parallel with control functions required by the input program. A solution to access conflicts is proposed, using a content addressable memory that holds the names of the variables whose modification is deferred. This architecture is currently in application for the design of a high-level PASCAL computer.

INTRODUCTION

Design of high performance computers can be achieved using the technique that is called "pipeline" design, characterized by the fact that concurrent operations are supported by the machine.[10] A high-level instruction can be initiated within a module, and in the same time the other modules are executing some operation related to a preceding instruction. The IBM 360/91[1] and the CDC 6600[2] are two examples of pipeline execution. Efficiency of pipeline computers depends strongly on the way that they are programmed. Many attempts were made to solve this problem and several techniques are proposed for generating optimized code in terms of pipeline execution.[3-5] These techniques imply an important amount of preprocessing, which does not always justify the complexity of pipeline execution.

The solution proposed in this paper is based on a *natural* decomposition of the work to be executed in a pipeline manner. The first aspect of a natural decomposition is related to the kind of language proposed to the machine. Tomasulo[9] gives an efficient algorithm for exploiting a pipeline architecture, but its application is limited to a low level language. On the other hand polish-string code appears as best suited for the execution of high level language.[6]

Stones[7] proposes a pipeline architecture for a push-down stack computer, but he suggests to translate the input polish-string code into three address instruction code. This paper shows, in a first section, how polish-string code can be directly executed by a pipeline computer. The second aspect of a natural decomposition, as shown by Abrams,[8] is related to the decomposition of input string code execution into three *natural* processes that are control, access to operands and execution of operators. It would be interesting to have the three above processes concurrently running in a pipeline manner: the execution of an instruction would be initiated within the control station, and in the same time preceding instructions would be currently in process either within the access station or within the execution station. Such a pipeline organization is made possible using a FI-FO queue instead of a push-down stack as a work area for expression evaluation. Operands are accessed from the queue by means of two pointers whose modifications are controlled by the control station which generates extra-orders. The generation algorithm is presented and the rate of extra-orders is evaluated in the first section.

The second section of this paper gives the general architecture of the pipeline polish string computer. Concurrency between access to operands and evaluation of expression to be assigned to variable leads to the well-known problem of reading the value of a variable whose modification is not yet performed. This problem, that is called "dependency" problem, is solved at execution time using a content-addressable memory which holds the name (not the address as in classical pipeline computers) of the variables whose modification is deferred.

A brief summary is given at the end of this paper, which shows the possible applications of the proposed pipeline architecture.

PIPELINE EXECUTION OF POLISH STRING CODE

This section first explains the choice of a FI-FO queue as a work area for evaluation of polish string. A model is introduced for polish string expressions which allows the definition of two pointers for operand access. The operator set is reduced to monadic and diadic operators. The management of the two pointers is controlled by special extra-orders generated by a Control station. The generation algorithm is presented and discussed.

The central characteristics of the pipeline execution is that the input polish stream is analyzed by a processor which generates two parallel instruction streams towards two concurrent processors specialized the one for access to operands, the other for execution of operations.

Polish string evaluation

A polish string can be seen as a sequence of groups, each group being a sequence of operands followed by a sequence of operators. An operand is either an immediate value or the internal name of a variable (for example, lexical level and offset) which allows the calculation of the variable address in main memory.

example:

$$\underbrace{[A,B,C,D,+,*,]}_{\text{group 1}}\quad\underbrace{[E,F,+,]}_{\text{group 2}}\quad\underbrace{[G,*,+,-]}_{\text{group 3}}$$

The evaluation of such a polish string requires the use of a working storage classically organized as a push-down stack.

All the operands of a given group are pushed, one after the other, into the stack, in the same order as in the input string, next operators are sequentially executed, poping the two topmost elements from the stack, and pushing the result onto the stack.

When all the operators of the current group are executed, the operands of the next group are pushed onto the stack, and the above process is performed again.

Therefore, two processes appear when evaluating a polish string:

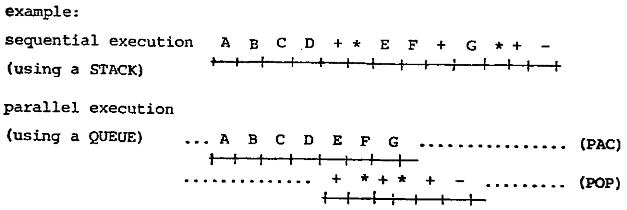
- —an ACCESS process which stores the operands into the working storage (either from the string when immediate access, or from main memory in the other case)
- —an EXECUTION process which executes the operators, taking its operands out of the working storage and storing intermediate results into it.

Using a push-down stack as working storage implies the sequentiality of the two above processes. The aim of this paper is to propose an evaluation method which allows parallel execution between ACCESS and EXECUTION process: parallelism is made possible using a FI-FO queue instead of a PUSH-DOWN stack.

Organization

The above two processes are executed by two independent processors. Let PAC be the processor which stores the operands into the FI-FO queue, and POP be the processor which executes the operators, taking its operands out of the queue.

Hence, when POP is executing an operator, PAC can ACcess to a new operand and store it into the queue.



example:
sequential execution
(using a STACK)
A B C D + * E F + G * + -
parallel execution
(using a QUEUE)
... A B C D E F G .... (PAC)
.... + * + * + - .... (POP)

Such an organization requires a third processor which is called PAN, whose work is the ANalysis of the input polish string in order to generate instructions for both processors (PAC and POP).

The architecture is given by Figure 1.

THE EVALUATION PROCESS USING A FIFO QUEUE

Variables whose names appear in the input polish string are stored into the FIFO queue by the Access Processor. The sequence of the access instructions is the same as the sequence of the variable names in the input string. So, we can define the relative location of any variable in the queue, depending on its relative location in the input string.

Let $\bar{S}=(V_1^1, \ldots, V_1^{n_1}, O_1^1 \ldots O_1^{m_1}, \ldots, V_p^1 \ldots V_p^{n_p},$

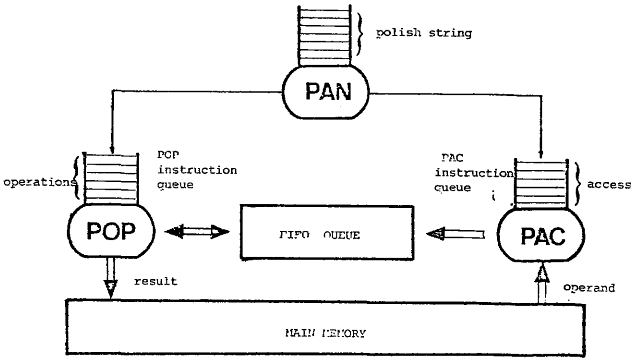


Figure 1

$O_p^1 \dots O_p^{m_p}$) be the input string, where V_i^j is a variable name, and O_i^j is an operator name.

If the relative location of the first variable V_1^1 is equal to 1, then the location of any variable V_i^j is given by the formula:

$$1(V_i^j) = \sum_{r=0}^{i} n_2 + j, \text{ with } n_0 = 0$$

How can we access to the operands located in the queue

The evaluation of polish string is a sequence of monadic or diadic operators execution. In a first approach, let us consider that all the operators are diadic ones. We must associate to each operator its two operands, whose locations are partly defined by the next two rules:

RULE 1: if O_i^1 is a diadic operator, then its second operand is variable $V_i^{n_i}$, and its first operand is either variable $V_i^{n_i-1}$ if $n_i>1$, or the result of the immediately preceding operator $O_{i-1}^{m_{i-1}}$ if $n_i=1$.

RULE 2: for $j=2$ to n_i, the second operand of operator O_i^j is the result of the preceding operator O_i^{j-1}.

We see that the variables are not referred to as operands in the same order as in the input string:

for each group $G_i = (V_i^1, \dots, V_i^{n_i}, O_i^1, \dots, O_i^{m_i})$ the first accessed variables are $V_i^{n_i}$ and $V_i^{n_i-1}$ as operands for operator O_i^1, the last accessed variable V_i^1.

Hence, it is idle to pull the operands out of the queue in a FIFO mode, since it should be necessary to store them again into another memory, organized as a Push-down stack.

So, we propose to use the queue as a working storage from which operands are accessed by means of two pointers, and into which intermediate results are stored during the evaluation process.

Definition of two pointers

Let us define P1 and P2 as two pointers which hold respectively the address of the first and second operand of any diadic operator during the evaluation process.

As an example, let $S = (V_1^1, V_1^2, V_1^3, O_1^1, O_1^2, V_2^1, V_2^2, O_2^1, O_2^2)$ be the input string. The variables are stored into the queue in the following manner:

	1	2	3	4	5	
...	V_1^1	V_1^2	V_1^3	V_2^1	V_2^2	....
	↑ first-in				↑ last-in	

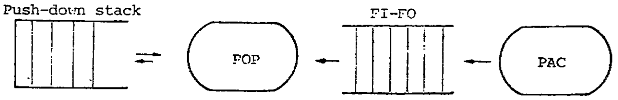

Figure 2—Classical organization

The input polish string defines the sequence of operations as follows:

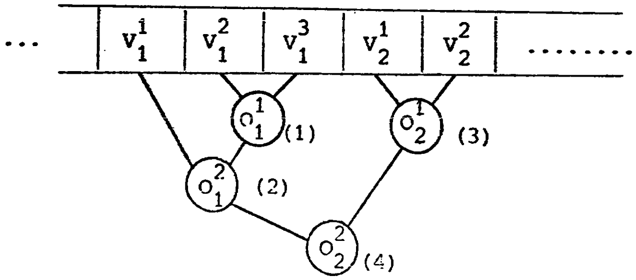

Figure 3

We must generate orders for initializing P2 on variable V_1^3, P1 on variable V_1^2 before executing operator O_1^1, whose result is immediately used as second operand for the next operator O_1^2, whereas pointer P1 must be decremented by one in order to give the address of variable V_1^1 as first operand for operator O_1^2.

The next diagram shows the successive states of the queue and the successive values of pointers P1 and P2.

Initialization of pointers

Both pointers P1 and P2 must be initialized after execution of the last operator of group G_{i-1} $(O_{i-1}^{m_{i-1}})$ and before execution of the first operator of the next group $G_i(O_i^1)$. We know that pointer P2 gives the address of the location which holds the results of operator $r(O_{i-1}^{m_{i-1}})$: this address is equal to $1(V_{i-1}^{n_{i-1}})$. We must assign to P2 the address of the second operand of operator O_i^1, which is variable $V_i^{m_i}$ (from rule 1), whose address is equal to

$$1(V_i^{n_i}) = \sum_{r=0}^{i} n_r = \sum_{r=0}^{i-1} n_r + n_i$$
$$= 1(V_i^{n_i-1}) + n_i$$

So we must increment the previous value of P2 by n_i. Moreover, pointer P1 must hold the address of the first operand of operator O_i^1, which is either variable $V_i^{n_i-1}$ if $n_i>1$, or the result of operator $O_{i-1}^{m_{i-1}}$ if $n_i=1$.

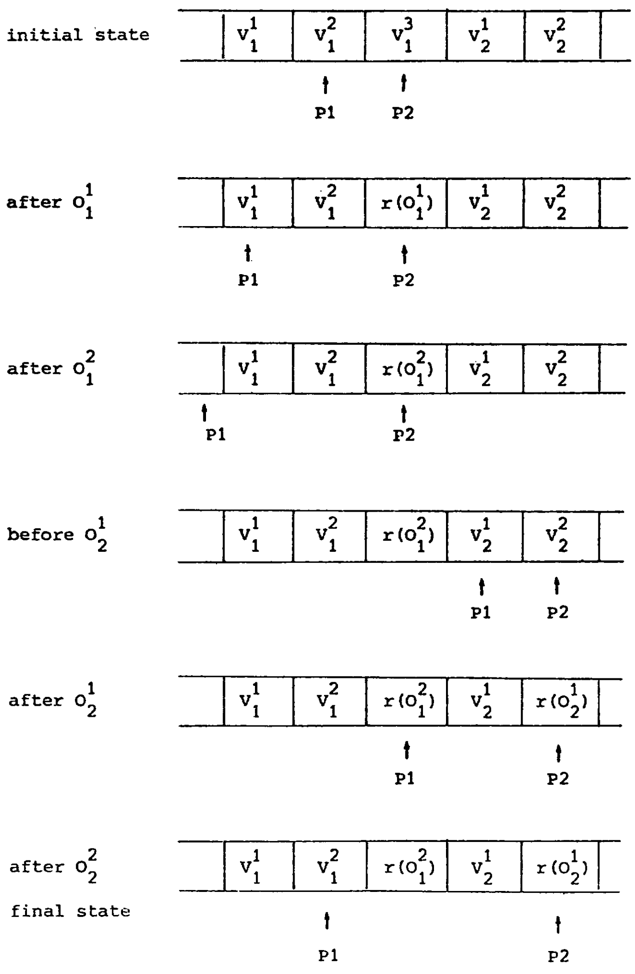

Figure 4

In both cases:

$P1 = l(V_{i-1}^{n_{i-1}}) = l(V_i^{n_i}) - 1 = P2 - 1$ if $n_i > 1$,

$P1 = l(V_{i-1}^{n_{i-1}}) = l(V_i^{n_i}) - n_i = P2 - 1$ if $n_i = 1$

So, we define an EXTRA-ORDER, generated between the execution of $O_{i-1}^{m_{i-1}}$ and the execution of O_i^1, called UP (n_i), which is interpreted as:

$$\boxed{P2 \leftarrow P2 + n_i \; ; \; P1 \leftarrow P2 - 1}$$

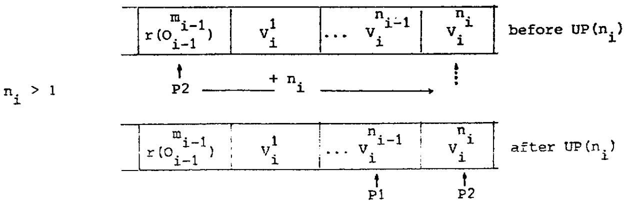

Figure 5

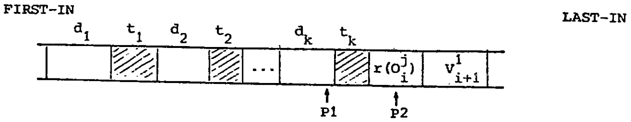
The intermediate states of the queue

Each time a diadic operator is executed, the location which holds the first operand will be no more accessed: we say that a "hole" is created or the the location becomes "empty". So, during evaluation process, the state of the queue is defined as a sequence of empty locations followed by full locations which hold either not yet accessed variables or intermediate results. We associate to the state of the queue, after execution of any operator O_i^j a finite sequence

$\{(d_1, t_1), (d_2, t_2), \dots\dots, (d_k, t_k)\}$, where each d_i is the length of a full location sequence, and each t_i is the length of an empty location sequence



The successive values of pointers P1 and P2 can be defined related to the state of the queue:

P2 must hold the address of the result $r(O_i^j)$, and P1 must point to the full location downstream of the location pointed by P2.

Each time an operator is executed, a new hole is created, therefore the last element of the sequence $\{(d_i, t_i)\}$ must be modified: t_k is incremented by 1 and d_k is decremented by 1. During execution, pointer P1 will be decremented by one. However, d_k may become zero, in which case pointer P1 must be decremented again by a value equal to t_{k-1}, in order to point to the first full location downstream of P2.

In the same time, the queue state is updated, by suppressing the last element

$t_k \leftarrow t_{k-1} + t_k \; ; \; k \leftarrow k-1$

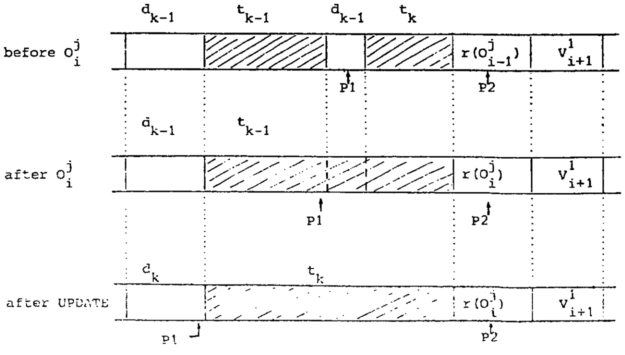


Figure 6

Conclusion—An extra-order called DOWN must be generated by the PAN processor, when the queue state is updated: its execution is defined by: $P1 \leftarrow P1-n$, where n is equal to t_{k-1}, when the order is generated.

Modification of the queue state before execution of a new group

Between execution of operator O_{i-1}^{m-1} (the last operator of group G_{i-1}) and execution of operator O_i^1 (the first operator of group G_i), an extra-order UP must be generated. This movement of pointers corresponds to a modification of the queue state: a new element (d_{k+1}, t_{k+1}) is created, initialized as follows: the new group G_i is defined as a sequence of n_i operands, hence $d_{k+1} \leftarrow n_i$, and zero hole has been created, hence $t_{k+1} \leftarrow O$.

Conclusion—An extra-order called UP must be generated by PAN processor in order to update the queue state before the first operator of a new group. Its execution is defined by:

$$P2 \leftarrow P2+n \ ; P1 \rightarrow P2-1$$

where n is equal to $d_k = n_i$, when the order is generated.

GENERATION OF EXTRA-ORDERS FOR THE MANAGEMENT OF THE POINTERS

The proposed evaluation process using a FIFO queue requires the generation of extra orders for the management of the pointers. As shown above, three kinds of orders must be sent to the execution processor:

—the first kind consists in all the monadic or diadic operators, whose execution is defined by:

$$Q(P2) \leftarrow Q(P1) <Op> Q(P2) \qquad \text{(diadic operator)}$$

or

$$Q(P2) \leftarrow <Op> Q(P2) \qquad \text{(monadic operator)}$$

The arithmetic or logical diadic operation is followed by a modification of pointer P1:

$$P1 \leftarrow P1-1$$

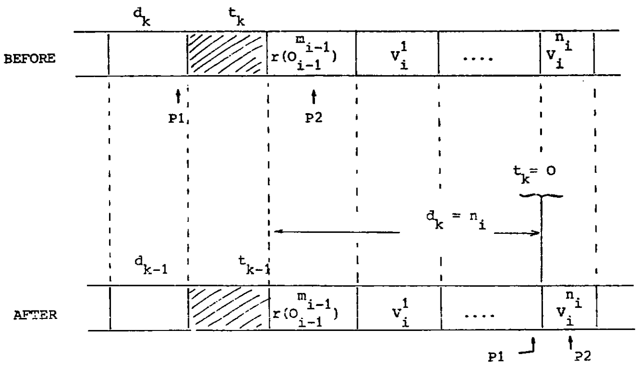

Figure 7

—the second kind is the UP(n) extra-order which is executed when a new group is entered. It is defined as:

$$P2 \leftarrow P2+n;$$
$$P1 \leftarrow P2-1.$$

—the last kind is the DOWN(n) extra-order, which consists in the updating of pointer P1; it is defined as:

$$P1 \leftarrow P1-n$$

Evaluation of the number of extra-orders to be generated

The number of extra-orders $(n_{up}+n_{down})$ to be generated only depends on the input string.

Let $S = (V_1^1, \ldots, V_1^{n_1}, O_1^1, \ldots, O_1^{m_1}, \ldots, V_p^1, \ldots V_p^{n_p}, O_p^1, \ldots, O_p^{m_p})$ be the input string.

Such a string contains

$N = \sum_{r-1}^{p} n_r$ variable names, hence N access instructions for the access processor PAC, and

$M = \sum_{r-1}^{p} m_r$ operators, hence M instructions for the execution processor POP. If all operators are diadic ones, then $M = N-1$, but in general we have $M \geq N-1$. Hence the initial number of orders is equal to $M+N \geq 2N-1$.

Each time a new group is entered, one must jump over its sequence of variables, that is to say that the number of extra UP orders to be generated is equal to the number p of groups in the input string. The evaluation of the number of extra DOWN orders is a bit more difficult to do. Let k_i be the number of extra DOWN orders generated during the execution of group G_i. The maximum value of k_i is equal to $i-1$, since the queue has a maximum number of holes equal to $i-1$. Furthermore, each executed DOWN order decreases the number of further possible DOWN orders by 1, since one hole is suppressed.

Hence we have $O \leq k_i \leq (i-1) - \sum_{j=1}^{i-1} k_j$, for all i.

When adding the above formula for all i, we get:

$$O \leq \sum_{j=1}^{p} k_j \leq \sum_{j=1}^{p} (j-1) - \left[\sum_{j=1}^{i} k_j + \ldots + \sum_{j=1}^{p-1} k_j \right]$$

which becomes:

$$\sum_{i=1}^{p} \left(\sum_{j=1}^{i} k_j \right) \leq \sum_{j=1}^{p} (j-1) = \frac{p(p-1)}{2}.$$

Hence we have the number of extra Down orders given by

$$O \leq \sum_{j=1}^{p} k_j \leq \frac{p(p-1)}{2} - \frac{(p-1)(p-2)}{2} = p-1.$$

However, if the number N of variables is less than 2p ($N \leq 2p$), than the maximum number of diadic operators is less than $2p-1$. As the p operators O_1^1, $O_2^1 \ldots$, O_p^1 cannot imply the generation of a DOWN order, we have only $p-1$ operators which can do so. Hence the maximum number of extra DOWN orders is equal either to

$$N-p-1 \text{ if } p+1 \leq N \leq 2p, \text{ or to } p-1 \text{ if } N \geq 2p.$$

Now it is easy to see that the minimum rate of extra-orders is given by:

$$\text{MINRATE} \leq \frac{P}{2N-1}$$

and the maximum is given by:

$$\text{MAXRATE} \leq \frac{N-1}{2N-1} \text{ if } p+1 \leq N \leq 2p,$$

$$\text{MAXRATE} \leq \frac{2p-1}{2N-1} \text{ if } N \geq 2p$$

Example:

$$S = (A, B, C, *, +, D, -)$$

In this case, there are $p=2$ groups, and $N=4$ variables. Hence $N \geq 2p$

$$\text{MINRATE} \leq \frac{2}{7}$$

$$\text{MAXRATE} \leq \frac{3}{7}$$

Trade off between compile time and execution time for the generation of the extra-orders

The generation of the input string is performed by the compiler, which could easily generate extra-orders. However, the compiler becomes machine dependent in such a case, and the size of generated code is increased, as the number of instruction fetches from main memory at execution time. Hence, the best solution consists in the analysis of the polish string at execution time, since the compile time solution would slow down the global performance of the machine. The generation is made by the analysis processor PAN, which can be considered as the control processor, and execute all the control function of the computer.

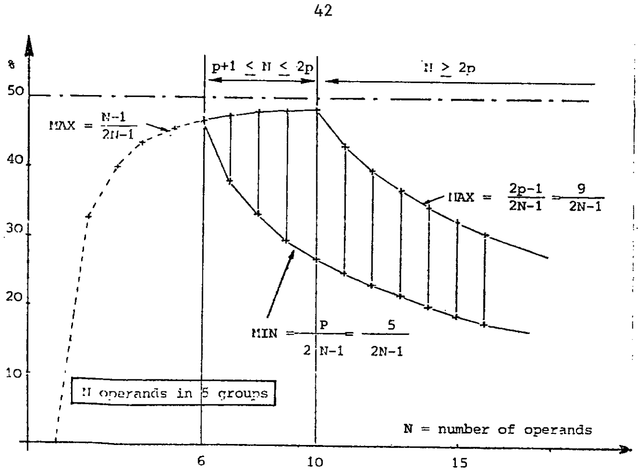

Figure 8

Algorithm for the generation of extra-orders at execution time

Generation of orders is performed by the analysis processor PAN. Given the input polish string, this processor must generate orders towards both processors PAC and POP, using the theoric state of the queue, represented by the sequence $\{(d_i, t_i)\}$ defined earlier. The sequence $\{(d_i, t_i)\}$ can be managed using a push-down control stack. Let TS and STS be the two topmost elements of the stack, which respectively hold the couples (d_k, t_k) and (d_{k-1}, t_{k-1}). These two variables TS and STS are structured as two fields called D and T, so d_k is equivalent to TS.D, t_k to TS.T etc.

The generation algorithm is illustrated in Figure 9, where the symbol (F_i) represents the name of the function to be executed when the next symbol in the input string defines the state transitions. The next symbol type is represented either by [variable] or by [operator].

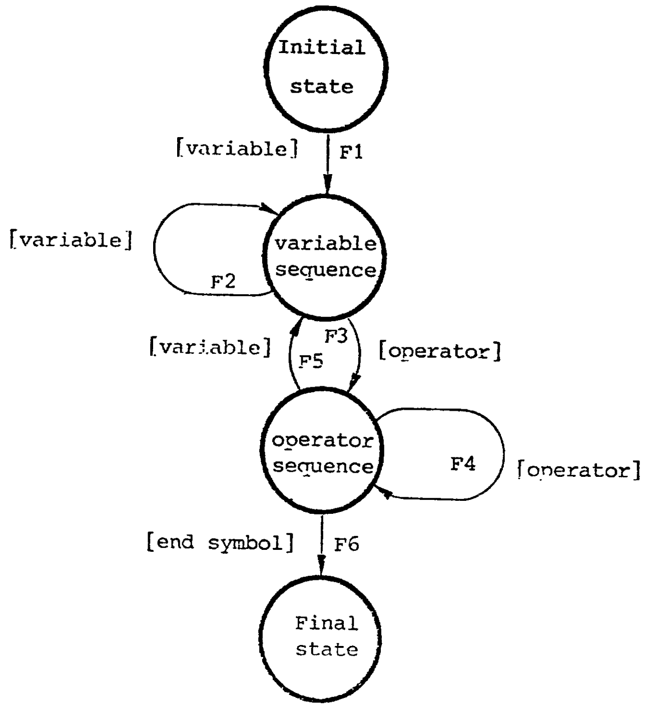

Figure 9

Function F1 initializes the queue state, by pushing the couple (−1,O) onto the control stack.

Function F2 generates an Access Order towards the Access Processor, next counts the number of variables in the current group, by incrementing the top of stack

$$(\text{TS.D} \leftarrow \text{TS.D}+1)$$

Function F3 is executed when the first operator of the current group is encountered. It occurs on the transition from $V_i^{n_i}$ to O_i^1. Its function is the generation of an UP extra-order, with a parameter n equal to the number of variables in the current group, which has been evaluated by function F2 (the parameter is equal to n_i since F2 has been executed n_i times).

Function F4 generates an Operation order towards the execution processor POP. If the operator is a diadic one, then the queue state is updated, modifying the top of stack element: TS.D←TS.D−1 since there is one less operand in the last group, and TS.T ←TS.T+1 since there is one more empty location in the last group.

If TS.D becomes zero, an extra-order DOWN is generated, with a parameter n equal to the second top of stack element STS: one generates DOWN (STS.T). Next the queue state is modified:

STS.T÷STS.T+TS.T since the length of the hole must be incremented and PULL(TS) since the topmost element is deleted (STS becomes the top of stack).

Function F5 is executed on the transition from $O_i^{m_i}$ to V_{i+1}^1, i.e. when the first variable of a new group is encountered. This function initializes a new element on the stack, only if the previous top of stack represents a real group.

if TS.D>O then PUSH(1,O)
else (TS.D←1, TS.T←O).

Function F6 is executed on the occurrence of the end-symbol, which is any separator symbol between two expressions (e.g. an Assign Symbol). It only verifies the correctness of the control stack state, which must be the empty state.

ARCHITECTURE OF A HIGH-LEVEL PIPELINE COMPUTER

The first section of this paper has shown that pipeline execution of polish string code is made possible using a FI-FO queue.

In this section, an architecture is presented for a high-level pipeline computer whose code is in polish string format. The dependency problem is first studied and a solution is given.

THE DEPENDENCY PROBLEM

Suppose, for example, that the high level instruction "X←<exp>" has been prepared in both PAC and POP instruction queues, or is in the process of execution by processor POP, when the access to variable X instruction enters the access processor PAC. The access processor must be able to detect the fact that both instructions refer to the same variable X, and that the second instruction might have to be deferred until the completion of the first instruction, since a reference to the location of X in main memory would not give the true value of variable X, but its old value.

The solution consists in the definition of a content addressable memory, organized in a FI-FO mode, which holds the name of the variables whose modification is deferred, and the name of the variables which have been just modified. In the first case (deferred modification), any reference to the variable is processed as an indirect reference by creating a link between the assignment and all the deferred references. In the second case a reference to main memory is eliminated, since the current value of the variable is available in the content-addressable memory after the completion of the last assignment.

Using the above mechanism, the access instruction (VALUE X) can be deferred until the completion of the assignment. All the deferred references are linked together, eliminating a number of memory references equal to the number of linked locations.

THE CONDITIONAL BRANCH PROBLEM

Both PAC and POP processors may be considered as SLAVES of the PAN processor in the following sense: then only execute the internal instructions that they receive from the PAN processor. Moreover, every in-

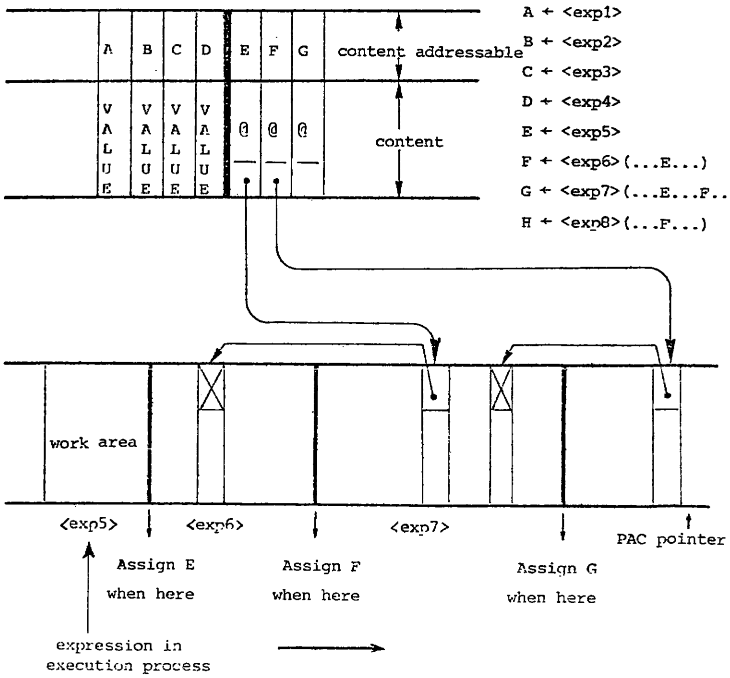

Figure 10

struction belonging to the input string is fetched by the PAN processor. So, this processor can be considered as the MASTER of the control, and it is involved in all control functions in the computer during execution of a single high-level program.

When a conditional branch occurs, the PAN processor is not able to fetch the next instruction, since the conditional expression is currently in the process of evaluation. However, the PAN processor may *choose* one instruction among all the possible next instructions (generally two). The probability of a bad choice strongly depends on the context of the conditional branch: it is much lower for a LOOP statement than for an IF statement.

When a choice is made, we say that the PAN processor enters a Conditional State, characterized by the fact that its activity is limited to a preparation work. Especially, if a conditional branch occurs during this conditional state, no choice is made, the processor waiting for the resolution of the first conditional branch.

When the value of the conditional expression is available, two cases may occur: either the choice was good, in which case the process goes on without any modification, or the choice was bad, in which case all the prepared work must be disabled. This is simply achieved by writing as "empty" the input instruction queues of both PAC and POP processors which hold bad instructions and updating both evaluation and dependency queues by deleting the sequence of "bad" operands or "bad" deferred variables (they are "bad" because they belong to the bad choice).

HOW TO SAVE THE EVALUATION CONTEXT

The evaluation context (intermediate state of the evaluation queue) must be saved when a "function call" occurs within an expression. Function calls are introduced in the input polish code in the following manner: any operand can be either a variable name or a function call.

The syntax of a function call is

(FCALL <name>, <parameter-list>, ENTER).

When FCALL is decoded by the analysis processor PAN, a special order is sent to the PAC instruction queue that calls for the address of a save area. This area is allocated on the top of a push-down stack, since several function calls can be nested. Next, processor PAN, which knows the current state of the evaluation queue, generates a sequence of DOWN and SAVE orders towards the POP instruction queue. Hence the current state of the evaluation queue can be saved before the function is entered, all previous results being compacted into the save area.

When the function is returned, processor PAC is capable to restore the initial state, pushing the function result just after the restored values, and the evaluation process goes on.

THE GLOBAL ARCHITECTURE OF THE COMPUTER

The pipeline computer architecture is shown by Figure 11. Each of the three processors can run concurrently. Their synchronization is data-driven. Processor PAN fetches high-level polish form instruction stream from Main Memory, and executes all the control instructions (IF, LOOP, GOTO, . . .).

It analyzes input expressions and generates two internal instruction streams towards both PAC (access instructions) and POP (execution of operation).

Two synchronous exchanges occur: the first one is concerned with the transmission of the entry address when a procedure is entered. The second one is the completion of a conditional expression which can disable the choice made by processor PAN on the occurrence of a conditional branch.

SUMMARY

The pipeline architecture described in this paper is potentially capable of high performance. Its input code is in a polish string format that can be directly translated from a block structured high-level language. The pipeline execution is based on a natural decomposition into control, access to operands and execution of operations, executed by three concurrent processors.

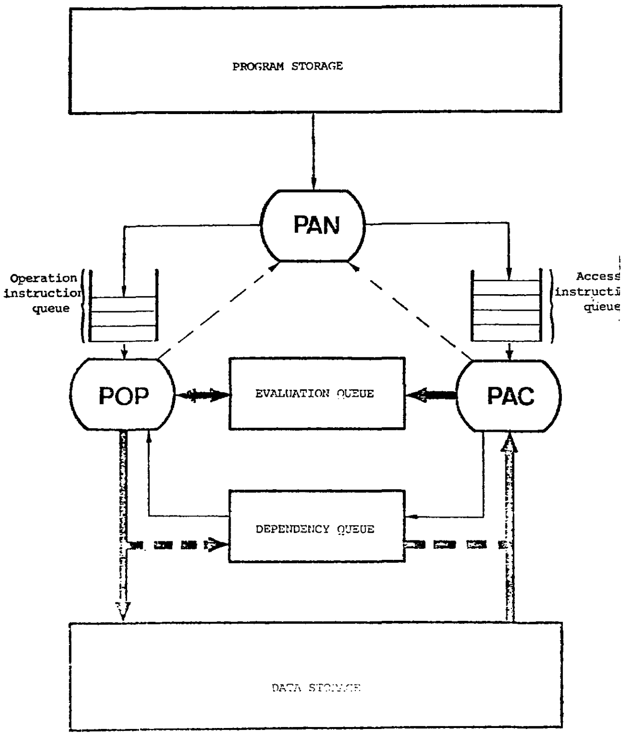

Figure 11—Architecture of the pipeline computer

This computer architecture is currently in application for the design of a PASCAL computer. Each of the three processors is in design using high speed macrologic components in Low Power Schottky Technology.[11,12]

ACKNOWLEDGMENTS

The authors would like to thank Dr. F. Anceau for his constant encouragement and helpful discussions and all members of the Computer Architecture Group of the University of Grenoble for their constructive criticism. Special thanks go to Mrs. H. Diaz for preparing the paper.

Evolution of computer memory structure*

by YAOHAN CHU
University of Maryland
College Park, Maryland

ABSTRACT

The memory structure of a computer refers to those hardware elements that store the data elements and the related information during program execution. It has a great impact upon the usage and the programming of the computer. Since the advent of commercial electronic digital computers, the memory has made great hardware advances in speed, capacity, size, cost and reliability. It has also made great organizational changes.

This paper reviews the memory structure of typical computers from the viewpoint of the software need. It emphasizes the structural advances in satisfying the software need of various types of data elements and data structures. It presents observations of the evolutionary nature of the memory structure development toward the high-level language architecture.

MEMORY STRUCTURE OF VON NEUMANN MACHINES

Von Neumann machines refer to those computers which make use of a random-access memory (often known as the main memory), in which the program and data are stored. One unique characteristic is that the program is a sequence of instructions, and each instruction typically has an op-code to represent an operator and an address to locate an operand in the main memory. Another unique characteristic is that there is no distinction between the program and the data that are stored in the main memory; thus, an instruction can be treated as the datum and vice versa. Most of the electronic digital computers that have been built are Von Neumann machines.

IBM 7090/7094 computers

The IBM 7090/7094 family of computers were among the most popular large-scale computer systems during the period of the early 1960's. The memory structure, shown in the block diagram of Figure 1, is quite simple. It consists of a main memory with a capacity of 32K 36-bit words, and 3 or 7 index registers. The structure recognizes only binary numbers; integers and real numbers have different formats. It did not recognize characters, strings, stacks, and the like; they must be interpreted by means of subroutines or program segments. It is apparent that the memory structure is rather rudimentary for high-level programming languages.

IBM 360/370 computers

Since 1964, IBM introduced System/360 family and later in 1969 System/370 family of computers.[1] The memory structure, shown in the block diagram of Figure 2, consists of a main memory, 16 general registers (each of 4 bytes), and four floating-point registers (each of 8 bytes). The main memory can be expanded to a maximum of about 16-million bytes. It can recognize binary and decimal numbers, strings of a varying number of characters, and strings of a fixed number of bits. There are four formats for binary numbers, two formats for decimal numbers, one format for a string of bits and one format for a string of characters. There are four kinds of operands that can be addressed: the register operand, the storage operand, the

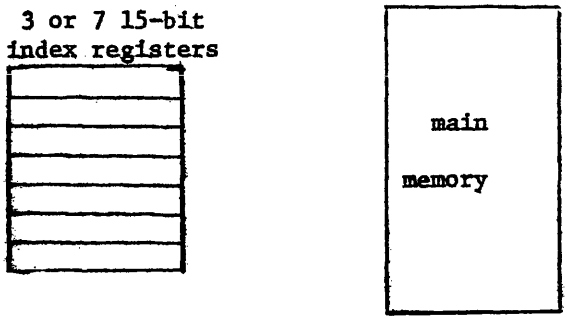

Figure 1—Memory structure of the IBM 7090/7094 computers

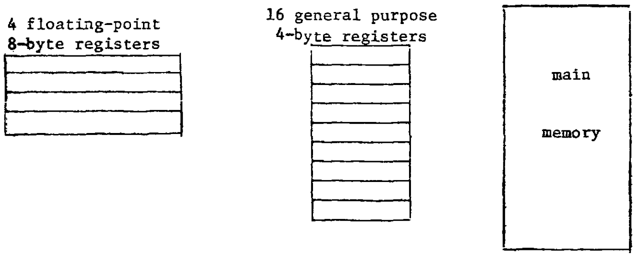

Figure 2—Memory structure of the IBM S/360 and S/370 computers

immediate operand and the string operand. It is obvious that the memory structure is more sophisticated than those of the IBM 7090/7094 family of computers, but it is still far from adequate for high-level programming languages.

IBM S/360-85 system was the first to have the so-called "cache memory."[13] It was a buffer memory installed between the main memory and the CPU. It was a very-high-speed semiconductor memory, whose presence was transparent to the programmer. The use of the very high-speed cache memory can greatly improve the speed of computer operation without increasing the speed of main memory operation. Thus the use of a buffer memory enhances the memory speed by means of memory organization.

The current IBM S/370 family of computers which succeeds the IBM S/360 family extensively provides the virtual memory. A virtual memory makes the main memory appear to have an enormous capacity to the programmer. It has been implemented by a combination of hardware and software to appear as a one-level memory. Thus, the use of one-level memory enhances the memory capacity by means of memory organization. The virtual memory was first made commercially available in Burroughs B5500 system early 1960's.[11] A hardware virtual memory (virtual memory becomes a misnomer) was demonstrated in the Symbol system early 1970's.[12]

MEMORY STRUCTURE OF STACK-ORIENTED MACHINES

Stack-oriented machines are those machines where there is a hardware stack. This stack is provided to perform only some of the functions in program execution control, data handling and referencing, and expression evaluation. For this reason, it is called a stack-oriented machine. It is a step in memory structure evolution. It is an intermediate between a Von Neumann machine and a stack machine. The memory structures of Intel 8008 and 8080, the DEC PDP 11/45 and the Burroughs B1700 systems are introduced below.

Intel 8008 and 8080 structures

The Intel MCS-8 and MCS-80 microcomputer systems are stack-oriented machines. The hardware stack is used only for subroutine return linkage and temporary operand storage. It is not used at all for arithmetic expression evaluation.

The Intel MCS-8 microcomputer system makes use of an Intel 8008 microprocessor.[9] It executes a typical instruction in 12.5 microseconds, and recognizes only an 8-bit binary number. The memory structure is shown in Figure 3. It consists of a main memory expandable to 16K bytes, an address stack of eight 14-bit registers and seven 8-bit registers. The address stack stores the return addresses of subroutine calls, which is transparent to the programmer. One of the seven registers is the accumulator; nearly all arithmetic and I/O operations use it. Because the 8008 does not have instructions that have direct addresses, two of the remaining six registers are used for all references to main storage. In order to fetch an operand from storage, the program must load an address into two specific registers. This means that at least three instructions must be used to refer to the arbitrarily placed data, this is a major disadvantage.

The Intel MCS-80 microcomputer system[10] is an outgrowth of the MCS-8. It makes use of an 8080 microprocessor. It executes a typical instruction in 2 microseconds. It recognizes only an 8-bit binary number and has only addition and subtraction instructions. The 8080 microprocessor offers 30 additional instructions, a speed improvement of at least 10 times, and possible code reduction of up to 30 percent. The memory structure shown in Figure 4 consists of a main memory with a maximum capacity of 64K bytes, six 16-bit registers, and an accumulator. Of the six registers, one is a stack

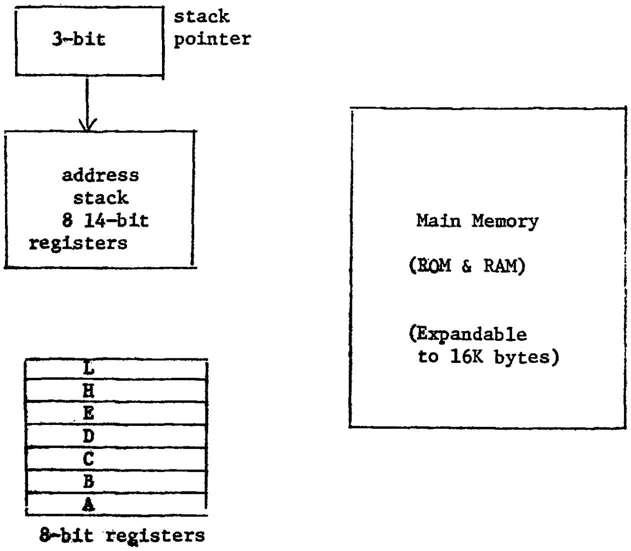

Figure 3—Memory structure of the Intel MCS-8 system

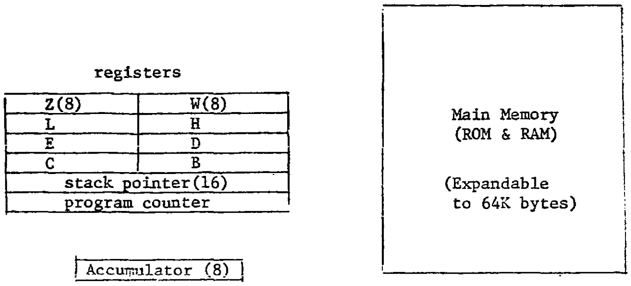

Figure 4—Memory structure of Intel MCS-80 system

pointer. The stack pointer is used to place all return addresses in the stack which is in the RAM. Instructions are available for directly handling the stack. Another of the six registers is the program counter. The Z and W registers are for the internal use of the microprocessor. The remaining three 16-bit registers can also be addressed as eight-bit registers.

The 8080 allows no index addressing, but it has instructions that permit explicit addressing of storage locations. Where the 8008 only allows a single pair of eight-bit registers to address the memory, the 8080 permits any of the three main registers to hold and output an address when using register-indirect addressing.

DEC PDP 11/45

The DEC PDP 11/45 is a stack-oriented minicomputer system.[8] It accepts a conventional machine-level language. Although it provides optional hardware for memory segmentation, its facility for the hardware stack is rather limited.

Memory structure

The memory structure of a PDP 11/45 with the memory segmentation hardware is shown in Figure 5.

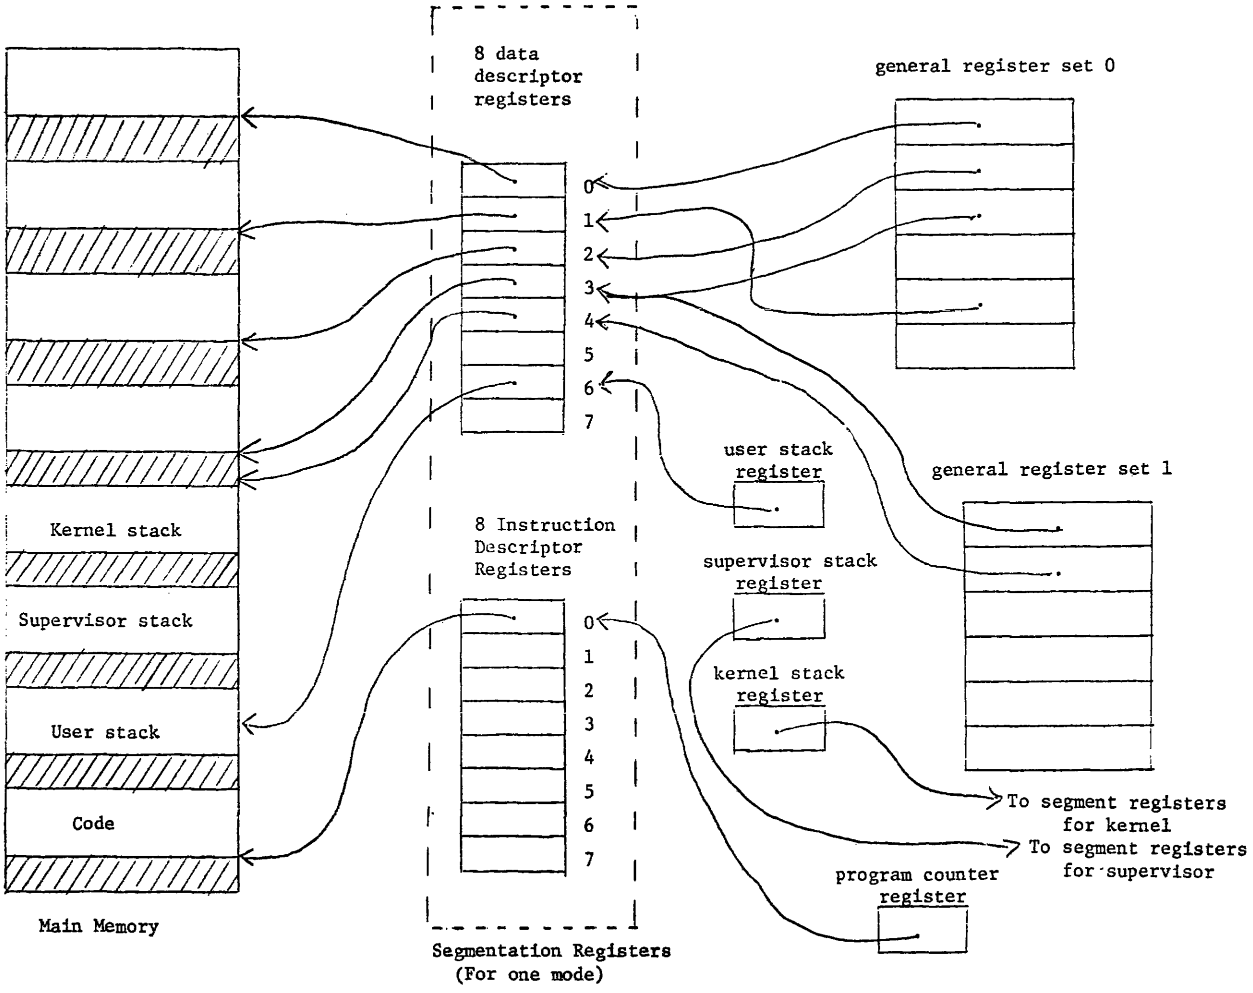

Figure 5—Memory structure of the DEC PDP 11/45

There are two sets of general purpose registers; each set has six 16-bit registers. Only one set is active at a time. Each set can be used to store either two 8-bit bytes, a 16-bit binary number, or a pointer to a segmentation register. There is also a program counter which points to the code currently being executed.

There are three modes (or states) in which the hardware may run: the kernel, the supervisor, and the user modes. There are three sets of segmentation registers; each set has 16 32-bit registers. Each set is for each mode; there is a total of 48 registers. Each 16-register set can be split into two sets of 8 registers: 8 Data Space Descriptor Registers and 8 Instruction Space Descriptor Registers. There is also one hardware utilized top-of-stack pointer register for each mode.

Hardware recognized data elements

The data elements that the hardware can recognize directly are a one- or two-byte string, or a 16-bit binary number.

Recognized data structure

The only data structure it recognizes is a stack which is in the main memory. The stack is used by the hardware only for subroutine and interrupt return linkage.

Referencing

The PDP 11/45 is interesting in that it is a byte or a word (2 bytes) addressable machine. There are two classes of instructions (including two types of load and store); one is byte-oriented and the other is word-oriented. The hardware stack can also be referenced by the software by the use of a powerful auto-increment and auto-decrement class of instructions.

All data elements and structures in the main memory are referenced indirectly through one of the 16 active segmentation registers. The referenced segmentation register contains a special pointer to an area in main memory. This pointer is called a descriptor. It not only points to the address of the area but also specifies other information about the area. A segmentation register descriptor basically specifies the main memory address of an area and its length, whether the area is stack or not or whether the area is read-only or read-write.

The stack (which is in main memory) is used by the hardware only for subroutine and interrupt return linkage.

Burroughs B1700 structure

The Burroughs B1700 is a recently available small-scale micro-programmable computer.[4] Like the Intel 8008 and 8080, it is a stack-oriented machine. The major innovation of the B1700 is the use of a writable control memory to store the microprograms. The machine-level language is an assembly-level but syntax-oriented language called S language. A high-level language source program is translated by a compiler into a S language code which is interpreted by a matched microprogram. There can be more than one pair of a S language and its matched microprogram.

Memory structure of the B1700

Figure 6 shows the memory structure. There are 6 general-purpose registers, a hardware stack for subroutine return linkages and for general operand storage, a control memory for microprogram, a register table to hold either base registers or general operands, register F to reference the contents of the main memory itself. Register MAXS specifies the maximum size of the main memory. Also shown in Figure 6 are two registers, BR (base register) and LR (limit register); they are used to mark the start and the end of the data area in the main memory of the current program. All data accesses made by the program are checked by the hardware to insure that they do not exceed these bounds.

The microprogram is stored in the control memory, but it can be extended into the main memory. Register MBR points to where the microprogram code overflow starts in the main memory. Register A is the microprogram instruction counter. The read-only register MAXM stores the available control memory. Register TOPM points to the end of the microprogram in the control memory.

Hardware recognized data elements

The B1700 hardware is capable of recognizing variable length binary numbers (1 to 24 bits in length), variable length decimal numbers (1 to 6 digits in length), and variable length strings (1 to 3 characters in length) explicitly. It can recognize any of these elements in longer lengths but the use of more than one micro-instruction is needed.

Hardware recognized data structures

Aside from the either 16 element (B1714 and B1716) or 32 element (1724 and B1726) hardware stack, the B1700 memory structure recognizes no data structures.

Referencing

Any data element in a register is referenced directly by the register name. Certain registers, as shown in Figure 6, have addressable fixed subfields. Register T

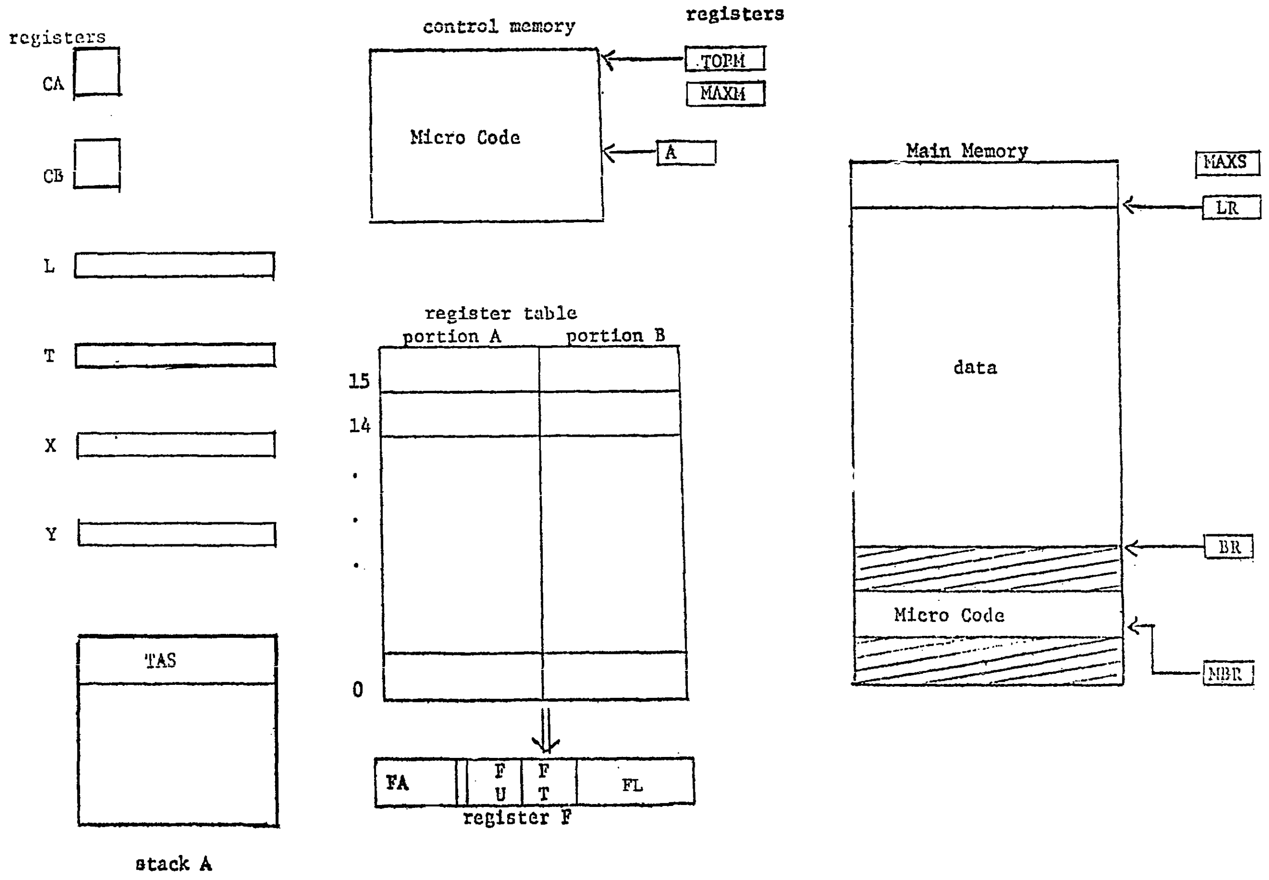

Figure 6—Memory structure of the Burroughs B1700 system

is also provided with special hardware so that any field of this register may be accessed. A data element in main memory is accessed by placing a data descriptor in register F. The format of this data descriptor, identical to that of register F shown in Figure 6, has four basic fields: FA (Field address), FU (Field unit), FT (Field type), and FL (Field length). Micro-instructions are available to transfer any one of these fields to some registers. Field FA contains the absolute bit address of the data area. Field FU may contain the number of bits per byte in the data item (e.g., binary is 1 bit/byte, octal is 3 bits/byte, etc.). Field FT may hold data type. Field FL may hold the length of the data area.

MEMORY STRUCTURE OF STACK MACHINES

Stack machines are those machines which have a hardware stack. The stack is particularly necessary for machines whose machine-level languages have a high-level syntax such as the polish notation. Burroughs B5500 system was the first stack machine.

In a stack machine, the hardware stack can push down or pop up an operand. It can test for stack overflow or underflow. It can be used for expression evaluation. It can store the return address and pass parameters of a procedure call. It can handle the interrupts. In fact, all operands go through the stack.

This section briefly describes the memory structure of the family of Burroughs B5500, B6700, and B7700 stack machines.

Burroughs B5500 structure

Burroughs achieved a great stride in computer architecture through the introduction of the B5500 system in early 1960.[2,3] This system was specifically designed for the execution of a high-level language called Extended Algol which is a dialect of Algol 60.

It is important to note that the philosophy of the design of the B5500 was to eliminate the assembly language programming. Aside from some rather rare occurrences within the operating system, this goal has essentially been achieved.

The B5500, as well as the B6700 to be mentioned later, is a stack machine. The stack is not only used for subroutine and interrupt return linkage but also for arithmetic evaluation and procedure parameter storage.

Memory structure of the B5500

The memory structure of the B5500 is sketched in Figure 7. There is a main memory with a capacity of 32K of 48-bit words, two registers S and R pointing to the main memory, two top-of-stack buffer registers A and B, two registers G and H which indicate a bit position within the A register, and two registers K and V which indicate a bit position within the B register. The pairs of G, H and K, V registers allow accessing any contiguous string of bits in either the A or B registers.

Hardware recognized data elements

The hardware can directly recognize and manipulate binary and decimal numbers, strings of a varying number of characters, and strings of a varying number of bits. There are two formats of binary numbers (real-single-precision and real-double-precision), one format of decimal numbers, and one format of character string, and one format of bit strings.

Hardware recognized data structures

The B5500 hardware directly interprets stack, single dimensional array structures, and singly linked lists.

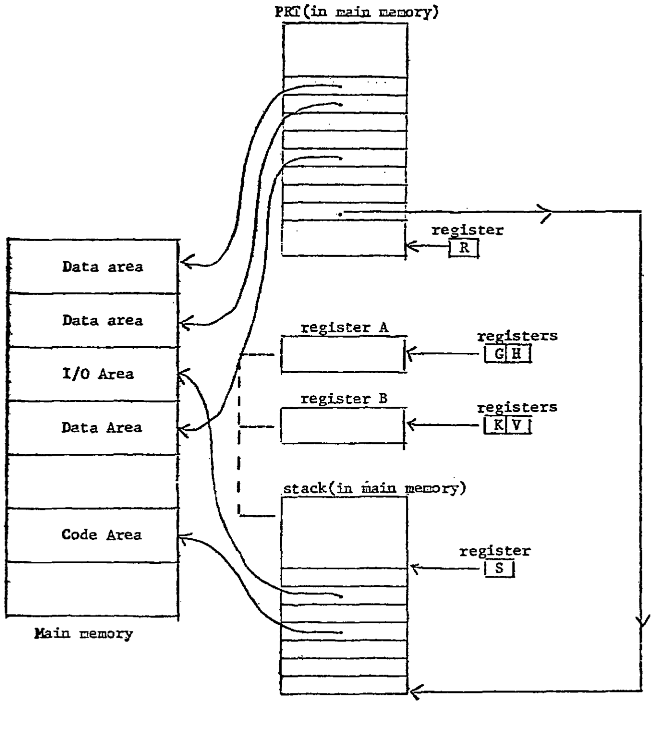

Figure 7—Memory structure of the Burroughs B5500 system

Referencing the data structures and data elements

Each program in execution has a PRT (Program Reference Table) which contains all scalar data elements and pointers to all arrays in addition to a hardware maintained stack. As shown in Figure 7 register R points to the base of the PRT of the currently executing program. Registers A and B contain the top two elements of the hardware maintained stack, while register S points to the top stack element in the remainder of the stack which is in main memory.

The B5500 has four different types of addressing it can perform: (a) R-relative (address an element of the PRT), (b) top-of-stack (e.g., multiply top two elements of stack), (c) stack relative address (a procedure programmer), and (d) absolute addressing.

R-relative addressing allows the accessing of binary numbers and bit strings less than 48 bits. in length. Top-of-stack addressing allows the use of the stack for evaluating arithmetic expressions and is also used for all temporary workspace (e.g. index operations are performed in the stack).

In order to access the other data types of decimal numbers, character strings, bit strings of 48 or more bits, and arrays, a combination of these addressing types is used. Each datum in main memory which is not merely a binary number or a 0-47 bit bit-string is pointed to by a special pointer in the PRT. This pointer is called a *data descriptor*. The data descriptor has 3 hardware recognized fields: P, WC, and ADDRESS. The one-bit P field indicates if the descriptor points to an area in main memory or on the disk memory. The VC field specifies the size of the area in 48-bit words (or 8 characters). The ADDRESS specifies the location of the data area either in the main memory or disk (depending on field P).

In order to reference a data item described by a data descriptor, an index (if needed) and the descriptor (via R relative addressing) are first pushed onto the stack. Next, if an index was specified, the hardware checks to see if it is within the size of the WC field. If it is, the index is added into the ADDRESS field of the descriptor to give the absolute address of the data item.

The descriptor can be used to either load or store a value into the item referenced. For example, to reference A[3], the value of the index, 3, is placed on the stack and a "value call" operator on the address of A is performed by the software. The hardware automatically: (a) add the index to the array's descriptor, (b) make sure the subscript is in bounds, (c) delete the index from the stack, and (d) place the addressed array element on the stack.

There is also a special instruction, LINKED-LIST LOOKUP, which searches a singly-linked list. This list is created by software.

Burroughs B6700/7700

The Burroughs B6700 and B7700 systems are basically large-scale, improved-versions of the B5500 system, commercially becoming available almost 15 years ago. Rather than indicating that the architecture of the B6700 and B7700 is antiquated, the fact is the architecture of the original B5000 and B5500 was greatly in advance of the time. The Burroughs B6700/7700 systems are perhaps the first stack machines, where all data storage other than arrays is actually performed by the powerful stack organization.

Memory structure of the B6700/7700

The memory structure of the B6700/7700 family of computers[6,7,14] is sketched in Figure 8. As shown, registers A, X and B, Y store the top two elements of the current stack (four registers for two double precision operands). Registers BOS, S, and LOS point to the base, the current top, and the limit of the current stack in main memory, respectively. There is a software-maintained but hardware-accessed Stack Vector Table in main memory. The Stack Vector Table stores one pointer to the base of each stack in main memory. The table entry for the current stack is pointed by register SNR.

Also shown, there is a 32-entry register-table D which is used for addressing and an associated register LL which specifies the highest register in the D table which is valid. There are 3 "vector mode" registers for storing Pointer A, Pointer B, and Pointer C; these are index registers for efficient one-dimensional array accessing.

Hardware recognized data elements

The B6700/7700 hardware recognizes by means of data descriptors binary numbers, strings of a variable number of 1 to 48 bits, decimal numbers, strings of a variable number of characters (either 6 or 8 bits). There are two formats of binary numbers: single-precision real and double-precision real. There is one format of all other types of data elements.

Hardware recognized data structures

The B6700/7700 hardware recognizes stacks, multidimensional arrays, and singly linked lists.

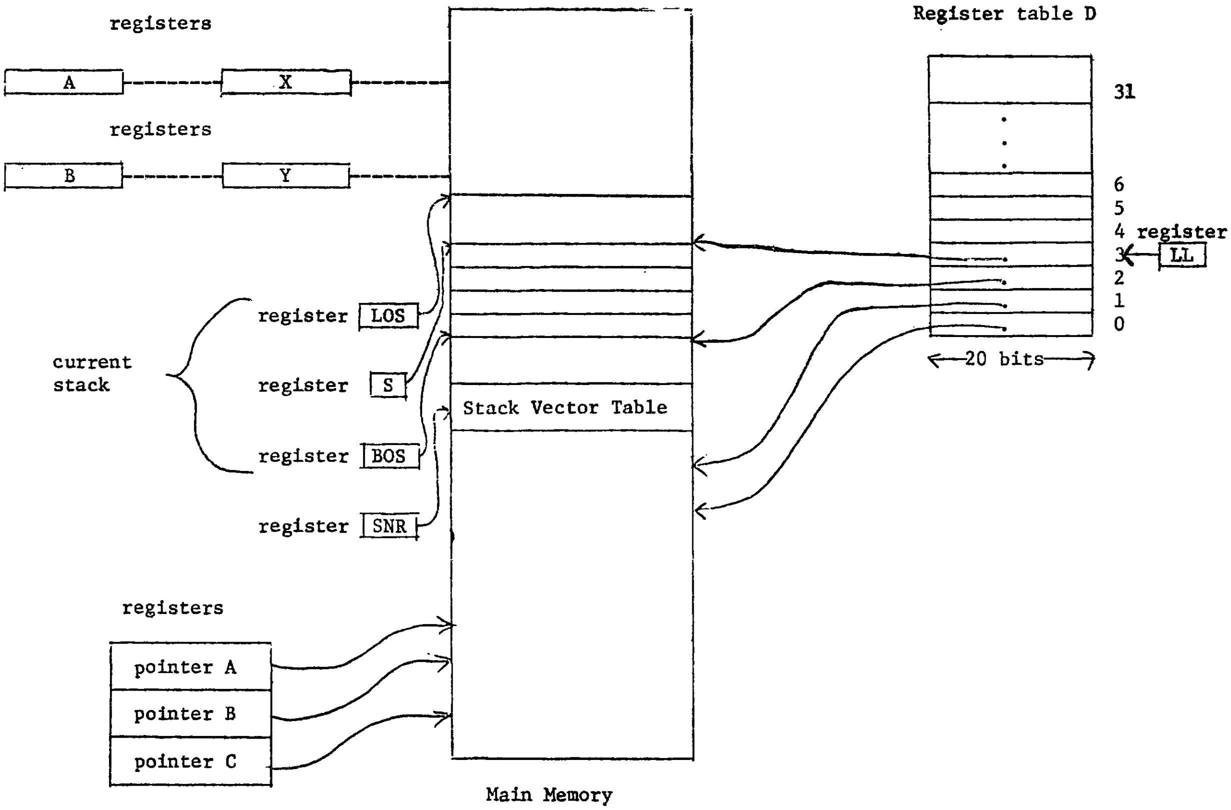

Figure 8—Memory structure of the Burroughs B6700 and B7700 computers

Referencing

Every memory word has a 3-bit tag. To address a memory word, the hardware has three different addressing schemes which depend on whether the memory word to be addressed is in the current stack, in another stack, or external to all of the stacks (e.g., an array or a string). Figure 9 illustrates the stack addressing scheme. As shown, for each block level of the sample Algol program, there is a corresponding entry in the D register table which points to a special set of control words (i.e., MKSW and RCW) for that block. Above these control words are stored the declared simple variables for the block.

Representation of a three-dimensional array in the memory structure is illustrated in Figure 10. The array is structured as a tree with the first level having the array descriptor, the second and third levels having dope vectors of data descriptors, and the fourth level being actual array elements. To address array element A[1,1,1], each index is placed onto the stack and then a "value call" is performed on array A by software. The hardware automatically follows the data descriptors as indicated by the indices on the stack. It automatically deletes the indices and places the correct array element on top of the stack. It automatically checks the number of subscripts to see whether they are in bounds when the reference is made using the contents of the data descriptor dope vectors.

The B6700 (optionally)and the B7700 (standard) have three hardware index registers which are used in a special hardware "vector mode" to allow very efficient access to single-dimensional arrays.

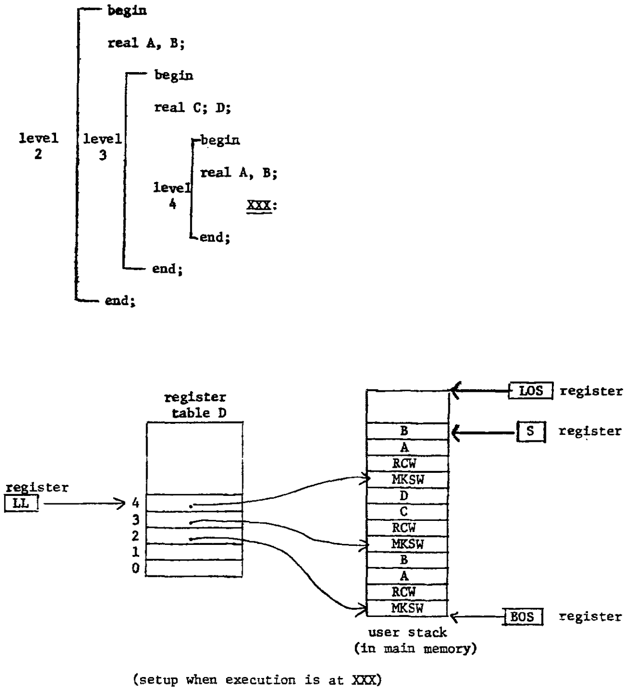

Figure 9—Stack addressing scheme in the B6700/7700

The hardware references the stack by using the hardware top-of-stack pointer, register S.

The hardware has a special linked-list search operator which will follow a software-constructed singly-linked list until the current mode has a value greater than or equal to a specified value.

In addition, the B6700/7700 systems have an interesting hardware operator which serially searches a data area from the end to the beginning for a data element identical to the given argument. This operator allows an easy software simulation of an associative memory.

Speed improvements in B7700

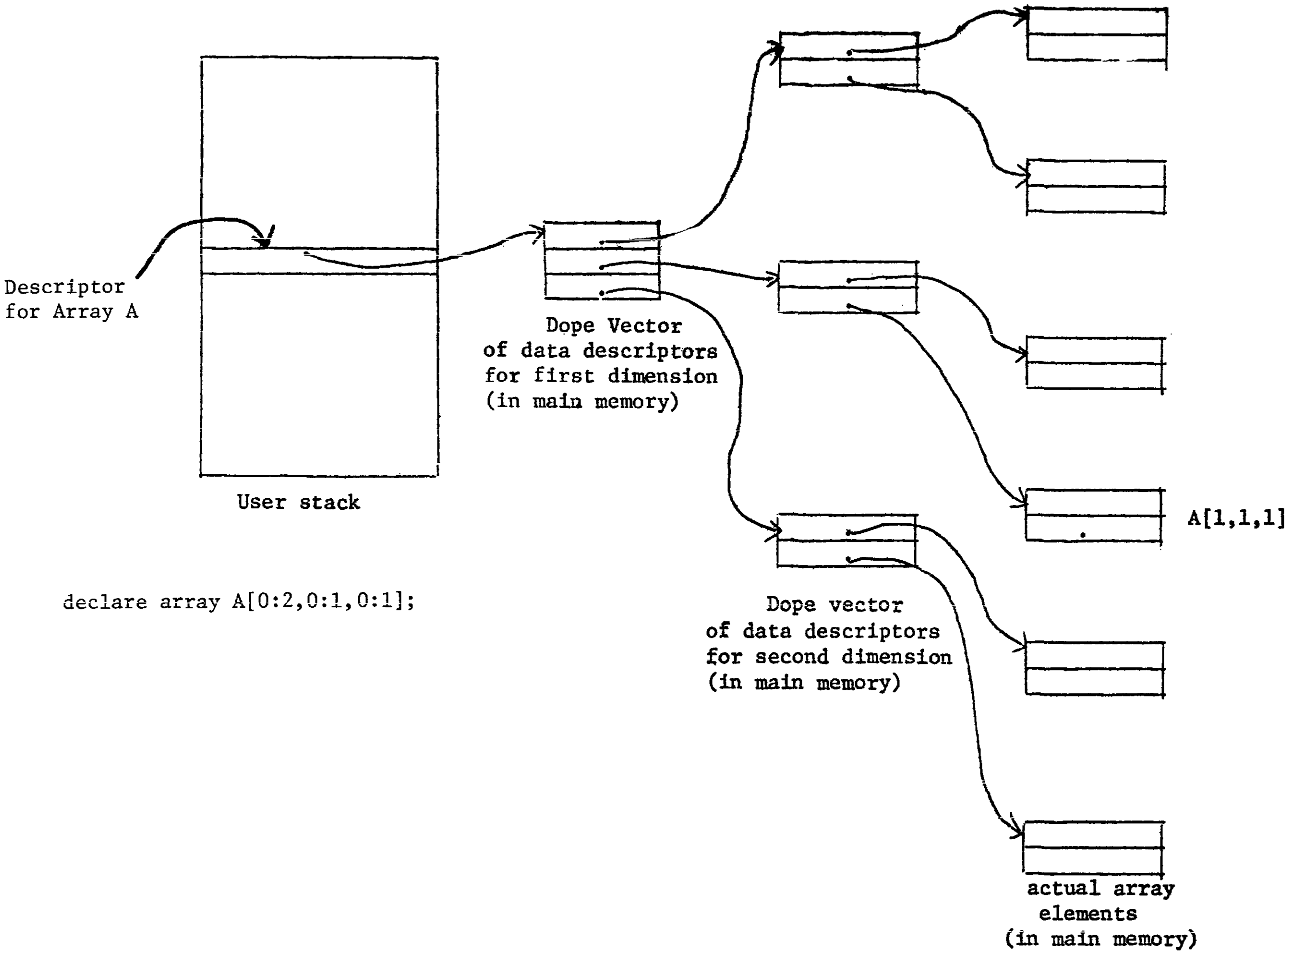
The Burroughs B7700 memory[7] has some major differences from the B6700 memory: a clock rate of 3 times as fast, extensive incorporation of fault detection circuitry, single-bit error correction in memory, 4-way interleaving of the main memory, sophisticated I/O operations, and the use of an associative memory.

The most interesting aspects of the B7700 memory structure is the use of a high-speed semiconductor memory and an associative memory to assist in stack handling. The high-speed semiconductor memory is basically used as a cache memory to hold the top words of the current stack. This memory can hold a maximum of 32 words, which can be operands, data descriptors, code descriptors, etc. The 32 51-bit word associative memory contains the most frequently-used operands and descriptors in the stack which are not in the semiconductor memory but can be any other words of the stack. Each entry in the associative memory essentially has two fields: a 20-bit address indicating the memory location of the original operand or descriptor, and a 51-bit copy of the operand or descriptor.

When any memory reference is made on the B7700, the storage control unit first checks the semiconductor memory and associative memory for the data item. If it is found and if it is a read operation, the reference is complete. If it is found but if it is a write operation, the word is overwritten in the semiconductor memory or associative memory. A write request to the main memory is hardware-queued for the memory controller so that the original item in the main memory is also updated.

MEMORY STRUCTURE OF THE SYMBOL SYSTEM

An historical event in computer architecture occurred during the 1971 Spring Joint Computer Conference. Rex Rice and others[12] of Fairchild presented a series of papers which described the design and con-



Descriptor for Array A

actual array elements (in main memory)

Figure 10—Representation of an array in main memory

struction of the Symbol computer system. The Symbol system has a high-level Algol-like machine language, called Symbol, which is additionally capable of describing variable length data and requires no type and size declarations (as conversion and memory allocation are handled automatically). It has no conventional set of instructions. It directly accepts programs written in the Symbol language. It is a functionally-organized multi-processor system and designed for multiple access by terminals. In addition to an arithmetic processor, a channel controller, and a disk controller, there are a hardware translator, a hardware text editor, a hardware format processor, a hardware reference processor, a hardware system supervisor, and hardware virtual memory. There is very little software. The Symbol system is now being evaluated at Iowa State University under the sponsorship of the U.S. National Science Foundation. This project has undoubtedly demonstrated the feasibility of a computer system whose machine language is a high-level language.

Hardware virtual memory

The memory structure consists of a main memory, an associative memory, and a paging disk memory. It is organized as a virtual memory with fixed-sized pages. There are 206 words in a page and 64 bits in a word. The main memory and the paging disk memory are divided into pages. There are 32 pages in the main memory. The associative memory has 32 words, with one word representing one page in the main memory. By means of the associative memory, the virtual address is translated into the physical address.

The pages are linked into page lists. There are many types such as available page list, user's page list, space available list and in-core list. A page is brought into

TABLE I—Symbol Memory Operations

Symbol	Memory Operation
KP	no operation
AG	assign group
IG	insert group
FF	fetch and follow
FR	fetch and reverse follow
FL	follow and fetch
FD	fetch direct
SA	store and assign
SO	store only
SI	store and insert
SD	store direct
DE	delete to end
DS	delete string
DL	delete list
RG	reclaim group

the main memory upon demand and returned to the same page location on disk when it is purged. Paging is managed by the hardware system supervisor.

Hardware linked structure *

Each page in the main memory has three regions: the page header, the group-linked words, and the data space group. The page header occupies 4 64-bit memory words. Each group link word occupies one word. Each data space group has eight consecutive memory words (which is the smallest unit for data memory allocation).

There are 28 group linked words and 28 data space groups with one group link word for each data space group. The link word stores the forward and backward links of the data space group. By means of these link words, the data space groups are doubly linked into list structures. The page header stores the list heads.

There is a Memory Controller associated with the main memory. This Memory Controller can perform 14 memory operations which are shown in Table I. These operations are available to all of the processors in the system, and are used in memory word linking and memory space allocation, but the processors do not have to directly keep track of the memory addresses.

Data types and structures

The memory structure can recognize numbers and strings. The numbers are of variable-length, packed-decimal, floating-point numbers, and carry a precision designation. Each string is represented by the special character SS, followed by a variable number of characters and terminated by the special character SE. Note that the information related to the data is carried and stored with the data itself. Source programs are a special form of strings.

The memory structure allows a linked data structure, which can be a varying length group of data elements where the data element can be a number, a string, or an address link to another group of data elements. With this recursive definition, this structure can represent a vector, a matrix, or a linked structure. An example of the matrix description by symbol language and representation by this structure is shown in Figure 11. Note that the special characters in Figure 11 are listed in Table II.

As another example, a source string and its object string of an assignment start name table are shown in Figure 12. The storage of the source string, the object string, and the name table, are shown in Figure 13. The object string is composed of name table addresses, literal data, operators, and links to the source string. Each identifier in the name table is associated with a control word. All references in the object string of the identifier point to the corresponding control word. The object string and the name table are totally independent of the future size and the data type of the variable.

MEMORY STRUCTURE FOR HIGH-LEVEL LANGUAGE MACHINES

High-level language programmers need to describe the high-level data structures such as stack, queues, tables and files as often used in the software design. If a highly descriptive, high-level programming language is used to write the program, this programming language should have language constructs that are capable of explicitly describing these high-level data structures. The hardware memory structure of a computer offers the structure for storing the data elements and the data structure that are specified in a program. If this is a high-level language memory structure, it should be capable of directly imaging these high-level language constructs.[16]

A memory structure is conceived for high-level language machines.[15] This structure is shown in Figure 14. It consists of a virtual memory, an associative memory and a data interpreter. The virtual memory stores the data elements, while the associative memory stores the structure names, the data types, the struc-

ture types and other necessary information. The data interpreter makes entries into the associative memory when the high-level language declarations are scanned. It then interprets the data when the data names are referenced. This is now illustrated for the data structures of stacks and table.

Source String:

Alpha ←— Beta * 3.2 − (Long Name join Beta);

Object String

A[Alpha] A[Beta] 3.2 * A[Long Name] A[Beta] join − ←— ;

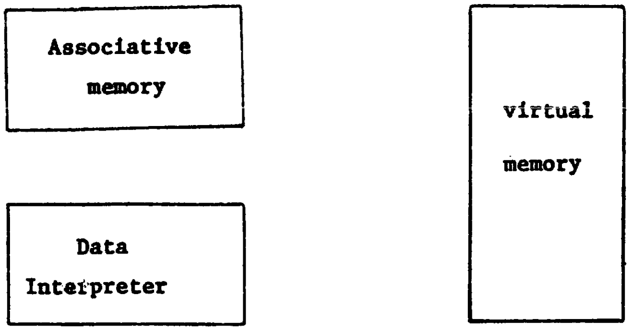

Figure 14—A hardware organization for data interpretation

Stacks

Stack is a vector with a changing number of data elements. Only at one end of the stack can the element be added (or pushed down) or deleted (or popped up), and only one element can be added or deleted at one time. A pointer is normally associated with the stack; it points to the top element where addition or deletion is permitted. It is a first-in-last-out structure. Each data element of the stack may have one or more fields; in this respect, a stack appears like a table. A stack is highly useful for handling subroutine calls, in evaluating expressions, and in traversing a tree.

Stack declaration

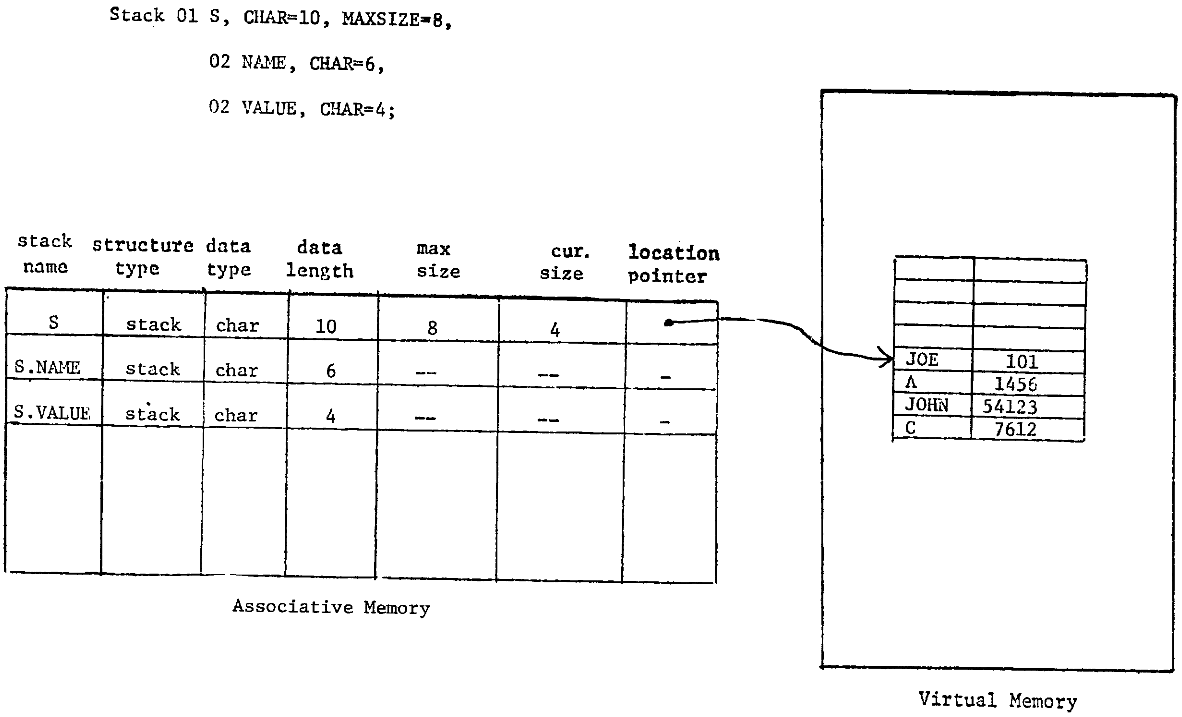
The present high-level programming languages have no explicit declarations for declaring the structure of a stack. In the case of Fortran, for example, a one-dimensional array is declared to describe the stack. Such a deficiency in the language construct is due to the inhibition of the language designer toward the conventional memory structure, though the stack should be and could be declared as descriptive and as concise as possible. Shown below is an example of a stack declaration:

```
Stack 01 S, CHAR=10, MAXSIZE=8,
            02 NAME, CHAR=6
            02 VALUE, CHAR=4
```

This statement declares a stack whose name is S, whose data element is 10 characters, and whose maximum number of elements is 8. Each stack element has two fields, the NAME field of 6 characters and the VALUE field of 4 characters.

Stack internal representation

The structural information of the above stack S can be stored in the associative memory as the three entries shown in Figure 15. Each entry has 7 fields. The first five fields store the stack name, the structure type,



```
Stack 01 S, CHAR=10, MAXSIZE=8,
        02 NAME, CHAR=6,
        02 VALUE, CHAR=4;
```

stack name	structure type	data type	data length	max size	cur. size	location pointer
S	stack	char	10	8	4	•
S.NAME	stack	char	6	—	—	-
S.VALUE	stack	char	4	—	—	-

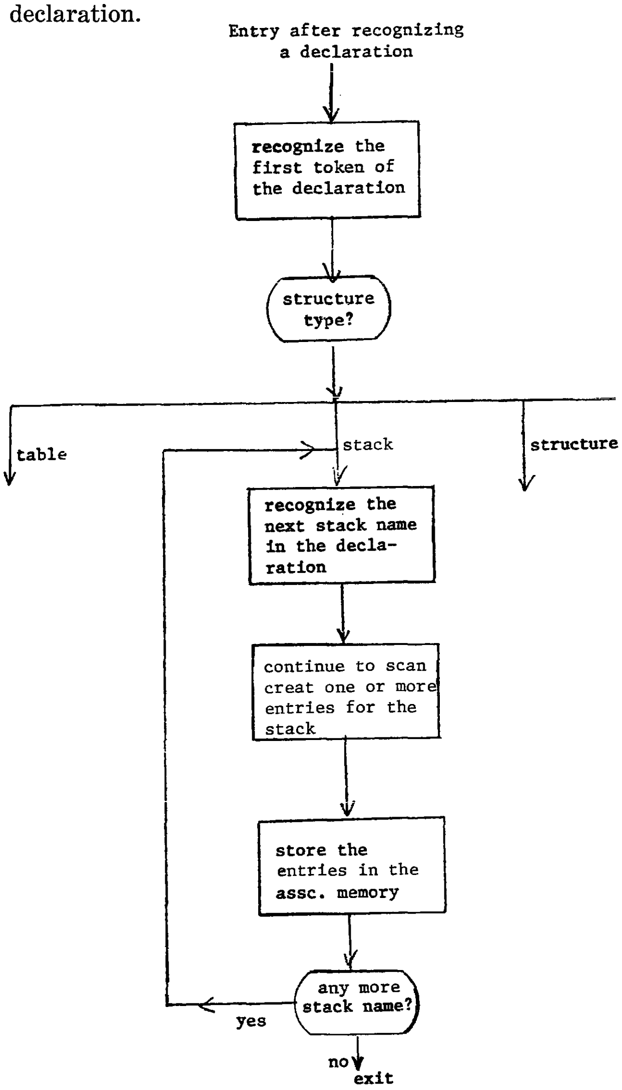
JOE	101
A	1456
JOHN	54123
C	7612

Figure 15—Internal representation of stacks

the data type, the data length and the maximum length of the stack. The current size field stores the relative location of the top element of the stack. The pointer field stores the memory address of the top element of the stack.

Interpretation of a stack declaration is to generate associative memory entries as shown in the flow chart of Figure 16. As shown, when a declaration is recognized, it recognizes the first token of the declaration. This token reveals the structure type. It can be a stack, a table, a queue, etc. In case it is a stack, it recognizes the stack id, continues to scan the declaration, creates one or more entries for the stack, and stores the entries in the associative memory. A memory allocator is called to allocate the main memory space for the stack. This process is repeated until no more stack id is found in the declaration.

Notice the closeness between the stack declaration and the stack internal representation; this closeness means a simple interpretation of the stack declaration.



Entry after recognizing a declaration
recognize the first token of the declaration
structure type?
table
stack
structure
recognize the next stack name in the declaration
continue to scan creat one or more entries for the stack
store the entries in the assc. memory
any more stack name?
yes
no
exit

Figure 16—Interpretation of a stack declaration

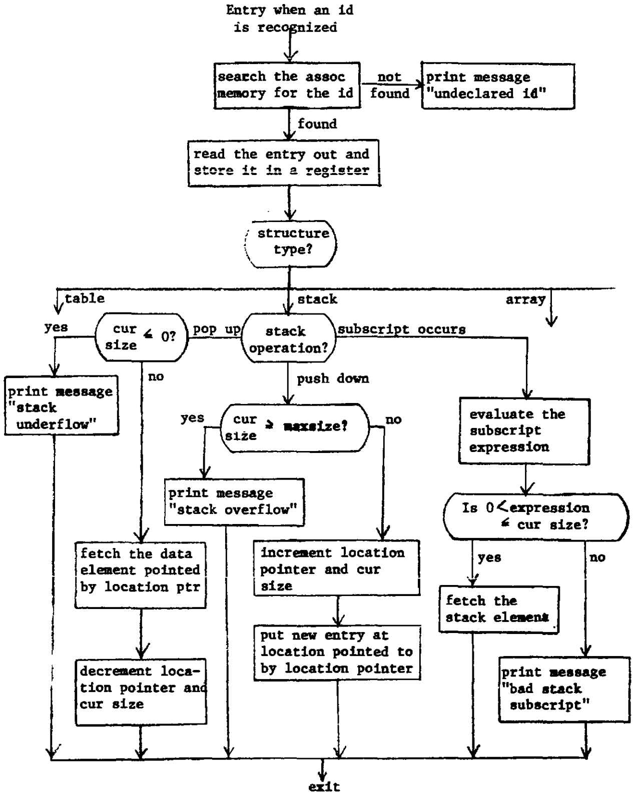
Stack references and operations

After the stack declaration is interpreted, the declared stacks can now be referenced. Some examples of referencing the previously-declared stack S are shown below.

```
B:=S(TOP);
B:=pop S;
B:=S(TOP)+S(TOP−1);
A:=S(TOP,NAME);
```

where B and A are char-string buffers. The first statement assigns the value in the top element of stack S to buffer B; the value in the top element is not changed. The second statement pops out the top element of stack S to buffer B; the original value in the top element is lost. The third statement stores the sum of the values of the two topmost elements in buffer B. The fourth statement assigns the value in the NAME field of the top element to buffer A.

Interpretation of stack reference and stack operation during the direct execution of a high-level language program is shown in the flow chart of Figure 17. As shown, when an id is recognized, the associative memory is searched for the id. A message is printed



Entry when an id is recognized
search the assoc memory for the id
not found
print message "undeclared id"
found
read the entry out and store it in a register
structure type?
table
stack
array
yes
cur size ≤ 0?
pop up
stack operation?
subscript occurs
no
push down
print message "stack underflow"
yes
cur size ≥ maxsize?
no
evaluate the subscript expression
print message "stack overflow"
Is 0<expression ≤ cur size?
fetch the data element pointed by location ptr
increment location pointer and cur size
yes
no
fetch the stack element
put new entry at location pointed to by location pointer
decrement location pointer and cur size
print message "bad stack subscript"
exit

Figure 17—Interpretation of a stack operation or a stack reference during the direct-execution of a high-level language program

out if the id is not found. When it is found, the entry is read out and stored in a register. When the structure type is recognized from the register to be stack, the interpreter scans for the required operation.

(a) If it is a stack pop-up operation, the stack underflow is checked. If there is none, the data element pointed by the location pointer in the register is fetched from the virtual memory. Both the current size and the location pointer are then decremented.
(b) If it is a push-down operation, the stack overflow is checked. If there is none, both the location pointer and the current size are incremented and the data element is then stored in the virtual memory.
(c) If subscript TOP is found, it is a reference operation; the subscript expression is evaluated. If the value of the expression is within the current size, the stack element is fetched from the virtual memory; otherwise, a message is printed to indicate a bad stack subscript.

Tables

Tables are two dimensional arrays which permit different data types among the fields (or columns) of the table. A table can be of a fixed or varying size. All entries of the table are accessible for examinations or modifications. The entry of a table can be located by using a subscript or by matching an argument with the contents of a field of the table.

Table declaration

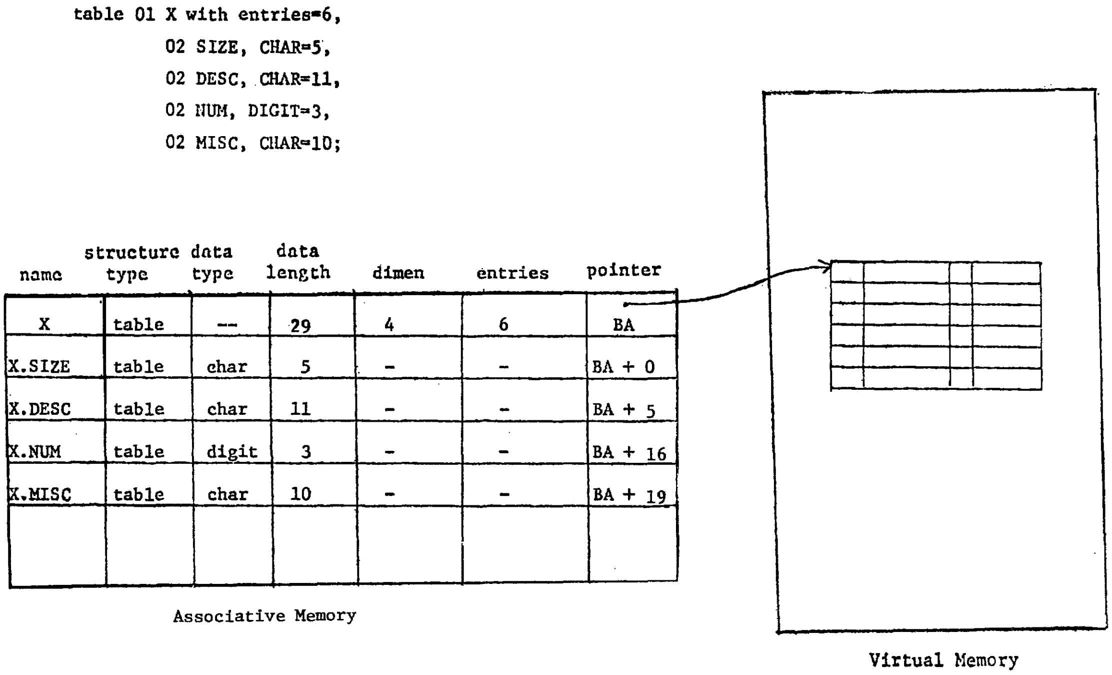
The current high-level languages have a structure declaration which can declare the table structure. However, a table cannot be declared explicitly and directly. An example of the table declaration is:

```
Table 01 X with entries=6,
         02 SIZE, CHAR=5,
         02 DESC, CHAR=11,
         02 NUM, DIGIT=3,
         02 MISC, CHAR=10;
```

This statement declares a table with name X which has 6 entries. There are four fields in each entry: the SIZE field of 5 characters, the DESC field of 11 characters, the NUM field of 3 digits and the MISC field of 10 characters. For simplicity, one digit and one character are assumed of the same length.

Table internal representation

The structural information of table X can be stored in the associative memory as the five entries shown in Figure 18. Each entry has 7 fields. The first four fields



```
table 01 X with entries=6,
         02 SIZE, CHAR=5,
         02 DESC, CHAR=11,
         02 NUM, DIGIT=3,
         02 MISC, CHAR=10;
```

name	structure type	data type	data length	dimen	entries	pointer
X	table	—	29	4	6	BA
X.SIZE	table	char	5	-	-	BA + 0
X.DESC	table	char	11	-	-	BA + 5
X.NUM	table	digit	3	-	-	BA + 16
X.MISC	table	char	10	-	-	BA + 19

Figure 18—Internal representation of a table

store the table name or the column name, the structure name, the data type and the data length. The dimen field and the entries field specify the numbers of columns and rows in the table, respectively. The pointer field stores the location of the table in the main memory. Note that the value of the data length field is the sum of the data lengths of all the fields of the table. Again, the syntax and the semantics of the table declaration are very close to the internal representation, allowing a simple interpretation of the table declaration.

Table references

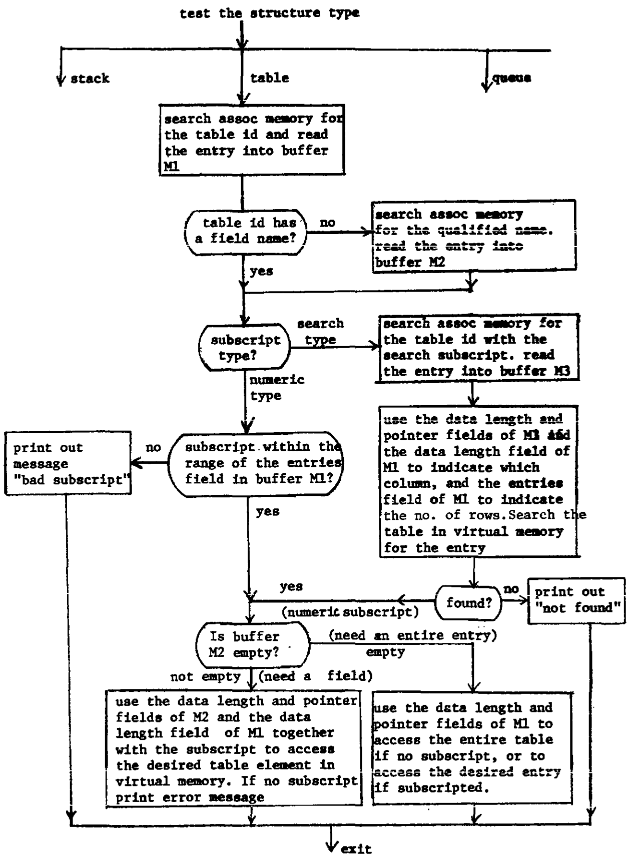
After the table declaration is interpreted, the declared table may now be referenced. Some examples of table referencing are:

```
X[2] := ("4x3", "TILE", "BLACK") ;
X.SIZE[3] :"JOHN";
B:=X[X.DESC='JOHN'];
B:=X.SIZE[X.DESC='JOHN'];
```

The first statement stores strings "4x3", "TILE" and "BLACK" to the SIZE, DESC, and MISC field of the second row of table X, respectively. (Nothing is changed in the NUM field.) The second statement stores string "JOHN" to the SIZE field of the third row of the table. The third statement searches for that entry in table X whose DESC field contains string "JOHN" and assigns this entry to buffer B. The fourth statement performs the same operation as the third statement except that the fourth statement assigns the SIZE field of the found entry to buffer B. The above four examples show that the table can be referenced either by a numerical subscript (in a square bracket) or by a search subscript (a qualified name indicated by a dot between the table name and the field name).

Interpretation of a table reference during the direct execution of a high-level language program is shown in the flow chart of Figure 19. After the identifier is recognized to be a table name, the associative memory is searched for the table name. (e.g., X); if it is found, this entry is read out of the associative memory and placed in buffer M1. Next, it is determined whether the table name is a qualified name (i.e., name with a field name). If it is, the associative memory is again searched and the entry is now read into buffer M2. Finally, the subscript type is determined.

(a) If it is a numeric subscript, it is checked to see whether the subscript is within the range.
(b) If it is a search subscript, the associative memory is searched for the search subscript, and the found entry is read into buffer M3. Then, the data length and pointer fields in buffer M3 and the data length field of buffer M1 are used to determine which column is located the table element. The entries field of buffer M1 is used to indicate the number of rows. The table in virtual memory is then searched for the entry. If this is not found, a "not found" message is printed out. Otherwise, the subscript is converted into a numeric subscript.



test the structure type
stack
table
queue
search assoc memory for the table id and read the entry into buffer M1
table id has a field name?
no
search assoc memory for the qualified name. read the entry into buffer M2
yes
subscript type?
search type
search assoc memory for the table id with the search subscript. read the entry into buffer M3
numeric type
use the data length and pointer fields of M3 and the data length field of M1 to indicate which column, and the entries field of M1 to indicate the no. of rows. Search the table in virtual memory for the entry
print out message "bad subscript"
no
subscript within the range of the entries field in buffer M1?
yes
yes
(numeric subscript)
found?
no
print out "not found"
Is buffer M2 empty?
(need an entire entry)
empty
not empty
(need a field)
use the data length and pointer fields of M2 and the data length field of M1 together with the subscript to access the desired table element in virtual memory. If no subscript print error message
use the data length and pointer fields of M1 to access the entire table if no subscript, or to access the desired entry if subscripted.
exit

Figure 19—Interpretation of a table reference during the direct-execution of a high-level language program

At this time, either of the above two cases has a numeric subscript. If buffer M2 is empty, it calls for a field of the table entry; otherwise, it calls for an entire entry.

(a) If a field is needed, the data length field and the pointer field of buffer M2 and the data length field of buffer M1 together with the subscript are used to access the desired table element in the virtual memory. If there is no subscript, an error message is printed out.
(b) If an entire entry is needed, the data length field and the pointer field of buffer M1 is used to access the entire table if there is no subscript, or to access the desired entry if there is a subscript.

At this point, the reference of a table name in either of the above cases is completed.

Other data structures

The memory structure shown in Figure 14 has been described for the declarations, the internal representations and the references of stack and table. This memory structure can similarly be used for other high-level data structures such as buffers, arrays, queues, structures and files.[15]

CONCLUDING REMARKS

Since the advent of commercial electronic digital computers, the memory has undergone an evolution during the past 20 years. It has made great hardware advances in speed, capacity, size, cost and reliability. The increase in memory speed has been realized not only by electronical technology but also in memory organization by using a memory buffer (i.e., cache memory). The increase in memory capacity has been realized not only by electronical technology but also in memory organization by using a one-level memory (i.e., virtual memory). The memory has also made significant structural changes in recognizing data elements and data structures. It can recognize number (fixed and/or floating-point binary and decimal), character strings for a set of 64 characters, and logical words. However, the hardware implementation of data structure is practically none except the memory structures of two recently available, commercial computers, where a hardware stack (this stack is not for the programmer to use in his program) and hardware arrays are implemented.

Where do we go from here? The memory structure of a computer has a great influence on the computing and processing capability of the computer. The usage of this capability is through programming. The programmer makes use of the memory structure to satisfy his software needs in implementing such data elements as numbers, characters, strings, pointers, and program segments and such data structures as stacks, tables, queues, arrays, tree, buffers, structures, and files. Therefore, it is apparent that the future memory structure would advance toward satisfying such software needs, and the hardware implementation of these data elements and data structures represents one of the most challenging structural advances in the forthcoming computer structures.

Cache system design in the tightly coupled multiprocessor system

by C. K. TANG
IBM Corporation
Endicott, New York

ABSTRACT

Cache is a fast buffer memory between the processor and the main memory and has been extensively used in the larger computer systems. The principle of operation and the various designs of the cache in the uniprocessor system are well documented.[1-9] The memory system of multiprocessors has also received much attention[10-17] recently; however, they are limited to the systems without a cache. Little if any information exists in the literature[18-20] addressing the principle and design considerations of the cache system in the tightly coupled multiprocessor environment. This paper describes such a cache design. System requirements in the multiprocessor environment as well as the cost-performance trade-offs of the cache system design are given in detail. The possibility of sharing the cache system hardware with other multiprocessing facilities (such as dynamic address translation, storage protection, locks, serialization, and the system clocks) is also discussed.

CACHE SYSTEM REQUIREMENT OF MULTIPROCESSOR SYSTEM*

In a multiprocessor system, the main store is shared by all the processors. A single copy of the operating system in the shared main store controls the entire system. Since the main store can be accessed by all the processors, it is also used as the 'mailbox' to pass messages between the processors.[10,16] In addition to the shared main store, some multiprocessor systems may use the 'private stores', each of which can be accessed by only one processor.[10,17] 'Private stores' are used to store tables of frequently used subroutines, tables for allocation of private resources, etc. Since the 'private stores' do not communicate with each other, they are not to be confused with the caches in the multiprocessor system. Furthermore, a multiprocessor system with cache (such as the IBM System/370 Model 158 MP and Model 168 MP) will not need the 'private stores', because the cache will provide the performance advantage that the 'private stores' offer. As a result, this paper will not address the 'private stores'.

A multiprocess system can have multiple tasks dispatched simultaneously, and each processor can independently execute its instructions. Hence from each processor's standpoint, it will have the complete access to the main store without the awareness of the existence of the other processor(s).[16] The logical relation between the processors and the main store can be shown in Figure 1. The I/O channel is an I/O processor; thus, from the main stores point of view, the I/O channel is logically equivalent to the other instruction processors. Figure 1 can also represent the 'timeshare' or 'common bus' main store system design.[17] Although 'crossbar switch' and 'multiple-bus' are frequently used in the main store system design for performance reasons (Figure 2 and Figure 3), the logical relation between the processors and the main memory remains the same. If a cache is attached to each processor, then logically the caches should be considered as a part of the main store, since each cache should be transparent to each processor in the same way that the cache is transparent to the processor in a uniprocessor system. Figure 4 describes such a relationship. The channel usually doesn't need a cache for performance reasons, but will be involved in the cache system design to maintain the cache transparency to the channel. Comparing Figure 4 to Figure 1, one can easily see that the communications among the caches and the channel are necessary so that the main store system will still preserve the logic view of Figure 1 to the processors. The basic cache design itself (e.g., the directory, the set associativity, the block sizes, etc.) should be the same as the cache of a uniprocessor.[1-8] In the following section, communication among the caches and the channel in the multiprocessor system will be given in detail, as well as the portion of the basic cache design that relates to such communication.

CACHE SYSTEM DESIGN IN THE MULTIPROCESSOR SYSTEM

In a typical uniprocessor cache design,[5] a directory is used to translate the main store addresses to the

* NOTE: Hereafter, all references to the "multiprocessor system" will mean "tightly coupled multiprocessor system."

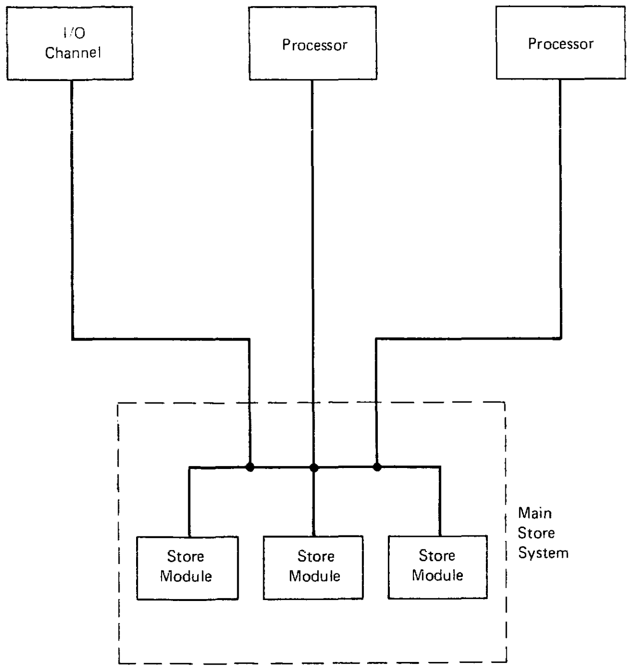

Figure 1—The logical relation between processors and the main store

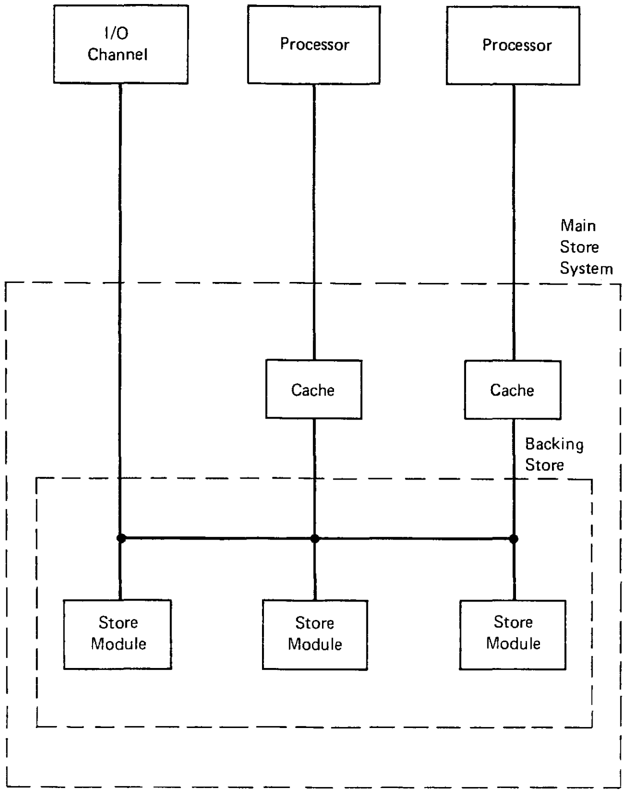

Figure 4—A multiprocessor system with caches

cache location of the data block in cache. Figure 5 shows the logical organization of such translation. No hardware detail is given since various designs are possible[1] and is irrelevant to the description of the subject issues.

In a multiprocessor system, the same cache organizations can be used for each processor, with the additional controls to facilitate the communication among the caches and the channel. The following definitions are needed to describe the communication:

Block the unit of translation, which is usually also the unit of data transfer between the cache and the main store.

Line block(s) that are associated with a given main store address. In a uniprocessor cache, a line is a block, whereas in the multiprocessor system, a line can exist in more than one cache. For example, a main store address refers to 64 bytes of data, and these 64 bytes of data exist at two caches, which can be addressed by each correspondent processor using the line address.

Shared Line a line that exists at the cache(s), which has not been modified (written) with respect to the copy at the backing store by the processor. The line is transferred to the cache from the backing store when the processor makes *read* reference and misses the line in the cache. A shared line should be allowed to exist simultaneously in more than one cache so that 'read only' data can be accessed more efficiently in the multiprocessor system.

Private Line a line that exists in a cache which has been modified (with respect to backing store) or is going to be modified by its corresponding processor. A private line should exist in only one cache so that at any moment, throughout the system, only one version of data exists for any address. This is a requirement implied by Figure 4 (cache transparency).

•	•	•	•

Figure 5—Cache organization in a uniprocessor

Status bits would have to be used in each entry of the cache directory to identify each line (shared or private).

There are many 'store algorithms' in a cache design.[7] In this section, the 'store only in cache' algorithm is used. It means that if the processor wants to write and a miss occurs in cache, then the line is always brought to the cache so that the processor can always write to cache. Minor changes would be necessary to the description below if another algorithm is used.

To control the communication among the caches and the channel, a 'store controller' is necessary (Figure 6). A set of commands from the caches to the store controller and another set of commands from the store controller to the caches are defined below. To perform the control functions, the store controller would have to know, at all times, the status of every cache, namely, what lines (shared or private) exist at which cache. This can be done in two ways: (1) use the store controller 'central directory' to keep track of every line in each cache, or (2) interrupt the caches to find out. The former approach certainly has the performance advantage, especially when the system has more than two processors. The description of the commands given below corresponds to the former approach; obviously a change of description should be made if the latter approach is used.

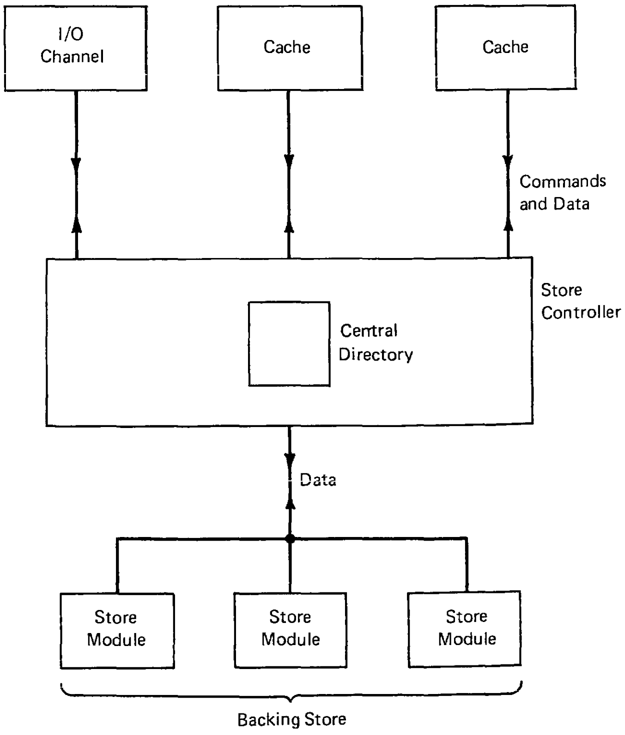

Figure 6—Store controller and control directory

COMMAND FROM CACHE TO THE STORE CONTROLLER

- Shared Read—This command is used when the processor wants to read (the main store) and a cache fault (miss in the cache) occurs. This command will signal the store controller to bring the line from the backing store to the cache. The line will be marked as a shared line in the cache directory and the central directory should record the fact that this cache (the cache that issues this command) contains the line as a shared line.
- Private Read—This command is used when the processor wants to write and a cache fault occurs. This command will signal the store controller to bring the line from the backing store to the cache. The line will be marked as a private line in the cache directory. The store controller should make sure (by using the store controller-to-cache commands described later) that only this cache has this line as a private line; no other caches can have this line shared or private. Such a fact should also be recorded in the central directory.
- Declare Private—When the processor wants to write, and if the line exists in its cache as a private line, the processor can write to cache and the line will remain private. No communication to the store controller would be necessary in such a case. On the other hand, if the line exists in its cache as a shared line, the line has to be converted to a private line before the writing to the cache can take place. Thus, this cache will change the status of the line in its directory from shared to private, and will inform the store controller of the change using this command. Upon receiving the command, the store controller will record the change in the central directory. In addition, the store controller will examine the central directory. If the central directory indicates that some other cache(s) has (have) this line as a shared line, the store controller will use the store controller-to-cache command (described later) to remove such a line from the cache(s). The removal is necessary since a private line in a cache means no other cache can have the same line shared or private. No data transfer is involved in this command.
- Replace Private Line—Replacement of the line in a cache is necessary to make room in the cache for the new line coming from the backing store. If the line being replaced is a private line, the backing store has to be updated using this command since the data in the cache have been modified with respect to the backing store. In addition to the data transfer from the cache to the backing store, the removal of the private line from this cache should also be reflected in both the cache directory and the central directory.
- Replace Share Line—If the line being replaced is a shared line instead of a private line, no data transfer from the cache to the backing store is necessary. The cache directory and the central directory should reflect such removal, and this command is used to signal the store controller to update its central directory for the removal. In hardware design, this command can be issued simultaneously with either the 'shared read' or the 'private read' for performance reasons, since these two commands cause the replacement.

COMMANDS FROM THE STORE CONTROLLER TO THE CACHE

- Unprivate Line—When some other cache issues a Share Read command to the store controller, the store controller will search its central directory for any cache that contains the line involved as a private line. If such a cache is found, this command will be issued to the cache found. Upon receiving this command, the cache directory of cache found will be changed to indicate that the line exists now as a shared line. The store controller will also update its central directory to reflect such a change. In addition, the line will be transferred from this cache to the backing store for updating since a private line contains modified data with respect to the backing store. This command is also used when the channel reads the main store directly.
- Remove Private Line—When some other cache issues a Private Read command to the store controller, the store controller will search its central directory for any cache that contains the line involved as a private line. If such a cache is found, this command will be issued to the cache. Upon receiving this command, the cache will remove the line from its directory. The store controller will also update its central directory to reflect such a change. In addition, the line will also be transferred from this cache to the backing store for updating. This command is also used when the channel writes to the main store directly.
- Remove Shared Line—When some other cache issues a Private Read command to the store controller, the store controller will also search its central directory for any cache(s) that contains the line involved as a shared line. More than one cache may contain such a line. The store controller will issue this command simultaneously to the cache(s) that contains such a line. Upon receiving this command, the cache(s) will remove the line from its (their) directory (directories). The store controller will also update its central directory to reflect such change(s). No data transfer from the cache to the backing store is necessary. This command is also used when the channel writes to the main store directly.

It should be clear now that by using the set of eight commands outlined above, in conjunction with the basic uniprocessor cache design, the multiple-cache system can meet the cache transparency requirement described previously. The channel still addresses the store controller using the ordinary 'Read Main Store' and 'Write Main Store' commands, which will invoke the store controller to issue the store controller-to-cache commands to maintain the cache transparency. For example, when the channel issues a Read Main Store command to the store controller, the store controller has to search its central directory for any caches that contain the line involved as a private line. If found, the Unprivate Line command is issued to the cache that contains it, and the store controller will also update its central directory to reflect such change. The backing store also has to be updated by the private line in the cache before the data can be transferred to the channel. Similar operation by the store controller is necessary when the channel issues the Write Main Store command.

CONCLUSION

A practical cache system design for the multiprocessor system is outlined in this paper. Although it does not represent exactly any of the cache system designs of the existing multiprocessors, it does illustrate the system requirement and design concept of the cache system. The use of a store controller was chosen (for managing the central directory, etc.) instead of using the interrupt approach. The store controller approach certainly requires more hardware, but offers much better performance especially when the multiprocessor system contains more than two processors. This should be apparent from the fact that a simple Share Read issued by a cache will cause the interrupt of all the other caches in the interrupt approach.

Many other system elements have to be handled with extra hardware facilities in a multiprocessor environment in addition to the hardware in a uniprocessor. These include the dynamic address translation, storage protection, locks, serialization, system clock, etc.[16,17] They all require communication between the caches/processors. This extra hardware can be conveniently incorporated into the store controller and can be used for these functions. These shared uses of the store controller would make the cost of the store controller less formidable.

ACKNOWLEDGMENT

The author wishes to thank many of his colleagues for the numerous discussions on the subject issues.

Coupling small computers for performance enhancement*

by FERNANDO C. COLON, ROBERT M. GLORIOSO, WALTER H. KOHLER and DOMINIC W. LI
University of Massachusetts
Amherst, Massachusetts

ABSTRACT

The advent of the microprocessor has opened up new avenues for the system designer to provide more powerful, more reliable and more user oriented computer systems to the user community for the same or lower costs. The problem confronting the designer is: How to achieve these goals? This paper describes one such method called Distributed Function Multiple Processor (DFMP).

The system described uses several micro processors each with its own memory to form a cluster. These processors are differentiated by the functions they perform such as file managing, intelligent terminal, etc. and communicate via a Restricted Cross Bar Switch (RCBS). Further, several clusters or nodes can be linked to form a local network. Interprocessor and internode communications are controlled by a special processor called the Interprocessor Controller (PC) located in each node. The IPC's use an adaptive technique to determine traffic flows.

INTRODUCTION

Rapid advancements in IC technology have increased the performance of logic circuits in terms of speed, gate density, reliability, and power consumption. Also, quantity production of LSI (Large Scale Integration) chips has made complex microprocessors and large memories available at low and decreasing costs. Such developments are beginning to force changes in some basic concepts of computer system design. Already, there exists computers on-a-card which include a reasonably fast CPU and basic memory. This cost is only a relatively small part of the total system cost. In many instances, peripheral devices and their controllers cost more than the CPU and basic memory. Therefore, the traditional concept of keeping the CPU and central memory fully utilized is becoming less and less important. One trend in computer design is to replace multitask monoprocessor systems with multiprocessor systems. These multiprocessor systems improve cost-performance by sharing expensive peripheral units. Computer networking is another approach that has become popular. A set of remote computers are interconnected through communication links in order to share resources. The potential advantages of building both type of systems include: (1) the sharing of resources (data, programs, special hardware); (2) reliability and availabiiity; and (3) performance enhancement.

Although multiprocessors and computer networks can be conceptually described as a set of interconnected nodes, they are significantly different in terms of the amount of "coupling" present.[1] Multiprocessor systems are "tightly" coupled in the sense that the processors share memory, I/O devices, and execute procedures under a single integrated operating system. Data in multiprocessors can be effectively transferred by the movement of pointers, as all processors share the same physical address space. Enslow[2] provides a historical perspective on the development of multiprocessors and discusses most of the major multiprocessor systems being considered or implemented today, and Baer[3] provides an excellent survey of the most important aspects of multiprocessing.

Computer networks, as exemplified by several loop systems and the ARPA Network,[4-6] are "loosely" coupled. There is no sharing of memory and the interconnecting media are fixed communication links where a datum of information is sent serially at rates of 100 to 50 Kbaud between nearly autonomous computers. While each computer can operate independently, it has higher effective capability when networked to the others. The papers by Farber[7] and Pyke[8] review the highlights of computer network technology and examine seven typical networks. Most of the research conducted in the area of computer networks that relates to this paper can be classified as follows: (1) models and analytic methods for network design;[9] (2) routing strategies;[10-12] and (3) coordination of processes and protocols.[13-15]

The multi-user, multi-task, *d*istributed *f*unction, *m*ultiple-*p*rocessor system DFMP to be described is

* This work was supported in part by a grant from the Digital Equipment Corporation.

designed to take advantage of the emerging technologies and to incorporate features of both multiprocessors and networks in an integrated manner. The basic element of DFMP is a microprocessor with its own memory. Collections of microprocessors are connected through a restricted cross bar switch to form a node of the system. Each node operates as a multiple-processor system which is coordinated by a special processor called the INTER PROCESSOR CONTROLLER (IPC).

The use of microprocessors in multiple-processor systems is certainly not new. (See the work by Ravindran[16] and Jordan[17].) However, research in this area has concentrated on "tightly" coupled systems and the problem of mismatch between microprocessor and memory cyle times. We have taken another approach. In DFMP each microprocessor is called a functional unit and is similar to a Computer Module (CM).[18] Basically, the functional units are processor-memory pairs with several special ports (connections to the restricted cross bar switch) or bus interfaces. There is no central shared memory in the sense of C.mup or HSM Imp[10] and the physical address space is the sum of all local memories. Thus, we will see that the functional units are more tightly coupled than the nodes of a computer network, yet less tightly coupled than the processors in conventional multiprocessor systems. The resulting intermediate coupling is a distinctive characteristic of the DFMP system, and for this reason we shall refer to it as a multiple-processor system.

The *a priori* design constraints for the system were:

(1) low cost processors must be used;
(2) the cost of the control and communications must each be limited to the cost of a single processor;
(3) the operating system must be incorporated as much as possible into the firmware and hardware;
(4) the system must be expandable with minimal modification to the operating system;
(5) to each user the system must appear as a medium powered general purpose computer.

Additional details of the design are presented in the following sections which are organized as follows. The second section discusses the system architecture; the third section is concerned with the execution of user's jobs in the system and the deadlock problem, and finally, the fourth section summarizes the concepts incorporated in our design.

SYSTEM ARCHITECTURE

An initial global view of DFMP reveals a network of independent computer systems, called nodes, interconnected by explicit communication links. The network may be a geographically localized one (i.e., installed in the same room) or a geographically distributed one (the nodes are far apart, i.e., in different states). The advantages of localizing the network are lower communication cost, simple network interfacing hardware, richer connection of the nodes, and a simpler communication routing procedure. In this initial phase of the design, a localized network is assumed, although the design principles involved apply to a geographically distributed network as well.

Figure 1 shows the block diagram of DFMP. For illustrative purposes only three nodes are shown, although in practice the number of nodes is only limited by the cost of the interconnecting cables and communications hardware. Each node is a distributed function, multiple-processor computer system consisting of three basic components: (1) a collection of Functional units; (2) an Interprocessor Controller (IPC); and (3) a Communications Switch. The main functions and the hardware structure of each element are described below.

(1) *Functional Units*—The functional units are the basic building blocks of a node. As will be described in the next section, jobs submitted by the users are dynamically partitioned into subtasks which are executed by specialized functional units. The hardware structure of a typical functional unit is depicted in Figure 2. It consists of a processor, local memory and interprocessor communication hardware. Each unit belongs to a particular class depending on the functions it performs, and may have additional hardware or

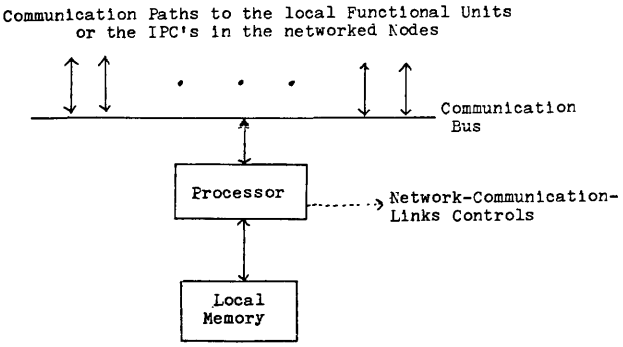
software peculiar to that class. For example, if the functional unit is specialized in Input/Output functions, it will also have its own I/O devices and I/O controllers as well.

(2) *Interprocessor Controller (IPC)*—The functional units can be regarded as autonomous system resources which are allocated and deallocated throughout the process of running a user's job. The main purpose of the IPC is to serve as the resource manager and network coordinator for a node. The hardware of the IPC (Figure 3) consists of a relatively fast processor and a local memory which stores the IPC control functions and the resource allocation tables. All local functional units are connected to the IPC via a direct Communication Bus. If the node is networked, the IPC also has (i) control lines for the Network Communication Links and (ii) a direct communication path to adjacent IPC's for network coordination.

(3) *Communication Switch*—The function of the Communication Switch is to provide for the interprocessor communications (both intra-node and internode) among the functional units. Several alternatives for the switch were examined: a fast processor serving as a communication processor; a common bus; and different kinds of cross-bar switches. Considering their efficiency in terms of speed, cost, reliability, availability and ease of networking, a Restricted Cross-Bar Switch (RCBS) was chosen. The cross-bar switch is restricted in the sense that

(a) only one-to-one connections are allowed, but there can still be many different one-to-one simultaneous connections;

(b) data transfer is done bit serial, synchronously through the switch, but the bit serial rate is high and the transfer time of one memory word is of the same order as the processor instruction cycle time.



Communication Paths to the local Functional Units or the IPC's in the networked Nodes
Communication Bus
Processor
Network-Communication-Links Controls
Local Memory

Figure 3—Block diagram of the IPC

The RCBS consists of the following four parts (see Figure 4(a):

(a) *Port*—A port may be connected to a local functional unit, or a port of another node to form a network link. Physically, a port is simply a socket in the RCBS module.

(b) *Cross-points*—A cross-point can be considered as a unit cell in the RCBS. The number of cells in a RCBS having N ports is $N(N-1)\div 2$. They are interconnected in such a way that each port can be connected to any other port by "turning on" a single cross-point. After turning on the particular cross-point, signals can be transmitted between the pair of ports. As shown in Figure 4(b), a cross-point can be simply made from four open-collector NAND gates and a single NOR gate. A full-duplex bit serial transmission path is accomplished by using two NAND gates to pass the bit serial data plus the clocking signal in each direction. The remaining NOR gate is used to turn on the cross-point when the input conditions are met (See below).

(c) *Port Selection Logic*—The port selection logic consists of 1-of-N demultiplexers, with one for each port. The input signals from a port to the demultiplexer contain the name of the port to which a connection is desired. The outputs of the demultiplexers are connected to the respective cross-points in such a way that a cross-point is turned on if and only if each port selects the other.

(d) *Interrupt Logic*—The interrupt logic also consists of 1-of-N demultiplexers, one for each port. The input to a demultiplexer gives the name of the functional unit to be interrupted. The use of this interrupt logic enables the functional units to synchronize their communications without going through the IPC.

The example in Figure 5 shows how the RCBS is used to facilitate both inter-node and intra-node interprocessor communication. In the next section we will describe how the different components of DFMP interact to carry out a user's jobs.

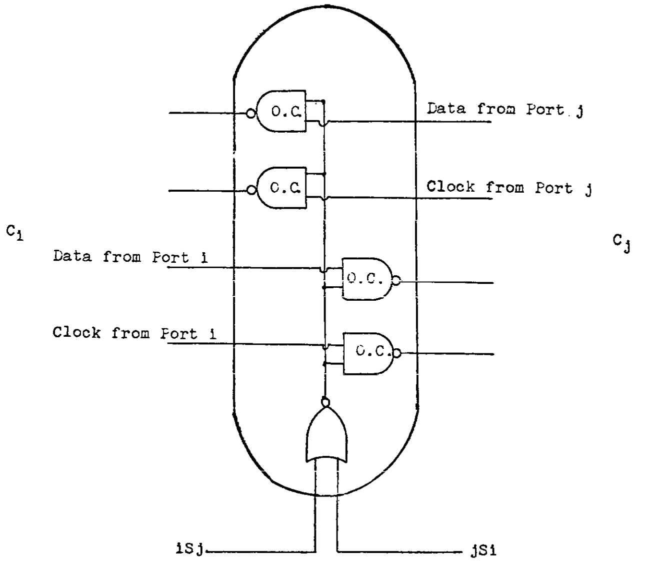

Figure 4(b)—A cross-point between port i and port j. The controls iSj and jSi are normally high. The cross-point is turned on if and only if both lines are low (when both ports select each other)

JOB PARTITIONING

The processor-memory pairs described earlier are grouped into different classes according to the functions they perform. Units from each class are requested as needed and coordinate their actions to carry out the execution of jobs submitted by users. This is an example of the division of labor method introduced in the GAMMA 60 design and further explored by Foster[20] and Spier.[21] Although the number of different classes and the mix of units is application dependent, in a general purpose environment there are five readily identifiable classes:

(1) *Intelligent Terminal* (*I.T.*)—An intelligent terminal is assigned to each user and remains dedicated to that user until his requests are completed and he relinquishes the unit. An I.T. enables interaction with the system and provides support to the user by performing functions such as command prompting, line editing, message buffering and command interpreting.

(2) *General I/O*—A functional unit in this class handles I/O devices such as line printers, paper tape readers/punchers, and cassettes. It performs I/O transfers between its devices and other functional units. This unit alleviates the problem of mismatched speeds between functional units and I/O devices by using a spooling system to handle all I/O requests.

(3) *Execution*—A unit in this class responds to the requests of an I.T. or another execution unit to execute a user-generated computational procedure. The microprocessors in this group may have extra hardware such as an extended arithmetic element. Also, they have special routines for linking and loading the appropriate segments of a user's program.

(4) *Program Development*—A unit in this class executes sharable re-entrant system programs such as compilers, assemblers, and text editors that are stored in local ROM's. It receives requests from other functional units and performs software support functions.

(5) *File Management*—A unit in this class manages a secondary storage system (disk, drum, extended core, etc.) and executes file functions such as "CREATE", "DELETE", "RENAME", "APPEND", and so forth. Furthermore, a File Manager stores and retrieves state information on logical tasks which have been suspended. The details of the "suspension" mechanism will be given in the next section.

Next, let us consider the actions and coordination of functional units in the execution of a user's task.

Resource allocation

In order to understand the coordination primitives used by the system and the different levels of interaction present among the functional units, we will follow a user's task through the system. First, the user logs into the system and is assigned an Intelligent Terminal. This I.T. will serve as the user's representative in his transactions with the system. The I.T. is the only functional unit whose binding to the user and user's job is permanent and thus independent of such factors as system loading, failure of other system functions, and so forth.

In general, the I.T. receives commands for the execution of jobs through a *job control language*. Typical commands would be: RUN, COMPILE, CREATE FILE, and EDIT. Also, each command would include an aggregate of information to make the command executable. For example, the "COMPILE" command would include the name of the compiler needed, the name of the source code, and the I/O devices involved. The I.T. interprets this system command language and transforms it into a sequence of subtasks and resource requests. In this way the "RUN" command would be transformed into the following sequence of subtasks:

(1) Compile (SOURCE NAME/LOC, OBJECT NAME/DEST)
(2) Execute (OBJECT NAME/LOC).

These subtasks may, during their execution, create other subtasks, i.e., the Compile task above would probably generate subtasks that involve file transfers and I/O listings. This description completes the discussion of the first level of interaction present in the system, that is, user to functional unit interaction.

The subtasks created by the system commands are considered as a series of resource requests. Hence, it

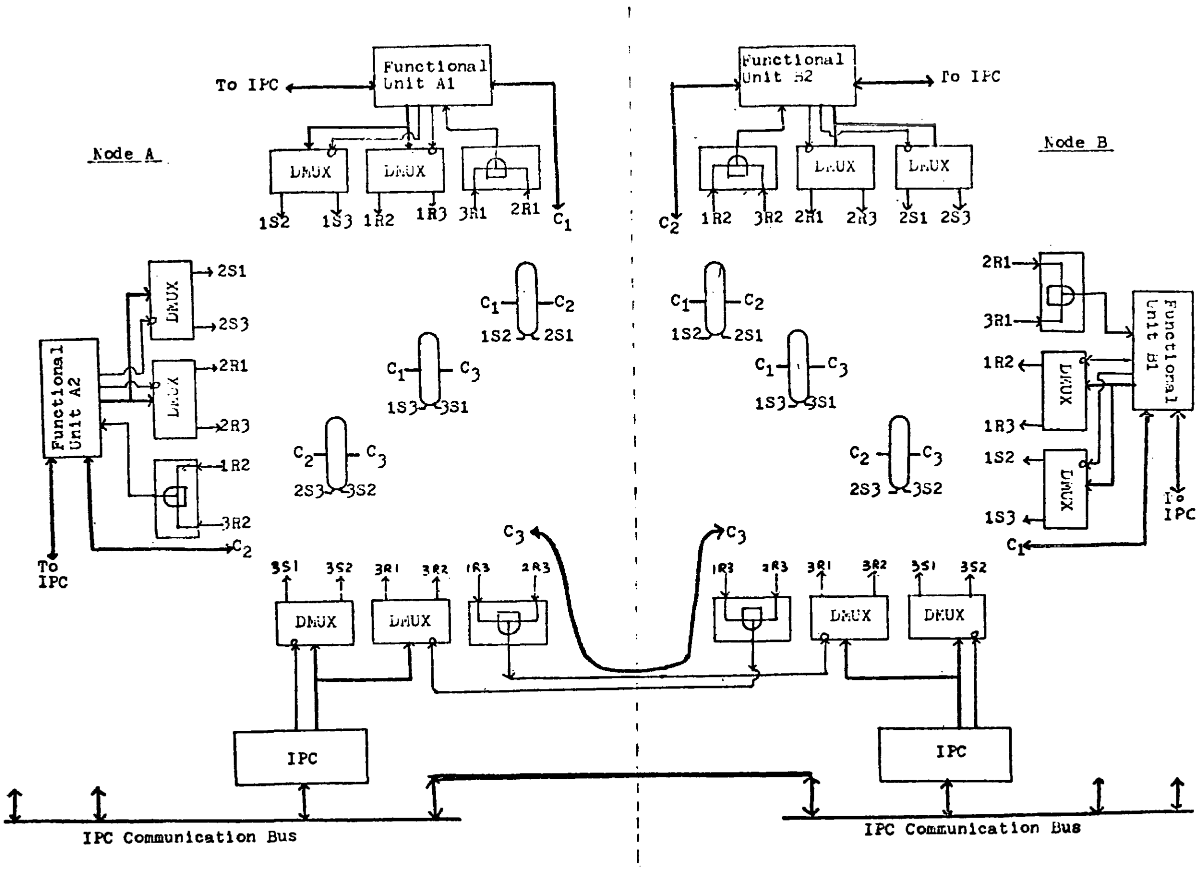

Figure 5—An example on the use of the RCBS to form a two nodes network. If a port is connected to a functional unit, the inputs to the demultiplexers (for the selection and interrupt controls) are controlled directly by the functional unit. If a port is used to form a network link, the demultiplexers are controlled by the IPC's in such a way that the network link is made transparent to the functional units in the two nodes

is the responsibility of the I.T. to initiate these requests by posting them with the resource allocator (the IPC) within the node. This interaction between functional units and IPC represents the second level of interaction. Such interactions are needed whenever tasks executing within the functional units come to a point where additional resources are needed to complete their work. In the present example the "COMPILE" task would require the allocation of a Program Development unit (P.D.) in order to complete its work. Such requests must be posted with the IPC.

Upon acknowledgment of the request, the IPC would initiate a search for a free unit of the resource type requested. This search involves a two-stage decision, where first a node and then a specific functional unit within that node is selected. The selection of the node will be based on the adaptive scheme of Glorioso and Colon.[22] The IPC makes its node selection using a set of network statistics. These network statistics are a measure of the likelihood of obtaining the desired resource for each node (including the local node) present in the system. Following the selection of a node, the requesting IPC will inform the selected node's IPC of its request. This involves a third level of interaction, namely IPC to IPC.

Within the selected node, a much simpler method is used to select a specific functional unit to service the request. Each node has an associated Availability Status Register for each of its resource classes. This register contains the status information (either busy or free) of each functional unit in the particular resource class. Therefore, the decision at this stage is made by a scan of the corresponding register for a free unit followed by allocation of this unit, if one is found. If no such unit is currently available, the pending request will be queued with all other requests in that node waiting for the particular resource type. This information and the queue length will be passed back to the node that originated the request (not necessarily a different node) to be used in the updating process of its network statistics. For a more detailed description of this process, see References 22 and 23.

The advantages provided by the selection scheme are as follows:

(1) The need for constant exchange of complete status information between nodes is eliminated. Considering the number of functional units within a node and a richly connected network, constant status information exchange can seriously degrade the performance of the system.

(2) Automatic load leveling is accomplished. That is, when functional units of a certain class are used up, the likelihood of selecting the corresponding node is "dynamically adjusted" by the adaptive scheme. Hence, the load will be diverted to other nodes in the system.

(3) Failsoft behavior is realized. Since failure of nodes will be reflected in the likelihood of service statistics from that node, the IPC's will avoid failed nodes.

Once a functional unit is selected, the selected unit is informed (by the IPC in the selected node) of the identity of the requesting unit, and the requesting unit is informed (by the IPC in the requesting node) of the identity of the selected unit. At this point it is the responsibility of the two units to establish a communication path through the RCBS and to coordinate their actions. This process involves the fourth and last level of interaction, namely functional unit to functional unit. In our example the I.T., after receiving the identity of a P.D. unit from the IPC, will initiate the compilation by transferring the necessary control information (SOURCE NAME/LOC, OBJECT NAME/DEST) to the P.D. unit. The P.D. on the other hand will proceed with the compilation task until completion or to a point where additional resources are needed. If additional resources are needed, the sequence of steps described above will be repeated with P.D. as the requesting unit.

Notice that as the user's job proceeds through the system, it is segmented into finer and finer procedures some of which may execute in parallel. This parallelism can be graphically represented by a timing diagram and a static tree representation. When a timing diagram is used, (See Figure 6(a)) resource allocations and deallocations are shown as vertical lines and the usage of resources is depicted as horizontal lines. It reflects the dynamic history of requests and allocations. On the other hand, a static tree representation, (See Figure 6(b)) can be considered as a snapshot of the system's outstanding requests at a particular time. It shows the logical relationship between units, i.e., who initiated whom.

When a task is completed by a functional unit, the functional unit is deallocated. Allocation and deallocation of resources continues until all tasks and subtasks are finished and the user is informed. Now, let us shift our attention to the tasks and their corresponding state transition diagrams.

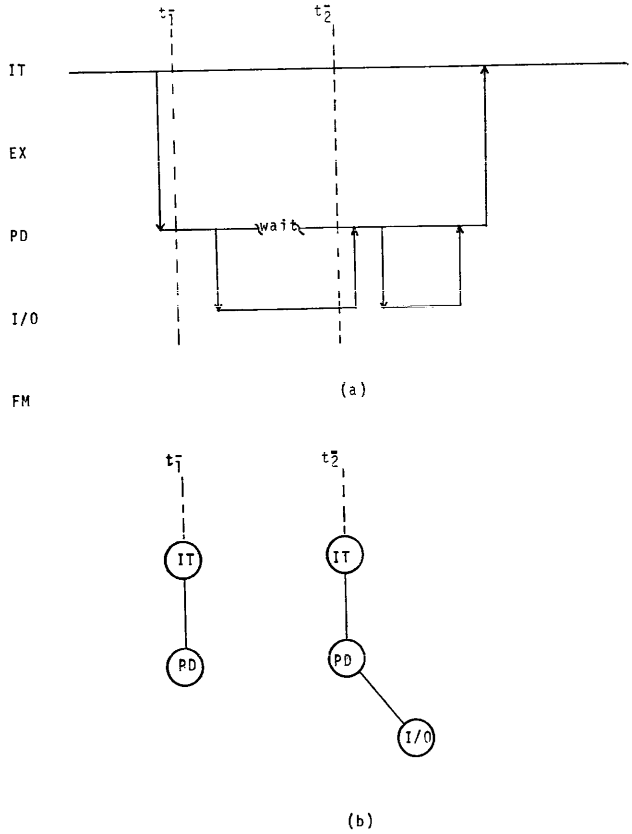

Figure 6—(a) Timing diagram representation
(b) Tree representation

STATES AND STATE TRANSITION DIAGRAMS

Tasks occupy one of the five states shown in Figure 7. A task is

(1) *terminated* before it has been created and after it has finished;

(2) *ready* if it has been created or reactivated by its parent but it is not yet bound to a functional unit;

(3) *waiting* while it is

(a) requesting additional resources for a subtask it is creating, or

(b) waiting for coordination with a subtask it has created;

(4) *running* while it is bound to a functional unit but not in the waiting state;

(5) *dormant* if it has been preempted while waiting, or after using a resource for a prespecified time limit.

Each task is created by another task, its parent. A newly created task enters a queue of tasks which are ready to run but are waiting for a functional unit. This queue of ready tasks is maintained by the IPC. When a functional unit becomes free, the IPC passes the

unit's identity to a parent of a task waiting for that type of unit. If the free functional unit and the parent task are successful in establishing a communication path, the ready task becomes bound to the functional unit and enters the running state. Tasks in the running state may create subtasks or request coordination with tasks they have already created. To do this they must enter, and then remain in, the waiting state until the request is completed or the task is preempted (for waiting too long for example). Preempted waiting tasks enter the dormant state as do preempted running tasks. When a task enters the dormant state, its state vector is stored and its associated functional unit is deallocated. A dormant task is reactivated at a later time by its parent.

Each task is a logical entity and is only bound to a physical functional unit during the running and waiting states. To describe the status of each functional unit we will use the state transition diagram given in Figure 8. Each functional unit is in one of the following four states:

(1) *free* if it is not bound to a task;

(2) *waiting* if it is bound to a task and the task is waiting for coordination with a subtask it has created;

(3) *running* if it is bound to a task that is in the running state;

(4) *posting request* if the task to which it is bound is entering a request for additional resources.

These states parallel those of a task since each task is executed in a functional unit. The Availability Status Register bit associated with each functional unit is enabled (set to one) when it becomes free. When a unit becomes bound to a task, two hardware timers are initialized. One is enabled whenever the functional unit is in the running state and the other whenever it is in the waiting state. If either of the accumulated times exceeds the prespecified system limits, the task will be preempted and the functional unit will be deallocated once the state of its associated task has been saved to enable restart. When a running task creates a subtask, it notifies the functional unit to which it is bound to post a request for an additional resource. The functional unit will then enter the posting request state and communicate the request to its IPC. If the task is able to continue running independently of the subtask, the functional unit will return to the running state; otherwise, it will enter the waiting state. In the DFMP system, each task will interact with its parent task and its subtasks by means of a small local monitor in the functional unit to which it is bound. These monitors will be the building blocks of the distributed operating system of DFMP.

Deadlock prevention

Whenever concurrent tasks contend for system resources a condition of deadlock may occur. This phenomenon has been studied extensively in connection with the design of computer operating systems and sufficient conditions for the prevention of deadlock are well-known.[24,25] One solution to this problem is to impose a linear ordering on all resource (functional unit) classes. If a task has been allocated a functional unit in class R[i] it may subsequently create a concurrent subtask requiring a functional unit in class R[j] only if j>i. This eliminates the possibility of a circular waiting condition. The linear order we have adopted is shown in Figure 9. We can in fact relax the requirement that j>i and allow j=i if a functional unit in class R[j] is immediately available. In this case the request need not to be queued and circular wait is prevented. When a functional unit is not immediately available and j=i, the requesting task must cancel its request and proceed to execute the subtask sequentially, using the functional unit in that class which is already bound to it. This modified rule allows parallel tasks using identical resources to be created as long as the system is not saturated. If saturation occurs, the potentially parallel tasks will be forced to run sequentially.

Task preemption and reallocation of resources

Preemption of a task enables the system to avoid the monopolization of resources by a group of one or more users. Preemption occurs when a functional unit has been in the waiting or running state for more than the specified time limit. We will describe this preemption process using an example. Assume that preemption occurs at time t in Figure 6(a). A snapshot of the state of the user's job at time t reveals the concurrent task structure represented by the tree in Figure 6(b). We will assume that the preemption occurred in the Program Development unit while in the running state. Upon encountering this condition, the local monitor would initiate a series of procedures to save the state vector of the interrupted task T and to then deallocate the functional unit. These procedures would carry out the following actions:

(1) Interrupt T's parent P.

(2) P becomes the logical parent of T's subtasks $T_1,\ldots,T_n$.

(3) Interrupt $T_1,\ldots,T_n$ and notify them of change in parent.

(4) Save T's state vector.

(5) Deallocate resource.

The state of the user's job following T's preemption is shown in Figure 10.

SUMMARY

The design of a networked multiple processor system, DFMP which has characteristics of both multiprocessors and computer networks has been presented. DFMP has a unique structure wherein many microprocessors each with its own memory and specialized in function are coupled to form a multiple processor. Also, several multiple processors can be joined into a computer network.

The operating system is distributed in each of the functional units. There is no central scheduler in DFMP but an Inter Processor Controller in each Multiple-Processor to coordinate communications between the functional units within and between nodes.

At this time DFMP exists only on paper. However, work on a single node using five Digital Equipment Corporation's LSI-11 Microprocessors is under way.

The CERF computer system

by NEIL WILHELM, DAVID PESSEL and CHARLES MERRIAM
University of Rochester
Rochester, New York

ABSTRACT

Multiprocessor systems are becoming increasingly popular because of the increased throughput possible and the possibility of system availability despite the failure of some of the processing units. This paper describes an innovative concept in multiprocessor system design, and suggests some of the research areas which have not yet been resolved but which can be studied on this system. The system architecture is patterned after Control Data Corporation's peripheral processor "barrel" except that it possesses much more powerful functional capabilities. In addition, high speed minicomputers were used to handle all of the system I/O requirements. Research areas for which this system is particularly appropriate include computer architecture-operating systems tradeoffs and multiprocessor operating systems design and implementation. The hardware system is entirely microprogrammable, allowing for increased flexibility in evaluating various research strategies.

INTRODUCTION

Two major questions present themselves in the design of multiprocessor computer systems:

(1) How can operating systems be designed to efficiently handle processor scheduling, memory management and file and I/O management on a multiprocessor system? An important aspect of this question concerns the management of the operating system itself: should it be executed by one dedicated processor or should its functions be distributed throughout the system in some fashion?

(2) What are the appropriate architecture and operating systems tradeoffs? Because of reduced hardware costs, it is becoming increasingly possible to implement many ramifications of this issue including the general ability to modify hardware implementations once they are completed without a major cost to the system.

We plan to investigate these questions, with the assistance of a unique tool: our Computer Engineering Research Facility (CERF) Computer System. This computer system, and some of our research objectives, are described on the following pages.

SYSTEM DESCRIPTION

The CERF Computer System is depicted in Figure 1. The primary elements of the system are the four Central Processing Units (CPU's). These are independent, microprogrammable processors, featuring 64 bit data paths and 72 bit microinstructions. Each processor has its own scratchpad of 64 (64-bit) registers, although microinstructions are fetched from a common (and expandable) 1024 storage. Each microinstruction features field extraction and branch capabilities, automatic stacking of subroutine return addresses to a depth of 16, indirect register references with no time penalty, and a large selection of arithmetic and logical operators. The processor clock is 10 MHz, providing 400 ns microinstruction execution times (all microinstructions take the same time).

The CPU's communicate to the external world *via* two buses, the Stunt Box Bus, and the Memory Bus. The Stunt Box Bus is used for the attachment of specialized hardware, such as multipliers, dividers, target machine instruction decoders, etc. The Memory Bus connects the CPU's to the main memory, which initially will be 128K bytes, arranged as 64-bit words, of solid state memory. Error detection and correction will be provided by an 8 bit Hamming code appended to each memory word.

I/O devices are divided into two categories, high speed and low speed. High speed devices, such as the disc (an 80 megabyte moving-head disc) or drum (a one megabyte fixed-head disc), are each connected to the I/O Bus *via* two Selector Channels. These channels are extremely fast, special purpose, programmable computers with 16-bit words.

Low speed devices are connected through an Interdata 7/16 minicomputer with 16k bytes of 1000ns primary memory. The card reader, printer and other miscellaneous peripherals are attached to the 7/16 by a special interface called the Multiplexor Channel. This channel provides these peripherals with direct access to the 7/16's memory on a time-multiplexed basis. The CPU console is simulated by an interface to the Multiplexor Channel. Terminals and communication equipment are connected to the 7/16 by the Terminal Controller, which is a very fast programmable computer similar to the Selector Channels. The Terminal Controller also provides the path between the 7/16 and the primary memory of the CPU.

In addition to handling the low-speed peripherals, the 7/16 assists in debugging the hardware *via* the simulated console, and, with its core memory, is a convenient means of bootstrapping the system.

CERF CPU description

The need to have multiprocessing capability with three or more processors poses a number of potential design problems, primarily problems with priorities, interference, and processor lock-out. In addition, having multiple processors generally means having multiple copies of the same hardware. All of these problems can be solved by a design technique similar to one used by Control Data Corporation[1] for the peripheral processors in their 6000 and 7000 series systems. The CERF central processor hardware is divided into four disjoint subsets, corresponding to four stages of microinstruction execution. Thus a processor, at any stage of a microinstruction's execution, needs only one of the four parts of the hardware, so that *four processors can share the same hardware* provided each is in a different stage of microinstruction execution. Such an arrangement, with several processors cycling through the same hardware, is often called a "barrel".

Figure 2 shows the data flow paths of the four processors. Each processor has its own bank of 64 registers of 64 bits each; these are the only elements which are not shared among the processors. The functional elements, which operate on data, consist of the field extractor, which can extract any field of contiguous bits from a word, the field depositor, which can deposit an arbitrary length field into a word, and the arithmetic-logic unit (ALU) which can perform the usual arithmetic and logic operations plus a number of specialized ones. Note that the B-bus, which provides one of the two operands required by the ALU and field depositor, is fed by the field extractor, so that one of the operands could in fact come from any field of a word in a register.

An important issue which must be considered is whether or not the operations shown can be done with reasonable dispatch, so that the processors are fairly fast. Calculations, using manufacturer's worst-case propagation delay specifications, show that a staging time of less than 100 nanoseconds, i.e., a clock rate of 10 MHz, is feasible. This yields a microinstruction time per processor of 400 ns which, from the rule-of-thumb that 10-30 microinstructions are required for each target machine instruction, implies a target machine instruction execution time of 4 to 12 micro-

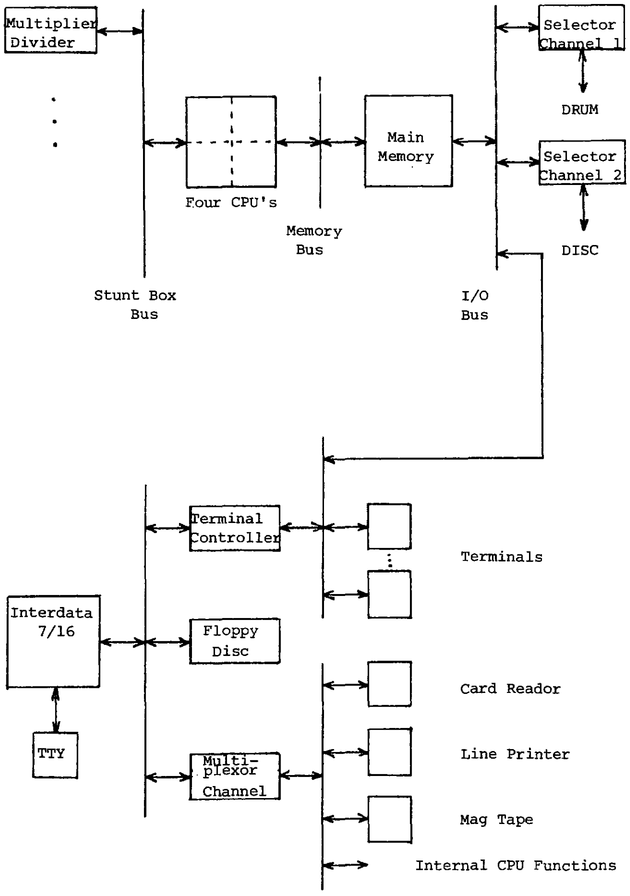

Figure 1—Computer Engineering Research Facility (CERF) computing system

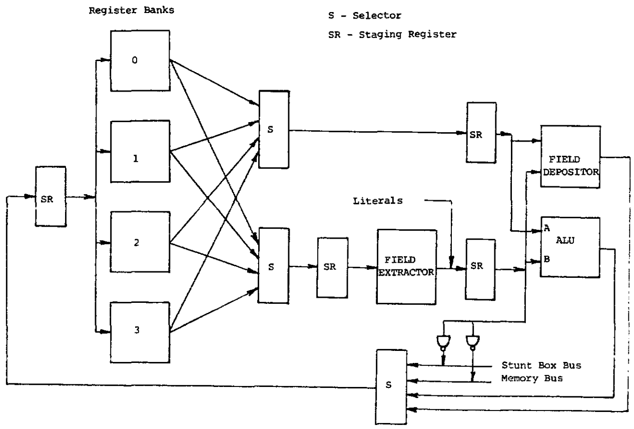

Figure 2—CERF computer system data flow

seconds on *each* processor. The *overall* execution rate would be 10^7 microinstructions per second, and .3 to 1 million target machine instructions per second.

It is essential that the microinstruction set be adaptable and powerful. To understand what this implies in terms of microinstructions, one must first realize what consumes most of the effort of emulators: decoding the instructions of the target machine. To reduce this overhead the set of microinstructions must include ones for extracting fields of bits from words and for making conditional branches and subroutine calls. All of these objectives are met with the CERF CPU microinstructions.

The design of CERF is presently complete, and it is anticipated that its construction will be complete by June, 1976. Its design has been made in full cognizance of and with careful consideration for the research areas described here. CERF will provide a unique research vehicle, and has been configured in such a way so as to provide a general purpose timesharing system to the University community. This user community is necessary to provide a load on the system during the testing of research problems.

We now describe some aspects of the hardware implementation.

HARDWARE IMPLEMENTATION

The CPU's

The Schottky TTL logic family was selected for the implementation of the CPU's. Emitter-coupled logic (of the ECL 10K family) was considered, but it was rejected because of power consumption, wiring (particularly the need for pulldowns), and interfacing problems (requires level translators to mate with other logic families), because of a shortage of MSI and LSI function as compared with TTL, and because of its high cost. An ECL or ECL-TTL hybrid system could easily run twice as fast.

Recent advances in bipolar memory technology not only reduced circuit complexity over preliminary estimates, but also reduced system cost. Processor register banks are implemented with 64×9 RAM's (Fairchild 93419) which provide a worst-case access time of 50ns (actual measurements with a lGHz sampling system show an address-to-output access time of about 30ns). Thus the entire set of four banks of 64×64 registers requires only 32 integrated circuits. The microstore is constructed from 1024×1 bipolar RAM's (Fairchild 93415) with a worst-case access time of 70ns (measurements show a typical access time of about 37 ns), requiring only 72 integrated circuits for a 1024 word storage.

The primary limiting factor in CPU speed is the delay in the ALU-test-branch decision path. Because branch options on every microinstruction are desirable, and because branching should carry no time penalty (since it is done so frequently in microprograms), this path is crucial to the machine's performance. The only solution is to calculate *both* of the possible successors to each microinstruction, and select the correct one at the last possible instant.

Main memory

Dynamic MOS RAM's were the choice for the main memory, because of their low cost, availability, and reliability. Memory system reliability is enhanced by using an 8 bit Hamming code, which provides single error correction and double error detection, on each 64 bit datum. Thus memory words are 72 bits in length.

Four-way interleaving is used to increase memory bandwidth which, for an approximate cycle time of 500 ns, is 8 megawords or 64 megabytes per second. The useable bandwidth is somewhat less than this. New memory accesses can be initiated while others are in progress, thereby reducing idle time.

Selector channels

The selector channels are implemented with 4-bit slice processor elements (AMD 2901), being essentially very fast 16 bit minicomputers. Each has typically 1024 words of bipolar memory (the same as the microstore) for programs and data. Special "vector" instructions are used to handle the extremely high data rates of the disc drives. Special functions, such as error correcting coding, are implemented in hardware.

RESEARCH GOALS

Most conventional operating systems are almost exclusively oriented towards the concept of single processor systems. Although these operating systems may allow multiprogramming, the ramifications of multiprocessing are generally avoided. Multiprocessing systems have been examined in limited detail elsewhere.[2, 3] This study will consider in depth various aspects of multiprocessor operating systems. In particular, we will study whether one operating system can effectively and efficiently coordinate the activities of more than one processor in a multiprocessor system. In a multiprocessor system each processor may have an independent address space mapped onto one physical memory, or independent memories may be available to each processor. In either case, the operating system is now faced with the task of coordinating various memory maps. Similarly, each processor in a multiprocessor system may execute programs from independent job streams or there may be only one job stream being scheduled onto all of the processors. In both cases, the operating system must handle scheduling of a far more complex form than on a uniprocessor system. Finally, a separate file and I/O system may exist for each processor. This results in yet another set of operations more complex than on conventional systems. Various problems may arise as a direct result of this type of system. Among these are: (1) primary memory contention: since more than one simultaneously active processor and task can address the same memory module, techniques must be explored to reduce or avoid memory contention at that module, and (2) file protection: adequate file protection is complicated because of the existence of simultaneously active processors and tasks which may access the same files. File structures which insure data integrity must be developed and implemented.

A second area to be considered concerns architecture operating systems trade-offs. An operating system is very dependent upon the architecture (i.e., the instruction set, registers, etc.) of the processor on which it is run. This relationship is so close that not only the effectiveness and efficiency of the operating system but the very *structure* of the operating system is determined by the processor architecture. For example, the "cactus stack" design of the B-6700[4] leads naturally to the tree-like hierarchy of processes used by the operating system. Of course one can always *impose* an operating system design on an unsuitable processor, at the risk of losing efficiency.

We can delineate three basic areas in which the operating system-processor interaction is crucial. These are processor scheduling, memory management and file and I/O management. For each of these areas, trade-offs can be made between performing important functions as "hardware macro's" (e.g. as special processor instructions or using dedicated processors) or as "software macro's" (i.e., aggregates of primitive hardware instructions). We can increase system speed by using more "hardware macro's" in exchange for greater processor cost and complexity and reduced system flexibility. On the other hand, we can reduce system cost and increase flexibility by using "software macro's", but at a reduction in efficiency.

Existing systems are examples of *a priori* decisions regarding the distribution of functions between hardware and software. For the IBM S/360,[5] essentially all operating system functions are implemented without hardware assistance. On the other hand, the Berkeley Computer Corp. BCC-500[6] (now at the University of Hawaii) features specialized processors performing such functions as scheduling and memory management.

We propose to investigate, theoretically and empirically, several specific areas of operating system-architecture tradeoffs, using the CERF multiprocessor computer system as a tool. One of these areas is the design of operating systems for multiprocessors, emphasizing the synchronization primitives and the architectural features necessary to support them. Hardware provisions for mutual exclusion are especially important in a multiprocessor system, since the simple expedient of turning off the interrupts and simulating mutual exclusion primitives in system software works only for a uniprocessor system. Since P and V operations may imply changes in processor scheduling, the relationship between the hardware and software is very close at this point.

Another important consideration is the distribution of the operating system functions to various system processors. Should important functions such as processor scheduling be shared among the central processors (as in the original plan of the CMU Hydra system), should one of the central processors be dedicated to these operations, with the other processors as slaves, or should these functions be distributed to more specialized "peripheral processors" (as done in the BCC-500 and the CDC 6000 and 7000 series)? The CERF system is ideally suited for this type of investigation. One could write special microcode for one of the central processors, making it the master. On the other hand, the drum controller can be reprogrammed to handle the memory management, or the Interdata 7/16 could be programmed to perform processor scheduling.

Our current plan, now under way, is to develop an initial target architecture which is "extensible" so that we may add the features we need with relative ease, and is also well-structured, so that ALGOL-like languages can be fully-supported and compiled efficiently. Because the basic machine architecture will remain relatively fixed, we can expect to get meaningful performance comparisons as we explore the various possibilities.

CONCLUSION

We have described an innovative approach to multiprocessor system architecture, yielding greatly increased hardware flexibility and applicability at only a slight increase in cost. This system provides a unique vehicle for research in multiprocessor architecture and operating systems. The research objectives have been briefly described, and the results of these studies will be presented in future publications.

A parallel processor for evaluation studies

by GARY J. NUTT
University of Colorado
Boulder, Colorado

ABSTRACT

The Multi Associative Processor system is a multiple control unit parallel processor capable of executing a maximum of 8 single-instruction-stream, multiple-data-stream programs simultaneously. The architecture supports parallelism at two levels: the lower level is the tightly coupled parallelism typical of array processors, and the higher level is the more loosely coupled parallelism between independent processes. The architecture of the machine is described and an example program for the machine is given to illustrate many of the concepts of the architecture. Measurement and evaluation studies on the machine are also briefly discussed.

INTRODUCTION

The needs of present day, large scale computer users have led to the development of a variety of parallel processor systems. The exploitation of parallelism becomes necessary for these users since electronic signal propagation has become a limiting factor to the speed with which certain computation can be carried out on a sequential processor.[2] There exist a number of architectural families that exploit parallelism in one way or another—pipeline processors, vector machines, multiprocessors, array processors, and associative processors.[6] The inherent complexity of these processors magnifies the need for measurement and evaluation techniques to design and tune the systems. The design of a system includes the organization of the software as well as the hardware; performance evaluation has often been shown to be important in the design phase of sequential processor systems, e.g. see Reference 5. Past experience has also pointed out the need for evaluation techniques in tuning sequential processor systems, e.g. see Reference 9. Since the parallel processors must include more complex hardware and software, the need for sound measurement and evaluation techniques is even more important than it was for the third generation sequential processor systems.

In order to investigate design and evaluation techniques for any given class of computer systems, one must either employ a prototype system, or construct a model to represent members of the class. The ultimate test for any hypothesis is to carry out experiments with the real subject; in the case of measurement investigations for computer systems the ultimate test is to try techniques on a physical computer. There are, however, certain advantages to experimenting with models rather than the real system: economics is an obvious advantage. Other advantages include the ability of the model to ignore certain factors in the analysis. It is also easy to try various designs and configurations with a model, where real systems are not only expensive to modify but also time consuming to test. Extensive modeling should precede prototype testing.

In this paper a hypothetical associative array processor system is described, where the primary intent for introducing another "paper" machine is not only to display a novel architecture, but also to provide a model to be used for investigating measurement and evaluation techniques for parallel processors. To help explain the design concepts of the machine, a sample program is provided, following the architecture description. The paper serves to document the system model, to display the current state of work on the project, and to describe future work.

THE ARCHITECTURE OF THE SYSTEM

The medium of this study is called a Multi Associative Processor (MAP) computer system. The machine is a member of the class of single-instruction-stream, multiple-data-stream (SIMD) parallel processors.[6] These computers employ a control unit to decode a string of instructions stored in a main memory and to cause a collection of arithmetic units to execute the instructions on data stored in private memories associated with each arithmetic unit. Some prominent members of this class of computer systems include the ILLIAC IV,[3] the PEPE system,[7] and the Goodyear STARAN.[13] The MAP system shares many properties of these systems, but also has others unique to its architecture.

Figure 1 is a block diagram of the system, and the

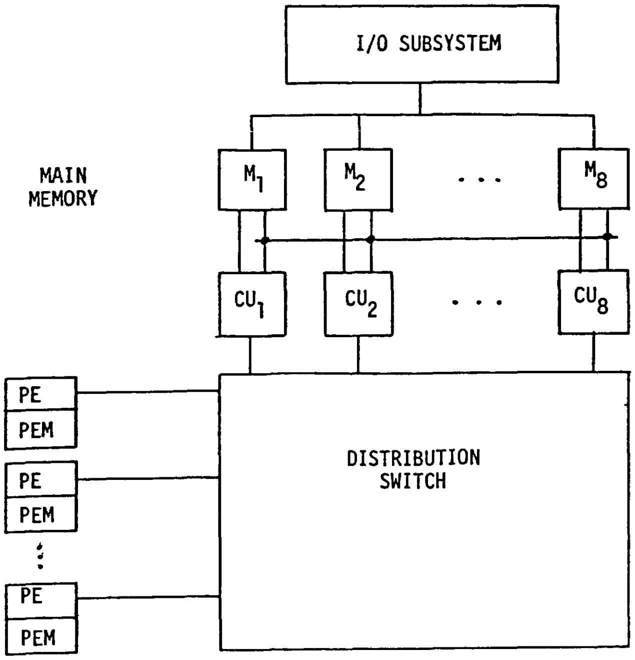

Figure 1—MAP block diagram

components are first briefly described with more detailed description given in subsequent subsections. (An even more detailed description of the components is given in Reference 1). The most striking difference between MAP and the production systems mentioned above is the existence of eight control units rather than one. Each control unit (CU) along with a subset of the arithmetic units, (called processing elements or PEs), corresponds to a SIMD architecture; MAP supports eight SIMD programs simultaneously. Another prominent difference is the absence of a "host processor" to execute system software, e.g., the operating system, compilers, etc. All system software is executed on the MAP by a CU and one or more PEs. The main memory system incorporates eight memory modules interconnected by a bus connected to the I/O system and by a bus connected to each control unit; each memory module (MM) is preferred by one CU and, normally, the instruction stream for CU_i is stored in MM_i.* The distribution switch shown in the figure routes commands and data from a CU to the subset of PEs currently allocated to that CU, and between PEs. The I/O subsystem is one of those portions of the system for which no explicit design has been considered. It is assumed to be a conventional system that handles peripheral devices and provides for the transmission of data to and from the main memory.

The control unit organization

The primary purpose of each CU is to implement the concept of a process. Each process that is implemented on a CU is assumed to be decomposed into a set of identical tasks which can be executed in parallel by a set of PEs. Other instructions decoded by the CU, such as branching instructions, are executed directly in the CU without referencing the set of PEs. The CU must also implement interprocess communication between processes on different CUs.

Figure 2 is a conceptual block diagram of a control unit. The main memory interface consists of three registers: the Data Register is used to transmit data words to/from the main memory, the Address Register is used to send CU-generated addresses to the main memory address register, and the Instruction Word Register holds an instruction word from main memory that is to be decoded and executed. It would be possible to replace the Instruction Word Register by a look-ahead buffer to decrease CU idle time while waiting for the next instruction to be read from main memory. (Current work on this approach is in progress.) The Index Register, CX, allows indexed addressing of the main memory by the CU.

The CU Instruction Processor executes those instructions that are not broadcast to PEs for execution. The functions implemented by this processor include conditional and unconditional branching, (using CX and the Compare Register, CR); and CU intercommunication instructions, (using the 8-bit Signal Register and the 8-bit ID Register). Most conditional branches are determined by inspecting the relationship between contents of CR and CX, or only the contents of the main memory index register, CX. The use of Signal and ID in interprocess communication is discussed in a later portion of the paper.

The Data Input (Output) Broadcast Register is used to send (receive) data from the currently allocated set of PEs via the distribution switch. Loading or unloading of the registers is controlled by the Instruction Processor under the supervision of the Instruction Decode Unit.

The Instruction Decode Unit invokes the Instruction Processor for the execution of CU-executable instructions, and generates the sequence of microinstructions that are to be executed by PEs. The 6-bit Instruction Broadcast Register is used to put a single microinstruction into the distribution switch, which subsequently routes the microinstruction to the set of PEs currently allocated to the given CU for execution. The decode unit must handle all timing considerations for broadcasting microinstructions and data over the distribution switch. It must also coordinate its operation with that of the distribution switch.

* If a distributed operating system is employed in MAP, then the program for CU_i may not be stored in MM_i, but may either be distributed over the modules, or a ninth module for operating system code and data might be incorporated.

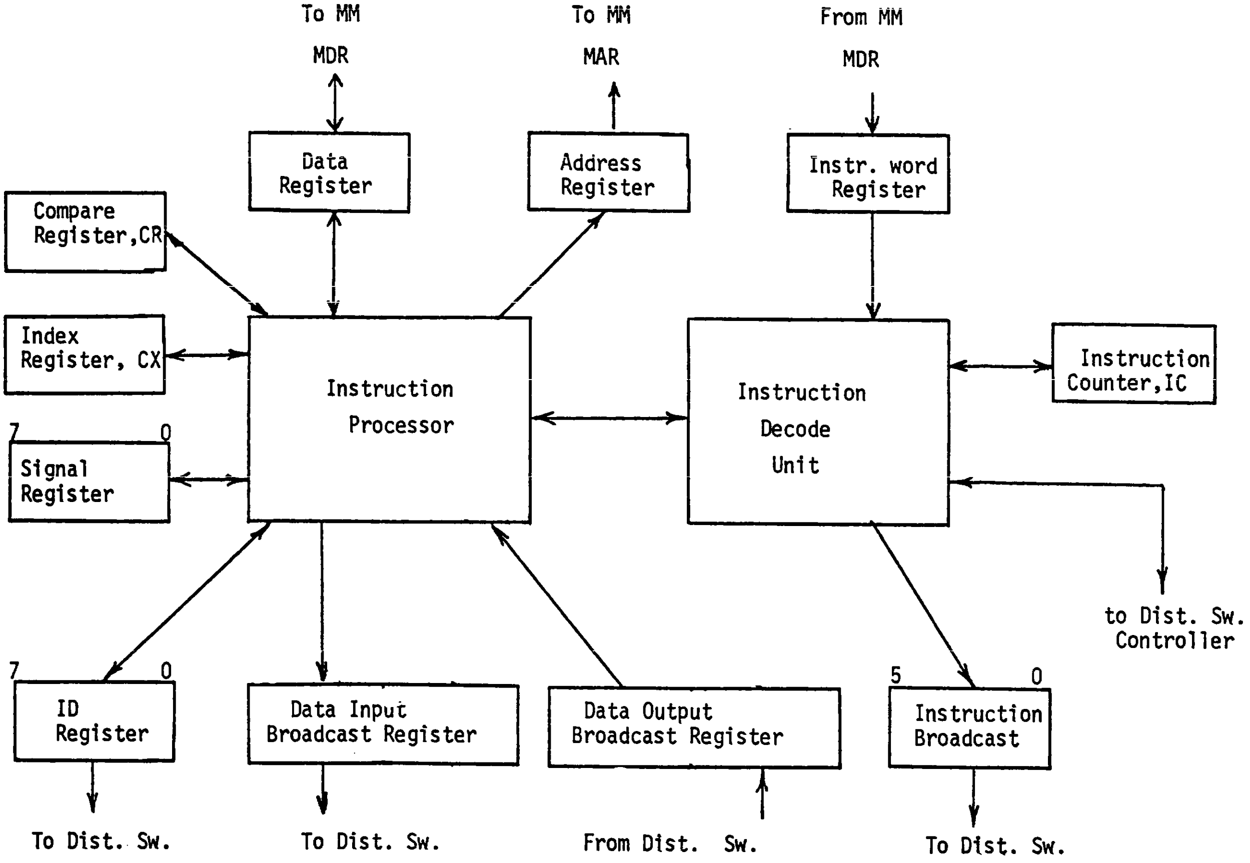

Figure 2—Control unit organization

The processing element organization

PEs correspond to the arithmetic/logical unit of a conventional computer system. Their purpose is to carry out a particular microinstruction execution on multiple data items in parallel with one another. All PEs are treated as identical resources, and conceptually, there is no addressing relationship between any two PEs; no linear relationship exists between PEs as it does in the ILLIAC IV.[3]

Figure 3 is a block diagram of the PE organization. The dynamic connection of PEs and CUs takes place via the distribution switch discussed in the next subsection, and the interface to this bus system takes place at the Instruction Selection Unit, the Input (Output) Data Register, IDR (ODR), and the Input (Output) Control Register, ICTL (OCTL). The Instruction Selection Unit contains an 8-bit Owner Register; when a PE is allocated to a CU, the owner register of the PE is set to match the ID Register of the CU. Each microinstruction broadcast by a CU is tagged with the ID Register content, and the Instruction Selection Unit compares ID and Owner Registers to identify microinstructions intended for the given PE. The microinstruction is then passed on to the Associative Unit of the PE.

The architecture of a SIMD processor allows all PEs allocated to a CU to simultaneously execute a microinstruction, but in most programs, it is necessary to be able to selectively deactivate some of the PEs during the execution of some code segments. For example, a program may be organized such that each element of an n dimensional vector is loaded into a distinct PE memory and that the PEs should perform a computation sequence on only those coordinates in the vector that are greater than zero. The code sequence would cause each coordinate to be loaded into a PE register from the respective PE memory, and then only those PEs whose register content is greater than zero would continue to execute microinstructions, while the remaining PEs would remain idle. The Associative Unit is used to control this selective activation/deactivation on the basis of conditions that exist in a PE at any given time. PE selection status is determined by the contents of the programmable 8-bit Key, Mask, and Select Register within the Associative Unit as follows: If Mask bit i is set then Key bit i is compared with Select bit i, and if all such bits have the same value,

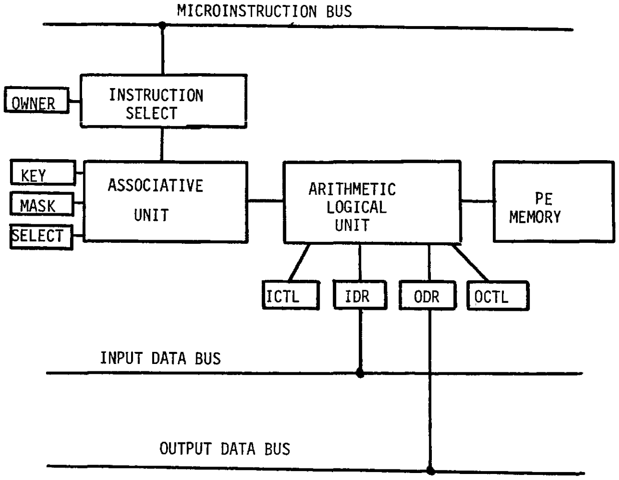

Figure 3—PE organization

the PE status is active. In the case that Mask bit i is reset, the Key and Select bits are ignored. For example, if Key=10101010, Mask=00111100, and Select=01101011, then the PE is active; if the same Key and Select are used with Mask=00001111, the PE is deactivated because the least significant bits of Key and Select do not match. This approach allows up to eight independent activation conditions to be stored in the registers, implying that extensive subsetting of PE conditions can be saved without recomputing those conditions. All three registers can also be stored/loaded to/from the respective PE memories if more than eight activation conditions are to be used in a code segment.

The Associative Unit modifies Key and Mask whenever an associative instruction, (i.e., microinstruction sequence) is broadcast to redefine conditions under which PEs allocated to the CU should be activated or deactivated. The Select register contents are determined by a different set of associative instructions that are related to PE arithmetic register contents. Examples of the use of the registers are given in a subsequent sample program segment.

The Arithmetic/Logical Unit is a small processing unit with a double-length accumulator and a PE index register. Operands for the ALU may be stored in the PE Memory (accessed with the PE index register), or may be global operands loaded from (stored into) the IDR (ODR). The ALU executes floating point and integer arithmetic instructions, and logical instructions.

The interchange of data between PEs and a CU over the distribution switch uses the ICTL and OCTL in conjunction with the IDR and ODR respectively. A discussion of their use appears in the next subsection.

The distribution switch organization

The distribution switch is used to route microinstructions from a CU to an arbitrary subset of the PEs, to route data between a CU and an arbitrary subset of PEs, and to route data between individual PEs.

The mechanism for routing 6-bit microinstructions is a crossbar switch, where crosspoint connections are determined by ID and Owner registers in CUs and PEs. The connection mechanism precludes a requirement for resolution and queuing mechanisms at each crosspoint. It also disallows any form of simultaneous PE sharing by two or more CUs. This approach has been taken since CUs are expected to broadcast microinstructions at a high rate—on the order of one microinstruction per 100 ns.

Data transfers occur much more infrequently—previous MAP interpreter monitor results indicate that data (or a PE memory addresses) are broadcast about once every six microinstruction cycles.[11] Since the data bus is expected to be much wider than the microinstruction bus, a combination of bus sharing and a crossbar switch has been employed in the design. Figure 4 is a diagram of the data bus organization; it consists of an $8 \times k$ crossbar switch where $8 \leq k \leq 12$. Each of the k buses, called *bus sectors*, are shared by approximately 100 PEs for data transmission. In a previous study, it was shown that this configuration does not introduce appreciable performance degradation due to bus conflicts.[11] PEs from a given sector may be allocated to any CU, but sector conflicts are minimized if the number of CUs owning PEs in any given sector is minimized. In another study, some PE allocation algorithms that reduce sector sharing among CUs were investigated, and cost-effective algorithms for the sector organization were determined.[12]

Data is transferred over the bus system using the ICTL and OCTL registers mentioned in the PE description. Input and output operations are symmetric, and so only the input operation is described. The ICTL is initially loaded with a value representing a delay time. For each cycle to which the CU controlling the operation has access to the data bus, ICTL is decremented by one. When the ICTL reaches zero, the data currently on the input bus sector for the PE is gated into the IDR of the PE. By setting the ICTL registers of PEs to different values, it is possible to rapidly transfer an entire data stream from the main memory into a set of distinct PEs; the ICTL and OCTL can also be used to transfer data from one PE to another via the bus system and the data registers in a common CU. In the case that two or more PEs have identical ICTL contents, all such PEs retrieve data from the input data bus, if two or more PEs have identical OCTL contents, the data placed on the output data bus is the logical OR of all ODRs.

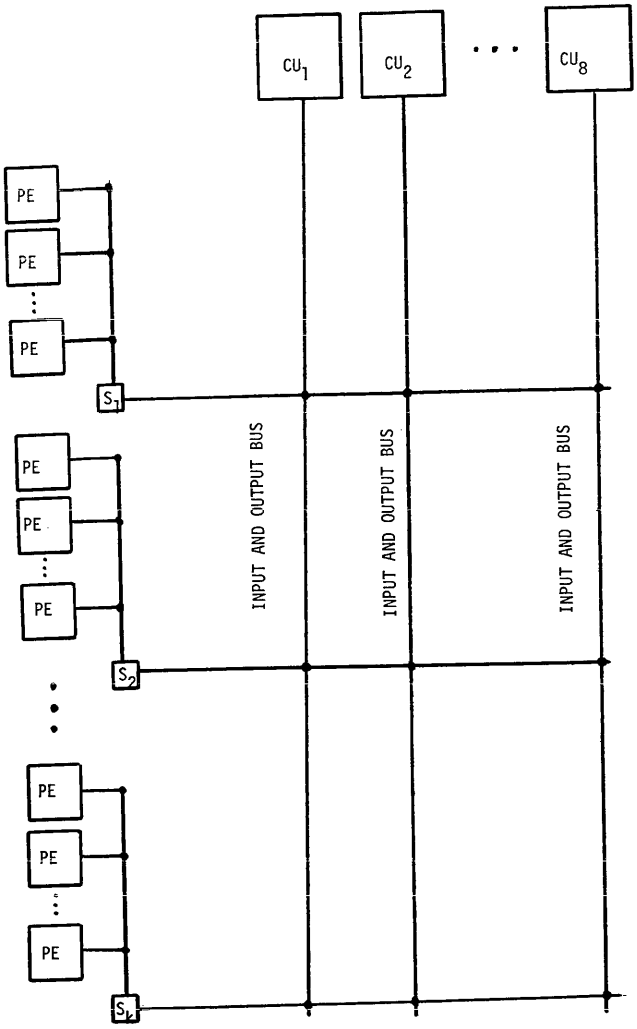

Figure 4—The distribution switch

The main memory subsystem

The main memory subsystem can be accessed by the I/O subsystem or the set of CUs, as indicated in Figure 1. Each main memory module is preferred by a particular CU, although any CU can access any module. The rationale for this organization is to reduce memory conflicts due to CU access. Previous work indicates that this main memory organization using core technology is an acceptable design, for most applications.[11]

Control unit intercommunication

The mechanism for allowing communication among the various control units is open to revision and refinement as experience in the design of an operating system progresses. The mechanism should allow a variety of system implementations ranging from a basic operating system that is executed on a single CU which supports only uniprogramming on the remaining CUs, to a more sophisticated distributed system that runs on any CU, perhaps in parallel with itself. This latter design strategy would also support multiprogramming of all CUs.

The process identifier is the ID register content. Let $ID_K(i)$ denote the K^{th} bit of the ID register in CU number i. If $ID_K(i) \wedge ID_K(j) > 0$ for some bit K, then CU_i can *cooperatively communicate* with CU_j, and vice versa; otherwise, no communication is possible between the two control units. Suppose that in addition, $ID_K(j) \leq ID_K(i)$ for all K. Then CU_i can communicate with CU_j in a *privileged manner*, (it is not allowed for two CUs to have exactly identical ID registers); privileged communication implies cooperative communication.

Each CU contains three 1-bit registers to aid in communication: ARM_i is used to disable any privileged interrupt directed to CU_i if $ARM_i = $ *false*. Similarly, $ABLE_i$ is set to *false* if CU_i cannot accept an interrupt in a cooperative manner. The ACK bit is used to acknowledge the receipt of an interrupt. An interrupt register contains an address to be branched to when a cooperative interrupt is received. The Signal register is used to designate the CU that is to receive a message.

Only some of the CU intercommunication instructions can be executed successfully by CU_i if CU_i has privilege with respect to CU_j. The PREEMPT instruction allows CU_i to interrupt CU_j provided that $ARM_j =$ *true;* otherwise, the interrupt is refused, and $ACK_i =$ *false.* (CU_j cannot disarm itself.) The preemption results in CU_j being disarmed to prevent other interruptions from occurring, CU_j finishing its current machine instruction execution, saving the instruction counter in main memory module j at location zero, and restarting CU_j on another code segment after passing an address through the CX registers. CU_i then continues execution.

Once CU_j has been preempted by CU_i, CU_i can alter the ID register of CU_j; the new ID register content is determined under the following restriction:

$$ID_K(j) \leftarrow ID_K(i) - y$$

where

$$0 \leq y \leq ID_K(i)$$

i.e., CU_i can define any new ID register content for CU_j (or itself) as long as no bit in ID of CU_j is set when the corresponding bit in CU_i is reset. This prevents a CU from increasing its communicative power either directly or indirectly. Whenever a preempting CU returns a preempted CU to its state preceding the interruption, it must restore the state of the interrupted CU.

The above discussion was concerned with communication in a privileged manner; cooperative communication is implemented as follows:

When a SIGNAL instruction is executed by CU_j with $ID_j \equiv Signal_i$, an interrupt is passed to CU_j provided that ARM_j is *true* and $ABLE_j$ is *true.* The interrupt activity includes temporarily preventing a PREEMPT, and disabling cooperative interruption. The current instruction count of the signaled CU_j is saved in memory module j at location 1. The address of the next instruction is then obtained from the interrupt address register. CU_j is then armed for privileged communication and remains disabled for cooperative communication until an ENABLE instruction is executed by CU_j. A BLOCK command can be used after a SIGNAL to wait for a response from the signaled CU.

If a CU is executing in disabled mode, then any signal directed to the process might be queued on the process descriptor that has an ID content matching the signaling CU signal register. No hardware provision is made for actually appending signals to process descriptors of processes not currently running on a CU, nor for handling signals to nonexistent processes since these are software tasks of individual operating systems. The operating system design must handle such situations, perhaps in a manner similar to the message buffering scheme used in the RC 4000 multiprogramming scheme.[4]

SAMPLE MAP PROGRAMS

Previous machines have often been aimed at particular application areas, e.g., the Illiac IV is primarily intended for floating point matrix computations, while PEPE and STARAN have often been used to do nonnumeric processing. MAP is an attempt at a design appropriate for both areas, although it is weak in its I/O capability. To illustrate the design philosophy, a brief description of a MAP algorithm is now presented.

A typical numerical algorithm employed in matrix computation is the Gaussian Elimination Method for solving a system of linear equations. The method can be efficiently implemented on MAP as the Gauss-Jordan method with full pivoting. It is assumed that the coefficient matrix and column vector of the right sides of the equations have been stored in the main memory module of a CU. The method employs n+1 PEs for an $n \times n$ system of equations, and each PE is loaded with one column of the coefficient matrix: the right side column vector is loaded into the n+1st PE. PE memory loading is accomplished by the following code segment (stated in prose form rather than as mnemonic MAP instructions):

1. Clear all Select Registers.
2. Deactivate all PEs but one and set its Select bit 0 (bit 0 corresponds to the condition that the PE is being loaded).
3. Load a column vector from main memory using CX to index main memory, PX to index PE memory.
4. Reset Select bit 0 and set Select bit 1. (Bit 1 indicates that the PE is loaded.)
5. Activate all PEs such that Select bit 1 is reset.
6. If at least one PE is active, go to step 2.

This code segment requires about 10-15 MAP instructions, and is executed n+1 times.*

In the next part of the program, the elimination algorithm is implemented. Select bit 0 is used to save various temporary conditions in searching for a pivot element, bit 1 marks the PE containing the maximal element in any row of the coefficient matrix, bit 2 marks columns to the right of the column being reduced, bit 3 marks the PE containing the columns currently being reduced, bit 4 indicates that a column has already been reduced, and bit 5 marks the PE containing the right side vector. The algorithm requires n loops through code that determines the largest coefficient in a row, and after determining a maximal coefficient, row transformation is accomplished by activating all PEs and executing two indexed loads and stores on the two rows to be interchanged. Column transformation is implemented by exchanging column number identifiers stored in the PEs and requires only 4 instructions. (A copy of the original column numbers must also be saved in each PE in order to trace the column transformations performed during the execution of the algorithm.) The elimination process requires n loops through code containing a division, a multiplication, and a subtraction, where each operation is applied to all columns (PEs). The order of time for executing this Gauss-Jordan algorithm on MAP is n^2 compared to n^3 on a sequential processor. The algorithm could be speeded up by using n^2 PEs, or by skewing matrix entries in the PE memories as is commonly done in the ILLIAC IV.[8] The order of the algorithm reduces to linear time if n^2 PEs are used, since all rows can be reduced simultaneously, and pivot elements are determined by one associative instruction.

THE EVALUATION STUDY

As stated in the introduction, MAP is being used as a medium to test evaluation and monitoring techniques for associative and array processors. The basis for much of the work is an interpreter for individual MAP programs, called MAPSIM.[10] The program represents one CU and an arbitrary number of PEs as required by a MAP program. It ignores bus and memory conflicts, but allows one to write and test individual programs for the machine. Each program can be monitored during execution, with monitor resolution at the machine instruction (*not* microinstruction) level. Using this method, a detailed description of the effect of any given job can be measured and the data can be used to drive other high level models that introduce resource com-

* The PE loading is a sequential task, but the performance can be increased by loading the PEs one row at a time rather than by columns. To do this, the ICTL registers of all PEs are used to "stream load" the rows from main memory, where only one PE is removing data from the input bus at a time, but the time between PE load operations is small.

petition due to the existence of multiple CUs. The investigations of the memory and bus system design were carried out in this manner. A drawback to this approach is that it is difficult to effectively study CU intercommunication.

Now that the design has stabilized to some degree, current evaluation studies are directed at two major areas: operating system design and user program measurements. The approach taken in the operating systems work is to first compare three families of systems. The first strategy employs a dedicated control unit for the operating system and the remaining 7 CUs are uniprogrammed. The second strategy again uses a dedicated CU for the operating systems, but implements multi-programming on the remaining CUs. The final strategy multiprograms all CUs and executes the operating system as a set of high priority processes on all CUs. A comparison of the three strategies is forthcoming.

User program measurements can be carried out directly on MAPSIM. In conventional processors, a typical measurement of a user program results in the generation of an instruction execution distribution to determine frequently-used portions of the code. This measure is appropriate for MAP programs, but additional information about PE activation/deactivation is perhaps even more important. Current and future work on MAP is concerned with the investigation of such measures, and the implied monitoring tools required to obtain such measures.

ACKNOWLEDGMENT

The National Science Foundation has supported the study of MAP under Grant number GJ-42251. The original concept of the machine came from many long discussions with Clarence Ellis; the following graduate students at the University of Colorado have participated in the subsequent development: Roger Arnold, Karl Williamson, and John Burke.

Asynchronous speed-independent arbiter in a form of a hardware control module

by H. SECHOVSKY and S. JURA
Research Institute for Mathematical Machines
Prague, Czechoslovakia

ABSTRACT

The attained parameters and the development trends of LSI circuits make possible the realization of untraditional computer structures with higher number of cooperating processor and control units or modules. The parallel processes realized in these modules are in majority mutually asynchronous and the length of duration of individual parts of these processes and their mutual time relation cannot be determined in advance. In hardware realization of such systems it is often most convenient when the individual modules behave toward each other like asynchronous speed-independent automata. For interconnection of such modules and for synchronizing the processes realized in them it is advantageous to use so-called arbiters (also called semaphores) whose formal description has been introduced in the theories of parallel processes.

The text contains a detailed description of a hardware construction of the arbiter having the character of a universal control module guaranteeing the reliable function at arbitrary time sequence of input requests. This quality is important in view of the danger of metastability so that an arbiter cannot be excluded. In the design of the circuit the simplicity and speed of function have been especially considered and the measured time parameters of the arbiter are quoted.

INTRODUCTION

If we analyze the development trends of the computer technology and the influence (especially of the parameters) of the LSI circuits on the evolution of the structure of computer systems, we have to conclude that the increasing interest in the theories of parallel processes and multiprocessor, e.g., micro-multiprocessor systems is conditioned especially by reality, that the speed of the circuits produced by the technology of the semiconductor integrated circuits is coming close to the limit value for this technology, therefore the achievement of substantially higher speeds by its further development cannot be expected. Nor in the coming years an essential change in the technology of computer circuits is to be expected, considering the facts of low costs, easy mass-production and a high reliability at the same time—the facts imply that the semiconductor technology has nowadays no serious competition. The technology thus defines the speed limits which cannot be surpassed by one-processor system. This problem is solved with multiprocessor systems and other systems with parallel processes that enable, among other things, the achievement of higher speeds.

In all such systems, it is necessary to solve the problem of synchronization of parallel processes and of allocation of shared sources e.g., memories, peripherals, registers, information buses etc. This synchronization should be solved in hardware in case the system cannot be designed in the way of synchronous automata system with common clock signal.

A very broad application in the coordination of parallel working hardware modules has the arbiter, having generally n couples of speed-independent input and output signals: $R_1, A_1 \ldots R_n, A_n$. (See Figure 1.) The function of the arbiter is outlined in Figure 1 and it can be described on Petri-net. (See Figure 2.) The token from the initial place can fire only one of the transitions controlled by input signals $R_1 \ldots R_n$. The firing of these transitions is determined partly by the time sequence of logic ones arriving to inputs $R_1 \ldots R_n$

partly by the algorithm of the priority allocation to these requests. Under references to Petri-net in this paper, the authors have in mind so-called safe Petri-net, whose properties are described in detail in References 1, 4 and 8.

The important quality of the arbiter is the priority allocation only to one request R_i and sending out the logic one only to one output A_i. The signals R_i,A_i are in the hand-shake relation that guarantees the speed-independence of the circuit.[4] But the speed-independence of the couples R_i,A_i is the only regularity that is guaranteed for the input signals. The arbiter must work reliably in a common case when the time interval between leading edges of two requests R_i,R_j is not defined. In this case the occurrence of so-called metastable state in the flip-flops of the arbiter is possible.[3,6,7] In addition to the fact that during the metastable state the flip-flop output signals are outside of the tolerance field of logic one and logic zero it should be stressed that occurrence interval of that state is theoretically unlimited. For the security of reliable function of the arbiter the metastable state has to be considered and its unfavorable influence on the outputs A_i must be eliminated.

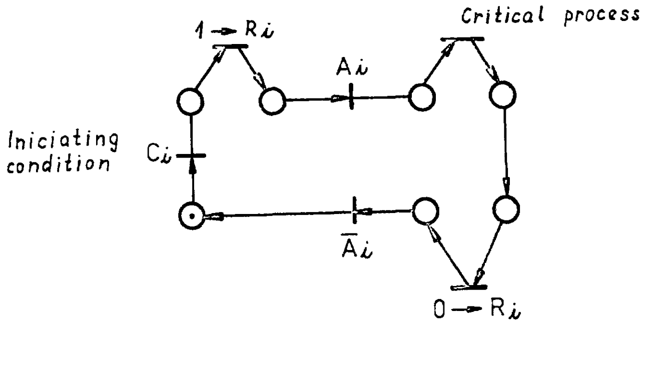

Figure 3

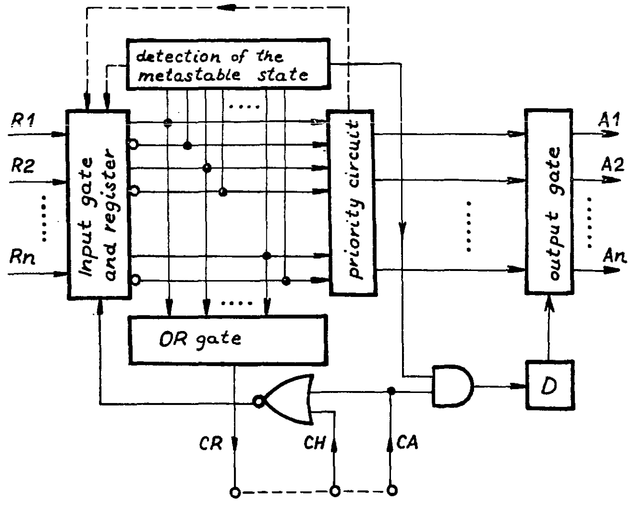

Figure 4

CONNECTION AND FUNCTION

For eliminating the undesirable influence of contingent metastable state the structure of circuit in Figure 4 has been selected. Let us suppose initially that the output CR is connected with the inputs CH,CA and the input signals $R_1 \ldots R_n$ being of zero value. In this case CR=CH=CA=0, the output gate is closed and the input one is open. The block denoted D represents a time delay τ of the leading edge. In this state the contingent requests on the inputs $R_1 \ldots R_n$ are recorded into the input register and at the same time are detected by the OR gate. On coming request R_i the OR gate generates signal CR=1, closing the input gate and in this way recording of further request is inhibited. The priority circuit respecting only the record of the request with highest priority erases in the input register all the contingent lower ones. Provided that during the closing of the input gate arises a metastable state in the input register all the time of its duration a zero output is generated by the detector of the metastable state and through the feed-back forces the relevant bit of the input register in the value one.[3,6,7] This is shortening the time of duration of the metastable state. On finishing of the metastable state the output gate is opened with the delay τ. The connection of the arbiter with four inputs and four outputs is given in detail in Figure 5. By signals M,CR,CH,CA the algorithm of the arbiter can be modified. If M=1, the requests with lower priority in the input register are erased in the described way. If M=0, all the requests which have had logic one before the closing of the input gate continue being recorded. But logic one is transferred only to one of the outputs A_i corresponding to the recorded request with the highest priority. On zero coming to the input of this request the input gate continues—the opposite of the case M=1—to be

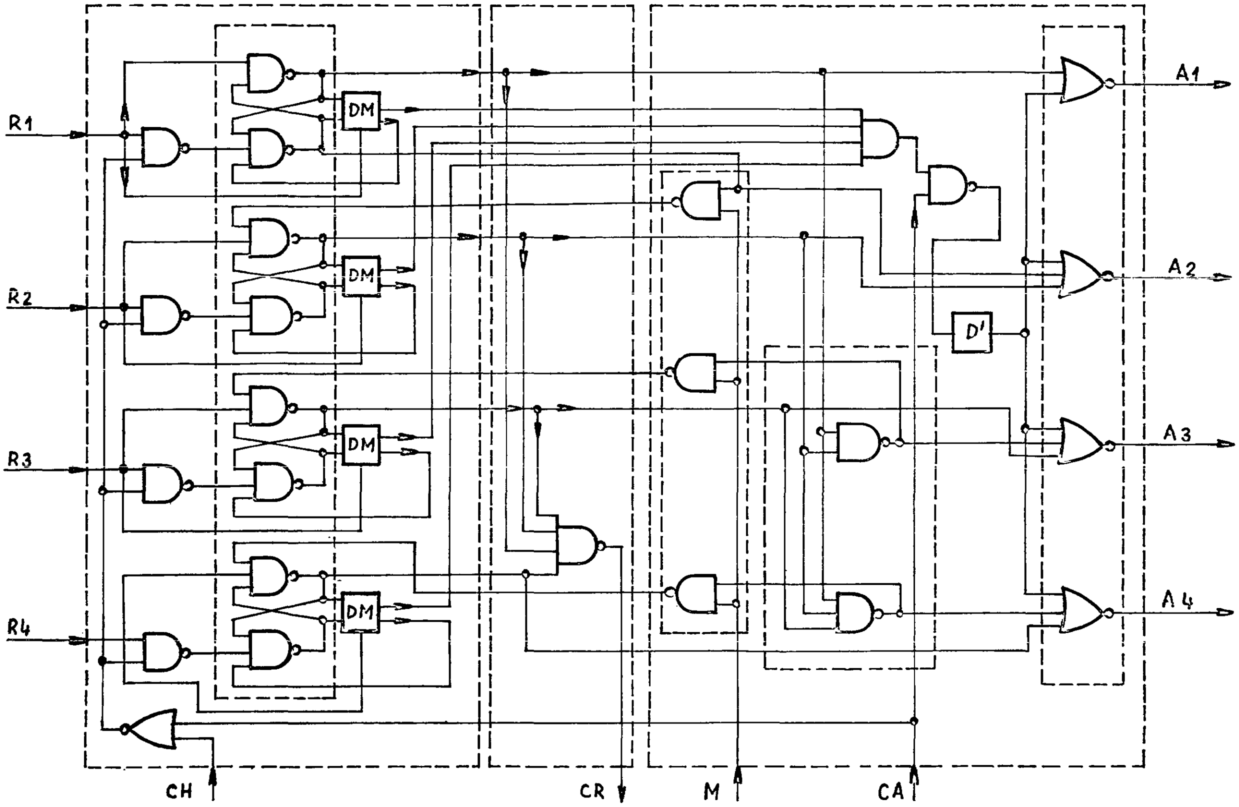

Figure 5

closed and the priority is allocated to one of the remaining recorded requests. This way all the recorded requests are consecutively executed and then on executing the last one, the input register is completely in zero state, signal CR turns to zero and the input gate reopens.

By the general connection of signals CR, CH and CA a further modification of the algorithm is possible. CR and CA represent a couple of speed-independent signals through which the arbiter can be connected with any other speed-independent automata. CR has a purport as a request of the arbiter for the approval of the priority allocation for the input signals $R_1 - R_n$, signal CA with value one makes this allocation possible. The connection of the signal CH either to CR or to CA determines whether the input gate will be closed already after the detection of the first request R_i or only when logic one is appearing on the input CA. Between leading edges of signals CR and CA generally a delay of any length can appear.

The block denoted D' in Figure 5 represents the delay of the trailing edge, blocks denoted DM represent the detectors of metastable state. The metastable state may occur only on appearance of logic one on the input R_i. During this state block DM on the one hand by one of its outputs sets the i-th bit of the input register to the value one and in this way shortens the duration of the metastable state, on the other hand by its second output it inhibits the opening of the output gate.

Signals CR,CA may be used, e.g., to form an arbiter with a larger number of inputs by connecting several smaller arbiters. The principle of such connection is demonstrated in Figure 6. By the concrete connection of signals M and CH of individual "elementary" arbiters a modification of the allocation algorithm according to the needs of desired application is possible.

In Figure 7, we can see Petri-net describing the behavior of the arbiter whose connection corresponds to Figure 5.

Though the connection in the Figure 5 is comparatively simple and contains a low number of gates, there are a number of applications of the arbiter in that the signals CR,CA,CH,M are not used for any specific purpose. In many cases like that also only a two-input arbiter may be used. For these applications the connection given in Figure 8 is more advantageous. An R-S flip-flop represents the input gate, register and priority circuit at the same time. Expanders SN 7460 N are used for the detection of the metastable state.

At the initial state, when signals R_1,R_2 are logic zero the flip-flop is in so-called undefined state when both

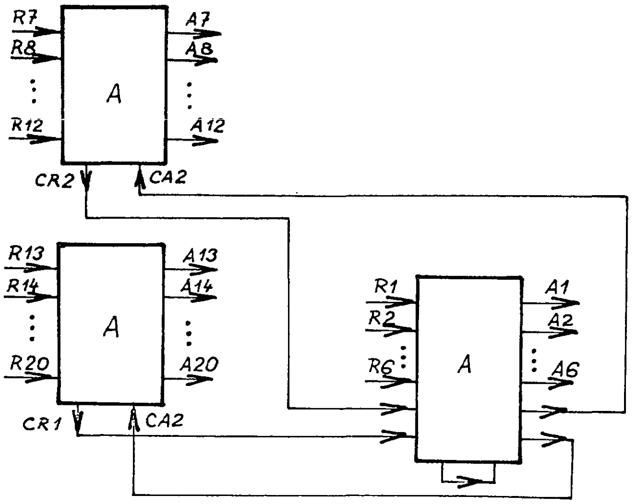

Figure 6

its outputs are logic ones. The voltage on the resistor in this state, the same as in the metastable state, is in the tolerance of logic one and the output gates are closed. In the case of simultaneous arrival of the leading edges of the signals R_1,R_2 the output gates continue to be closed all the time of contingent metastable state and they are opened by the detector of metastable state only when R-S flip-flop turns to the normal state, when the levels of its outputs are in a secure distance to the decision level. At this connection, nevertheless, the detector does not shorten the duration of the metastable state whose length is, theoretically, unlimited.

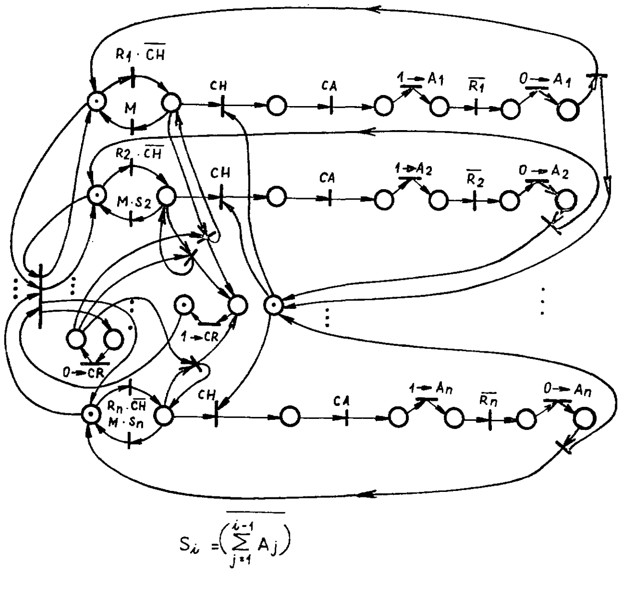

Figure 7

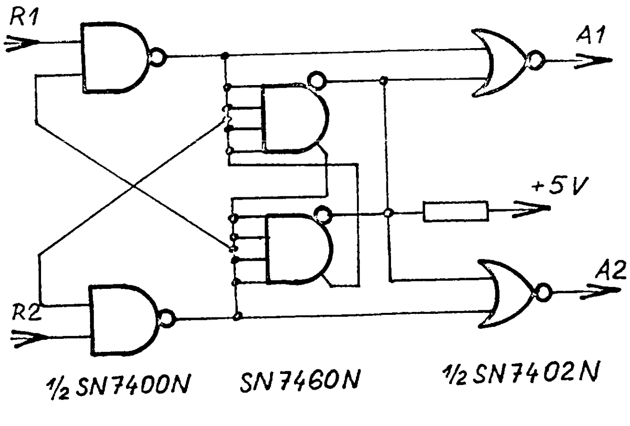

Figure 8

If on the contrary an arbiter with a larger number (e.g., eight) of inputs is needed and the speed requests do not allow use of the cascade connection (Figure 6), it is possible after some modification of the connection to use standard modules MSI but at the cost of lower universality.

THE EXPERIMENTAL RESULTS

For testing the function of the arbiter a sample connected according to Figure 5 has been built. On this sample the reliability of function even for the case of the occurrence of metastable states has been tested. The delay of the trailing edge in the block D had been adjusted $\tau = 30$ nsec. Three kinds of circuit delay have been measured. (See Figure 9.) The delay TLH 1 is defined as the length of the interval between the leading edges R_i and A_i when the others $R_j \neq R_i$ are of logic zero. TLH 2 is defined as the length of the interval between trailing edge R_j and leading edge A_i when $R_i = 1$ and $R_k = 0$, $k \neq i,j$. THL is defined as the length of the interval between trailing edges of signals R_i

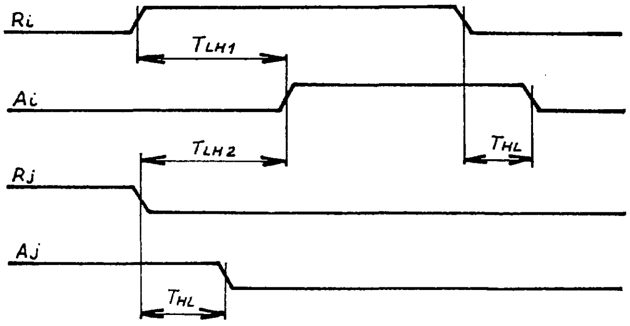

Figure 9

and A_i. The found out values in nsec are given in the following table:

TLH 1	TLH 2	THL		Remark:
90	110	20	i=1, j=2	without metastable state
135	—	—	i=1, j=2	with metastable state
90	110	40	i=2, j=1	without metastable state, regarding the priority of R_1 at metastable state it changes to j=1, j=2.

For the realization of the circuit the integrated circuits of series SN 74 N produced by Texas Instruments have been used. In the case of higher speed requirements the same connection may be realized on faster elements, e.g., series SN 74 S.

EXAMPLES OF APPLICATION

Besides the application of the arbiter as a control module in the systems with the structured hardware,[1,4] the circuit may find a broad application in classic computer and NC systems. In Figure 10, an application of arbiter for synchronization of external signal X by the clock signal Cl is demonstrated. The arbiter with two inputs is making use of the described principle of shortening and limiting the length of duration of the metastable state, flip-flop used is of the type T, sensible to the leading edge of the signal Cl. Applicating the arbiter we avert the occurrence of metastable state in the flip-flop T. The contingent signal X_T of the value one passes namely through the arbiter at least in the time TLH 1 after the leading edge of the signal Cl, e.g., for the mentioned realization of the arbiter in 135 nsec. If the period of the clock Cl is long enough the constant value of the signal X_T in the proximity of the leading edge of the clock is guaranteed.

In Figure 11, we can see a typical application of the arbiter for the control of communication of modules $M_1 \ldots M_n$ with a shared source e.g. with the memory SM and by that as well for the control of the communication on the bus. The module M_i transmits the logic one on the signal R_i as request for the communication with SM. The arbiter reports the allocation of the priority by logic one on the signal A_i. M_i holds the logic one on the signal R_i during the communication with the SM, on the arrival of logic zero on the signal R_i arbiter is released for further operation. The interconnection of signals CR,CA with SM makes the priority allocation possible only in the moment when SM is ready for the communication. The connection of the input M, $M = R_{n-2} + R_{n-1} + R_n$, guarantees to the modules M_{n-2}, M_{n-1}, M_n the allocation of SM after a certain time even in the case of "continuous" queue of requests $R_1 \ldots R_{n-3}$ having in the arbiter higher priorities.

Log-sum multiplier

by J. P. AGRAWAL and V. U. REDDY
Indian Institute of Technology
Madras, India

ABSTRACT

A scheme for implementing a fast parallel multiplier based on a log-sum method is presented. The scheme for an n-bit by n-bit multiplication uses Q, least integer greater than or equal to $(n^2-n)/4$, 4-bit Carry-Look-Ahead (CLA) adders. The worst case time for multiplying two sign + 12-bit numbers is estimated to be 180 ns when TTL 7400 series I.C.s are used. The scheme can easily be modified to use M-bit (M>4) CLA adders if and when available.

INTRODUCTION

Multiplication of an n-bit number $A(a_n a_{n-1} \ldots a_1)$ by another n-bit number $B(b_n b_{n-1} \ldots b_1)$ involves reduction of n^2 summands $a_i \cdot b_j$, i, j = 1,2, ... n, arranged in (2n−1) columns and n rows, into one 2n-bit row $(P_{2n}\ P_{2n-1} \ldots P_1)$, as shown in Figure 1. The summands are generated in parallel using n^2 AND-gates. A number of schemes have been given in the past[1–4] for implementing fast parallel multipliers which are different basically in the procedure used for the reduction of summands. Dadda's[1] and Wallace's[2] schemes are equally fast and take approximately $\log_{1.5}n$1-bit adding-stages (successive additions) to reduce the summands to two G (least integer $\geq 2n\text{-}2\text{-}\log_{1.5}n$)-bit numbers, which may be added using a G-bit Carry-Look-Ahead (CLA) adder or a ripple adder. Wallace's scheme, however, requires a larger number of adders. The carry-save scheme[4] takes (n−1) 1-bit adding-stages to reduce the summands to two (n−1)-bit numbers. Both Dadda's and the carry-save schemes require (n^2-2n) 1-bit full adders (FA) and n 1-bit half adders (HA).

Habibi and Wintz[4] have shown that the carry-save scheme is slower than Dadda's but cheaper since it makes greater use of 4-bit FAs. However, in both the schemes the 4-bit FAs are connected in such a way that the fast carry generation property of the 4-bit FA I.C. chip is not utilized.

The purpose of this paper is to present a log-sum configuration for the reduction of summands, in which the numbers of 1-bit FAs and 1-bit HAs required are the same as in Dadda's and the carry-save schemes. But these adders can be replaced fully by Q 4-bit FAs taking full advantage of the fast carry generation. Q is the smallest integer greater than or equal to $(n^2-n)/4$. Hence, the log-sum scheme is more economical than any other parallel multiplier and at the same time yields a high speed of operation. Another feature of the scheme is that it can easily be modified to adopt longer FAs if and when I.C. technology makes them available.

In the second section, we give a general scheme for reduction of summands using 1-bit FAs and HAs and then modify it for 4-bit CLA adders. In the third section, we present cost and speed analysis for the log-sum multiplier and compare it in the fourth section with other schemes. In the fifth section, we discuss how the scheme can be extended for M-bit FAs, and to include 2's complement multiplications.

THE LOG-SUM MULTIPLIER

In the log-sum method[5] the addition of n rows is performed in $\log_2 n$ adding-stages where each adding-stage reduces the number of rows by a factor of 2. Therefore, the adder-rows (row of adders to add two rows) required for the first, second, ... $(\log_2 n)$th adding-stages are $\frac{n}{2}, \frac{n}{4}, \ldots$ 1, respectively. This method of addition is used to yield economic and fast multiplication.

Preliminary scheme

The n rows, shown in Figure 1, are grouped into (n+k)/4(=L) sets (k=0,1,2 or 3 such that L is an integer), the last set consisting of (4−k) rows and the others 4 rows each. The 4 rows in a set are reduced to two rows by first stage addition and then reduced to yield one (n+4)-bit row by second stage addition, as shown in Figure 2 for n=7. As illustrated in the Figure, (n−1)-bit and (n+2)-bit adder-rows are required for first stage and second stage additions, respectively. Also, it is seen that in this configuration (i) the outputs of two successive sets always overlap

$$\begin{array}{ccccccccccl}
 & & & & & a_n & \cdots & a_3 & a_2 & a_1 & \\
 & & & & & b_n & \cdots & b_3 & b_2 & b_1 & \\
\cline{5-11}
 & & & & & a_n \cdot b_1 & \cdots & a_3 \cdot b_1 & a_2 \cdot b_1 & a_1 \cdot b_1 & \text{row 1} \\
 & & & & a_n \cdot b_2 & \cdot & \cdots & a_2 \cdot b_2 & a_1 \cdot b_2 & & \text{row 2} \\
 & & & \cdot & & & & \cdot & & & \\
 & & \cdot & & & & \cdot & & & & \\
 & & a_n \cdot b_{n-1} & a_{n-1} \cdot b_{n-1} & \cdots & a_2 \cdot b_{n-1} & a_1 \cdot b_{n-1} & & & & \text{row } n-1 \\
 & a_n \cdot b_n & a_{n-1} \cdot b_n & a_{n-2} \cdot b_n & \cdots & a_1 b_n & & & & & \text{row } n \\
\hline
P_{2n} & P_{2n-1} & P_{2n-2} & P_{2n-3} & \cdots & P_n & \cdots\cdots & P_3 & P_2 & P_1 & \\
\hline
\end{array}$$

Figure 1—Multiplication of two n-Bit Numbers A $(a_n \cdots a_1)$ & B $(b_n \cdots b_1)$

in n-bit locations and (ii) each mth set has an half adder in (n+4m−3)th column. Therefore, outputs of the mth and (m+1)th sets are added using one n-bit adder-row, feeding the overflow bit from this to the corresponding half adder in (m+1)th set. This corresponds to the third stage addition. In the same manner, only n-bit adder-rows are required for each of the 4th, 5th, . . . and ($\log_2 n$)th adding-stages. The total number of 1-bit full/half adders required in this scheme may, therefore, be written as,

$$N=\frac{n}{2}(n-1)+\frac{n}{4}(n+2)+\left(\frac{n}{8}+\frac{n}{16}+\ldots+\frac{n}{2^j}\right)n$$

$$=\frac{3n^2}{4}+\frac{n^2}{4}(1-2^{-j})=n^2-n, \text{ where } j=\log_2(n/4);$$

which is same as required by Dadda's scheme.

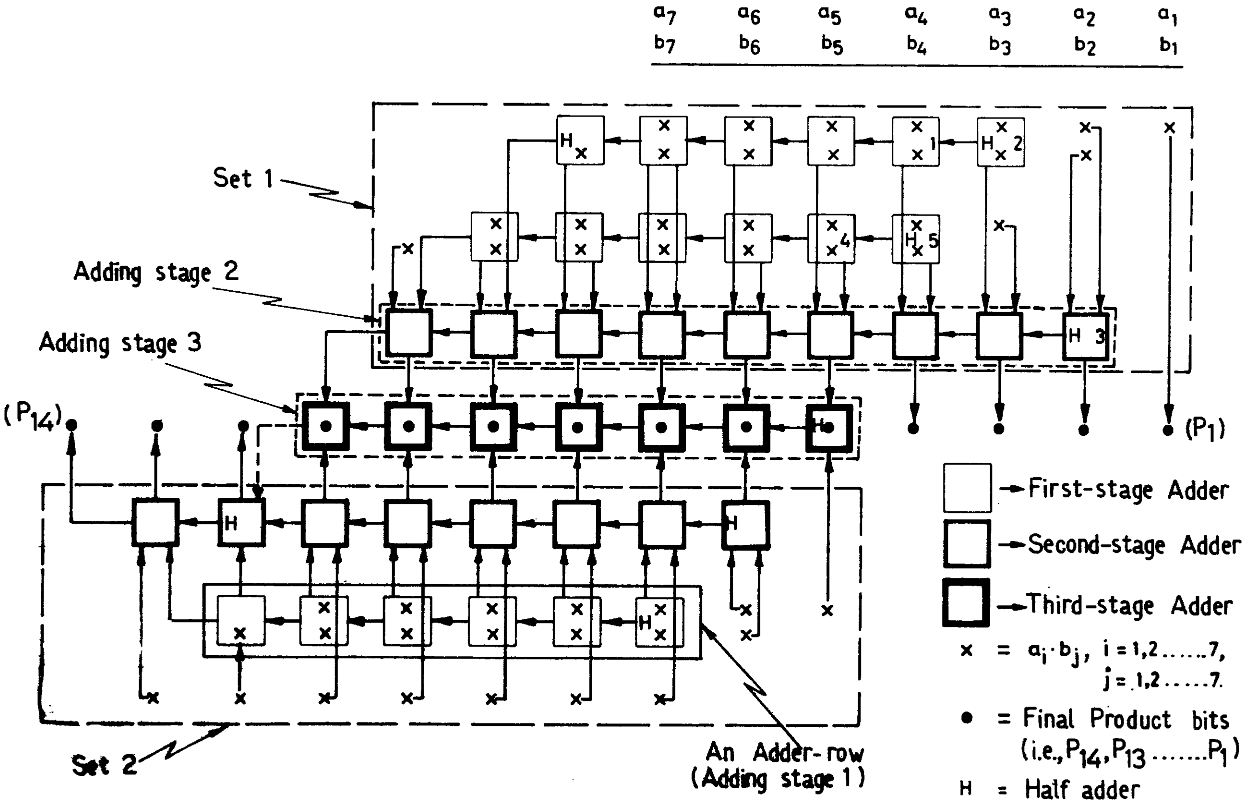

Figure 2—General scheme for 7-bit x 7-bit log-sum multiplier

Final scheme

A fast and economic multiplier is realized by rearranging a few adders in the above described scheme as follows.

(i) All the adders in the final propagation path which includes the final adding-stage are aligned in one row.

(ii) After (i) has been completed some adders are moved from one adder-row to the other and rearranged such that the number of adders in each row (except in one row if N/4 is not an integer) is a multiple of 4. An adder that is moved from one adder-row is rearranged in another adder-row, as far as possible, corresponding to the equivalent or higher adding-stage. This is illustrated in Figure 2 for n=7, where five adders marked 1 to 5 are rearranged to yield the final scheme.

(iii) The strings (or rows) of 1-bit full/half adders in (ii) are replaced by the strings of 4-bit adders.

(iv) In general, the least significant bit (lsb) adder in each adder-row is a half-adder. Such an HA in a particular adding-stage is interchanged with a corresponding FA in a lower adding-stage if it allows to reduce carry-dependence in that adder-row. This is illustrated in Figure 4 which gives final scheme for a 12-bit x 12-bit multiplier.

If the above four steps are carried out in the order listed above, $\log_2 n$ successive additions (i.e., one 4-bit addition in each adding-stage) would yield approximately $\frac{n}{2}+1$ lsb's ($a_1 \cdot b_1$ being the first lsb) of the final product, as seen from Figures 3 and 4. This is so because the two inputs to the final-adding stage are the sum of first $\frac{n}{2}$ rows and the sum of last $\frac{n}{2}$ rows, which are displaced by $\frac{n}{2}$ bits.

COST AND SPEED ANALYSIS

In this section we give expressions for the cost and the multiplication time of the log-sum multiplier. Costs and speeds of the 7-bit x 7-bit and 12-bit x 12-bit multipliers are computed from these expressions assuming Texas Instruments (TI) TTL 7400 series I.C. chips. Prices have been taken from the 1974 "Cramer Electronics Catalogue" and delays from 1974 Texas Instruments 'The TTL Data Book for Design Engineers'.

Cost estimation

The log-sum multiplier requires n^2 AND-gates for generation of summands and Q 4-bit FAs for reduction

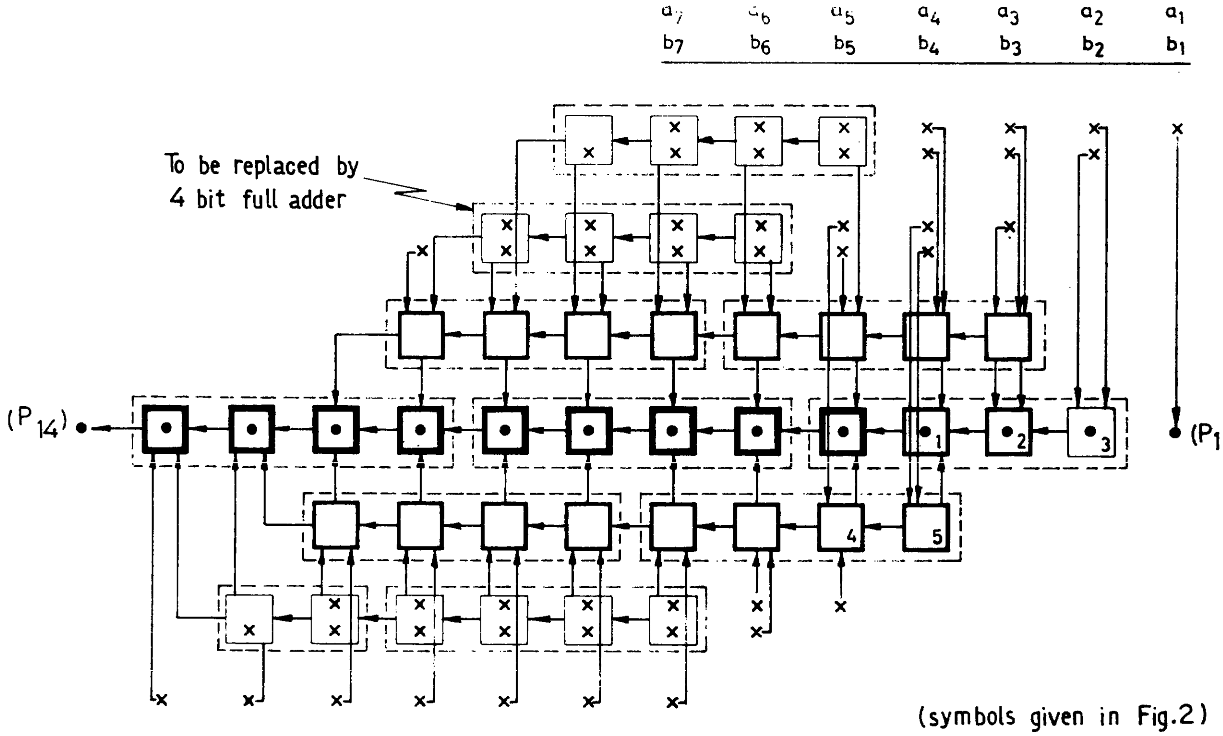

Figure 3—Final scheme for 7-bit x 7-bit log-sum multiplier

of summands. Hence, the cost of the log-sum multiplier may be written as

$$C = c_1 \cdot R + c_2 \cdot Q$$

where c_1 and c_2 are the prices of a quad 2-input AND-gate chip and a 4-bit FA chip, respectively. R is the least integer greater than or equal to $n^2/4$ and Q is the least integer greater than or equal to $(n^2-n)/4$.

The 7-bit x 7-bit log-sum multiplier requires 49 AND-gates and, hence, 13 quad 2-input AND-gate chips (SN 7408), and, 11 4-bit FAs (SN 7483A). The 12-bit x 12-bit multiplier requires 36 quad 2-input AND-gate chips and 33 4-bit FAs. The corresponding costs are about $40 and $115, respectively.

Speed estimation

As indicated earlier, $\frac{n}{2}+1$ lsb's of the final product are obtained in $\log_2 n$ 4-bit successive additions. The time required to obtain remaining product bits is the carry-propagation delay from $\left(\frac{n}{2}+1\right)$th bit to $(2n-1)$th bit. Therefore, the multiplication time required by the log-sum multiplier is given as

$$T_M = t_g + t_{ad} \cdot \log_2 n + t_c \cdot \left(2n - 2 - \frac{n}{2}\right)/4$$
$$= t_g + t_{ad} \cdot \log_2 n + (3n-4) \cdot t_c/8$$

where t_g is the time required for the generation of summands (i.e., propagation delay of one 2-input AND-gate), t_{ad} is the addition time for a 4-bit FA and t_c is the carry-propagation delay of the 4-bit FA.

Maximum values of t_g, t_{ad} and t_c, as given in TI 1974 catalogue, are 27 ns, 24 ns and 16 ns, respectively. Hence, the worst case multiplication time for $n=7$ and $n=12$ cases are 130 ns and 180 ns, respectively.

A 7-bit x 7-bit multiplier was built on a printed circuit board, using the scheme given in Figure 3, for use in a special purpose signal processor.[6] The multiplication time required for each possible combination of inputs was measured. The maximum time was found to be less than 110 ns which is well below the estimated worst case value of T_M.

COMPARISON WITH OTHER SCHEMES

Cost comparison

The log-sum multiplication scheme is most economical of all the array multiplier schemes, since it employs minimum number of 4-bit FAs. Each of the other schemes requires 1-bit and/or 2-bit FAs in addition to 4-bit FAs or can be implemented using larger number of 4-bit FAs. The adders required by the carry-save scheme, which is more economic than any other past schemes, are compared with those required by log-sum

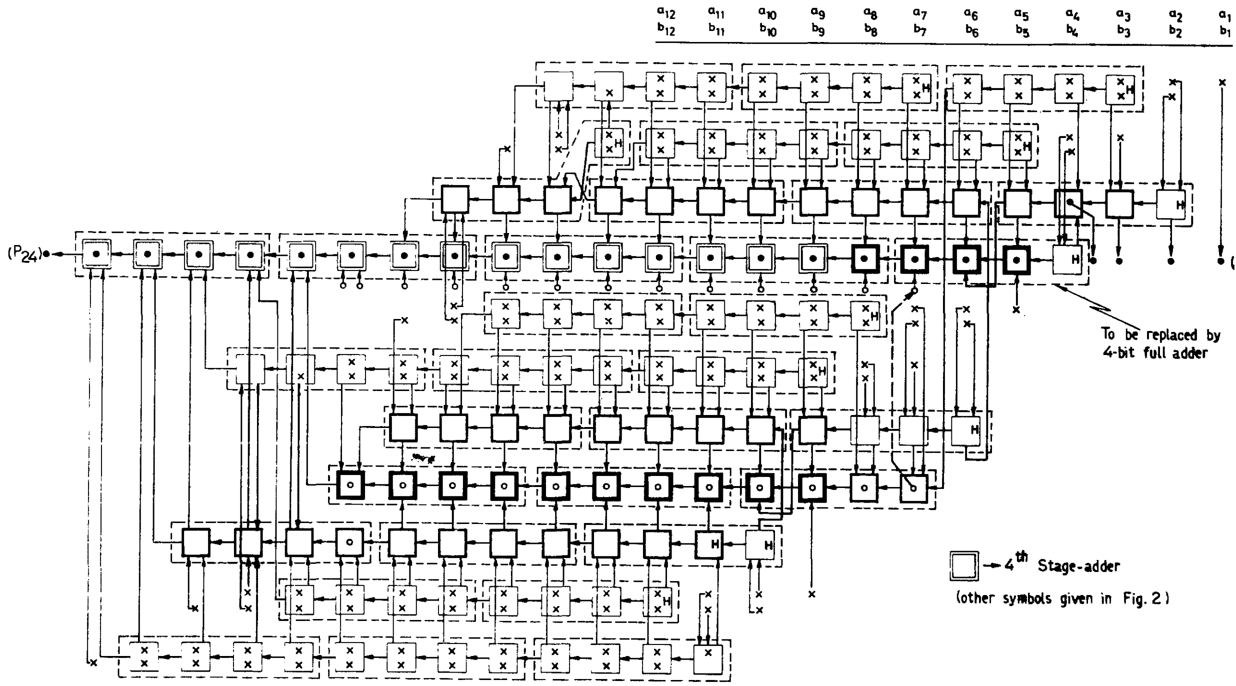

Figure 4—Final scheme for 12-bit x 12-bit log-sum multiplier

TABLE I

		Number of adders required		
k	Scheme	4-bit FAs	2-bit FAs	1-bit FAs/HAs
0	Log-sum	Q	—	—
	Carry-save	$Q-\frac{3n}{4}$	n	n
1	Log-sum	Q−1	1	—
	Carry-save	$Q-\frac{2n+2}{4}$	n	—
2	Log-sum	Q−1	—	—
	Carry-save	$Q-\frac{n+2}{4}$	—	n
3	Log-sum	Q	—	—
	Carry-save	Q	—	—

scheme for various values of k (defined in an earlier section) in Table I.

As seen from this table, the cost of the log-sum multiplier is at most equal to that of carry-save multiplier.

Speed comparison

Dadda's scheme requires roughly $\log_{1.5}n = 1.71 \log_2 n$ adding stages. The multiplication time required by Dadda's scheme, therefore, is approximately given by

$$T_{MD} = t_g + t_{ad} \cdot 1.71 \log_2 n + \frac{2n-2-1.71 \log_2 n}{4} \cdot t_c$$

assuming 4-bit FAs throughout (including the final addition). It is clear from the expressions for T_M and T_{MD} that for all n, $T_{MD} \geq T_M$. The worst case values of T_M and T_{MD} for n=7, 12 and 32 are given in Table II. If a G (let G be the smallest integer≥)-bit CLA adder, built from Schottky TTL I.C. chips, is employed to add the final two numbers in Dadda's scheme, T_{MD} reduces significantly. However (i) use of Schottky TTL I.C.s increases the multiplier cost enormously, and (ii) T_{MD} reduces to less than or equal to T_M only for large values of n(>32).

Pezaris[7] has given a 40-ns 17-bit x 17-bit array multiplier, using basically the carry-save scheme. However, he has used ECL logic and, hence, the cost and speed of his multiplier cannot be compared with those of log-sum multiplier using TTL logic, presented in this paper.

TABLE II

n	Log-sum scheme T_M(ns)	Dadda's scheme T_{MD}(ns)
7	130	170
12	180	230
32	330	450

DISCUSSION

The configuration presented in this paper yields a fast multiplier using the optimum number of 4-bit CLA adders. The scheme can be adapted to M-bit CLA adders by making the number of adders in each row a multiple of M instead of a multiple of 4 in step (ii) of the second section of this paper.

The scheme has been presented for the multiplication of two sign+n-bit numbers. The sign of the product is generated separately. Baugh and Wooley[8] have given an algorithm for 2's complement array multiplier, in which the multiplication process is same as given in Figure 1 except that the number of rows increases from n to n+2. Therefore, the 2's complement multiplication can easily be implemented by log-sum scheme.

A 4-bit x 4-bit multiplier from TI (requiring two chips, SN 74284 and SN 74285) costs approximately $26, and, the worst case and typical values of multiplication time are 60 ns and 40 ns, respectively. The same multiplier based on log-sum scheme costs approximated $11, while the worst case and typical values of multiplication time are approximately same as above.

Finally, the log-sum scheme fully exploits both the cost effectiveness and speed effectiveness of the 4-bit FAs and, therefore, is well suited for multipliers in special purpose hardware requiring high speeds of operation.

Distributed information systems

by GRAYCE M. BOOTH
Honeywell Information Systems
Phoenix, Arizona

ABSTRACT

Distributed information systems represent an increasingly important trend to computer users. Distributed processing is a technique for implementing a single logical set of processing functions across a number of physical devices, so that each performs some part of the total processing required. Distributed processing is often accompanied by the formation of a distributed database. A distributed database exists when the data elements stored at multiple locations are interrelated, or if a process (program execution) at one location requires access to data stored at another location. Examples of how these techniques are being used are provided, with comments on the advantages and disadvantages of the distribution of processing and databases in the current state-of-the-art.

INTRODUCTION

This paper discusses distributed information systems—what they are, and why they will become increasingly important to computer users. Distributed systems—also called distributed database systems—are in the early stages of development as yet, so much of this discussion will be theoretical. Whenever possible, however, practical examples will be supplied from systems now being planned, implemented, or in use.

DEFINITIONS

Information network

A distributed database system always exists within an information network environment. An information network is a combination of information processing facilities, data communications facilities, and endpoint facilities. Together these support the movement and processing of files, programs, data, messages, and transactions. An example of a complex information network is shown in Figure 1.

Data communications facilities include the transmission ("telephone") lines, coupling devices such as modems, and concentration devices such as multiplexors and terminal concentrators. The endpoint facilities include terminal devices, and also satellite processors used both as endpoints and for localized information processing.

Distributed processing

Distributed processing exists when a single logical set of processing functions is implemented across a number of physical devices, so that each performs some part of the total processing required. Two types of distributed processing have been defined, horizontal and hierarchical (or vertical).

In horizontal distribution all devices cooperate at an equal level, logically, to perform a set of tasks. There is no hierarchical relationship among the devices.

In vertical distribution the interconnected devices form a hierarchy, sharing tasks in a structured way with each component to some degree controlled by the higher-level member(s) of the hierarchy.

In a complex system, such as the Figure 1 example, both types of distributed processing may be present. Horizontal distribution is shown in the example be-

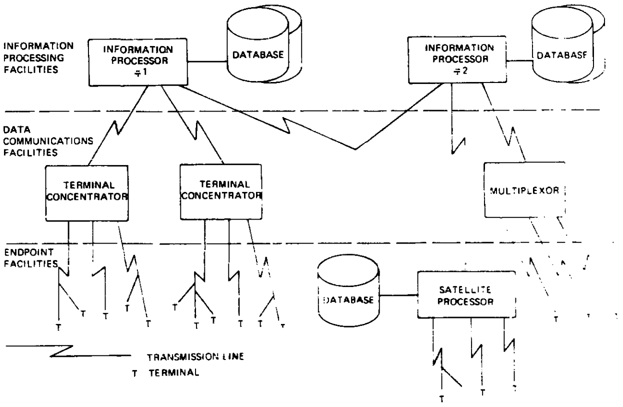

Figure 1—Information network

tween the two information processors, and hierarchical distribution is shown between Information Processor #2 and its satellite processor.

Distributed database

Whenever multiple processing devices are configured in an information network the possibility of a distributed database exists. In the broadest sense the data stored at all locations could be considered to form a distributed database. However, for practical purposes a distributed database exists only when the data elements at multiple locations are interrelated, or if a process (program execution) at one location requires access to data stored at another location.

A distributed database may consist of a single copy of a set of information, divided into increments which reside at multiple locations. This form is called a partitioned database.

A distributed database may also consist of a set of information, all or selected parts of which is copied at two or more locations. This form is called a replicated database. A single distributed system may make use of both of these forms of database.

EXAMPLE SYSTEMS

This section presents a small sample of distributed database systems which are now in the planning and/or implementation process.

Example #1

The first example, shown in Figure 2, is a horizontally distributed system. Two large-scale information processors, located remotely from each other, are linked using communications facilities.

The two computers communicate by exchanging files. A file may be a source-level program; in the company shown most program development takes place in City A, and copies of new programs are transmitted to City B for use there.

A file may also represent a job (an executable program and its accompanying input/output data), which is transmitted from one information processor to the other for load leveling purposes.

This example represents a "loosely-coupled" distributed system. The two information processors are largely independent, and exchange data only occasionally. A distributed database is not required to support this mode of operation.

Example #2

A manufacturing control system (Figure 3) is the second example. In this system the large-scale information processor is not directly involved in real-time process control. It maintains the master database, which is used for overall scheduling and control of the manufacturing process.

At the next level in the hierarchy there are several satellite processors, implemented using minicomputers. Each satellite handles a part of the manufacturing process, and maintains its local database, which is a subset of the central database and contains only the data applicable to the local task. This is an example of a replicated database.

The next lower level of the hierarchy consists of terminal concentrators. These minicomputers link the satellites to the lowest-level devices, concentrating data from many devices onto a few communications links and/or direct cables to each satellite processor.

The lowest-level minis (in some cases microcomputers are used) monitor and control the factory equip-

ment. Process status information is sent up to the satellite processors, while control commands are received from the satellites to guide the manufacturing process.

Distributed system architecture

The two major forms of distributed system architecture are horizontal distribution and vertical (or hierarchical) distribution. In a very complex system both forms may be used.

HORIZONTALLY DISTRIBUTED PROCESSING

The horizontal distribution of processing functions involves the interconnection of two or more components which are logically equal. Note the term "logically"; the components may be physically unlike and of different capacity and power. The important aspect is their logical relationship within the distributed system.

In a horizontally distributed system multiple information processors most often cooperate to exchange jobs and/or transactions so that the total workload is suitably distributed. An example is shown in Figure 4.

The example shows three information processors, geographically distributed but interconnected via data communications facilities.

In a configuration of this type each information processor will normally handle jobs/transactions which originate locally. The interconnections can be used for load leveling among the three information processors. Candidates for load leveling could range all the way from compilations to complex jobs which require that the referenced files be transferred between cities with the jobs.

This illustrates one trend among current users; the interconnection of hitherto independent computers to gain the advantages of load leveling and common access to all files (which may form a distributed database).

HIERARCHICALLY DISTRIBUTED PROCESSING

Probably the most basic rule in designing hierarchically distributed systems is to spread the processing load up and down the hierarchy by locating functions where they can be performed with the best cost/performance ratio. Functions which are required repeatedly and with quick response are moved out (or down) into the hierarchy as far as feasible. Other functions less often executed and/or with less stringent response requirements tend to move upward toward the center of the hierarchy.

As functions are relocated within the hierarchy the data which supports these functions must move with them, leading to the formation of distributed databases.

An example three-level hierarchy is shown in Figure 5. At the top of the hierarchy is a central computing complex, consisting of one or more large-scale information processors. At the next level there are several satellite processors, placed in factory locations, warehouses, or bank branches, depending on the type of application. At the lowest level there is a potentially large number of controllers, to which the terminals and/or other input/output devices (such as process-control equipment) are attached.

It is easy to visualize hierarchical systems with fewer levels or with more levels, although three is probably most typical today. A two-level hierarchy might omit the terminal controllers and handle the terminal/device interfaces directly from the satellite processors. A four-level hierarchy might separate each satellite processor into a local information processor and a terminal concentrator.

Distributed database architecture

In many distributed processing systems there is a strong probability that a distributed database will be required. Distributed databases can be separated into two categories:

- Partitioned databases
- Replicated databases

PARTITIONED DATABASES

The first category of distributed database exists when a conceptual database is separated into sections and spread across multiple computers. The term "conceptual" is used because in general a single database is not created and then partitioned; instead, the database is designed as a logical entity but actually only created in the form of its partitions. The separate sections, because of their interrelationship, logically form a single database.

Database access partitioning

Database partitioning often follows the natural distribution of database access requirements.

As an example, consider a wholesale company with two information processors. Their total database will probably be split into two partitions, and one attached to each computer. This separates both the processing load and the database accesses between the two information processors. If the company operates nationwide within the United States, the information processors might be located as shown in Figure 6.

In the example system it is logical to locate database partitions heavily accessed by east coast users at the eastern information processor and locate those most accessed by west coast users at the western information processor. Accesses from intermediate locations must be equitably distributed between the two computers.

An important reason for geographical grouping of data is the cost of transmitting data to/from remote locations. In general, the shorter the transmission distance the lower the cost.

In the Figure 6 example provision must be made for at least some use from outside of the area where the database partition is located. The east coast database partition will no doubt sometimes be accessed from west coast locations, and vice versa. In a distributed database system such accesses must be allowed. However, the great majority of the accesses to each section of the database will originate locally. If this is not the case, the database has not been partitioned correctly.

Vertical hierarchy partitioning

Another example of the use of a partitioned database is shown in Figure 7. In this case the database is partitioned over a hierarchy, rather than across a horizontally distributed system.

This example shows a processing hierarchy which corresponds to the organizational hierarchy—a fairly typical case. The large-scale information processor handles corporate-level processing, with a corporate database attached. Each division has its own satellite processor—two of these are shown. Each divisional satellite processor has associated with it a satellite database. This example assumes that there is no duplication of information among the databases shown. In effect, therefore, the data elements at all locations form a corporate database, which has been partitioned across the hierarchy.

Figure 7—Vertically partitioned database

Information is exchanged in both directions across the hierarchy. Corporate-level reports require information from the divisional database for consolidation with corporate data. Data also travels down the hierarchy, as goals and budgets are established at the corporate level and are passed down to the divisional level.

REPLICATED DATABASES

The replication of all or part of a database at two or more locations is another way to create a distributed database.

An example of the use of a replicated database is shown in the Figure 8 illustration of a complex banking system formed of the interconnection of two hierarchies.

In this system the central information processors maintain the master database of customer accounts, with the total set of customer records partitioned between the two computers. Each satellite processor maintains a database containing the accounts for its local customers. Each local database is created by copying the necessary information from one of the partitions of the central database.

The local databases are essentially work files, refreshed each night from the master database. On-line activity during the day is posted to the local databases; these are used for withdrawal authorization and similar functions. At night all activity is batched and used to update the master database, from which new local databases are then created, and the cycle repeats.

Distributed database system use

The two forms of distributed system architecture—horizontal distribution and hierarchical distribution—and the two categories of distributed database—replicated database and partitioned database—can be combined in a variety of ways.

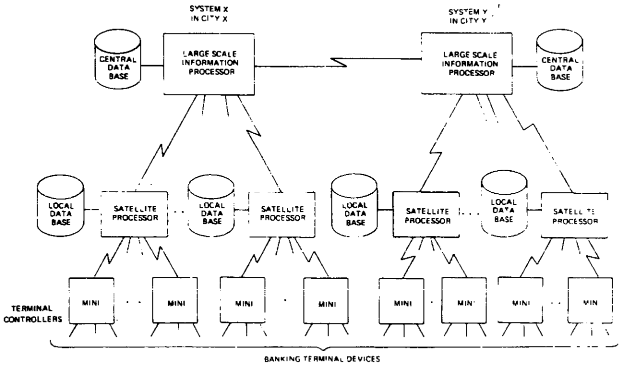

Figure 8—Complex banking system

DYNAMIC LOAD LEVELING

A distributed system can be used to dynamically spread the total processing/database access load across the available computers. In general, this mode of use is associated with horizontally distributed systems.

In a relatively straightforward situation an organization might have three identical information processors, as shown earlier in the Figure 4 example.

If all three information processors have the same capabilities, then jobs/transactions can be moved freely among them. It may be desirable to execute a specific job in a particular computer because it requires access to a database associated with that computer. On other occasions it may be desirable to move jobs, possibly accompanied by their data, from an overloaded information processor to one which has available capacity. The choices for load leveling can be summarized as follows:

- Move the process to the data
- Move the data to the process

In a batch-oriented environment the tendency is to transmit a job, or a subdivision of a job, to the information processor where the database is located. Because a batch job often does extensive processing against the database, and database size is typically large, it is more economical to transmit the job and its input/output data than to transmit the database.

In the Figure 4 example, if a job is entered at City A but requires access to Database B, then the job will normally be transmitted to Information Processor B, executed there, and output returned to City A if necessary.

In inquiry/response applications, in contrast to batch processing, usually only a small part of the database is accessed. It is therefore feasible to consider transmitting the data to the process and returning only updates (if any) to the computer where the data is stored. In this case the process, as specified by its process-state and program, may be considerably larger than the data involved.

STATIC LOAD LEVELING

In the second method of organizing a distributed database system the total load is leveled by preassigning functions and database segments to processors statically.

This method is most often used in a hierarchically distributed system, which may be formed of unlike computers; i.e., large-scale information processors, minicomputers, terminal/device controllers, and microcomputers.

In this situation control of a distributed database is somewhat less complex than in the preceding case. The functions which must be supplied are: (1) provide remote as well as local access to parts of the distributed database; and (2) move parts of the database up and down the hierarchy.

Referring to the complex banking system shown earlier in Figure 8, in this system enough information is included in each satellite processor's database to handle approximately 80 percent of the transactions which originate at the local terminals. Deposits and withdrawals can be handled by the satellite, provided that the customer's home branch is within the satellite processor's local area.

Conditions which the satellite cannot handle include withdrawals for a customer whose account is in a remote branch, and complex transactions such as loan applications and credit card applications. For this particular bank 80 percent of all transactions can be handled by application programs resident in the satellite processors, working with their local databases. The complex transactions are sent up to the large-scale information processors; these have a more complete set of application programs and a much larger database.

Perhaps the most complicated case to handle occurs when a customer enters a branch remote from the branch at which his account is maintained, and requests a withdrawal. Approximately 3 percent to 5 percent of all transactions are of this type.

In this case the withdrawal transaction is passed on by the satellite processor where entered, and travels up the hierarchy to the nearest central information processor. From there it is passed, via the other information processor if necessary, to the satellite which handles the customer's home branch. The withdrawal is processed by that satellite, using its local database, and the response is returned to the satellite where the transaction entered.

The banking system is a good illustration of the principles of distributing functions—application processing—and database information as close as feasible to the point of transaction origination. It also illustrates the principles of centralizing the handling of small numbers of complex transactions which cannot economically be handled by each of the satellite processors.

SUMMARY

Today the computer industry and its users are in the early stages of a developing trend toward the use of distributed database systems. Not all information system users will follow this trend; many will continue to be served satisfactorily by more conventional centralized system structures.

However, advances in both hardware and software technology will make distributed architectures attractive to an increasing number of users. Information networks will become more and more common in the next five to ten years. Accompanying these information networks and distributed system architectures will be an increased use of distributed databases.

These distributed database systems, although complex, will provide a degree of efficiency and cost/effectiveness often impossible to achieve in centralized system architecture.

Error detection in data base systems*

by MICHAEL HAMMER
M.I.T. Laboratory for Computer Science
Cambridge, Massachusetts

ABSTRACT

Incorrect data poses a serious impediment to the effective use of computerized data bases. Conventional approaches to the design and implementation of automated data error detection systems are inadequate for large and complex data bases. Partly, this derives from the inherent intricacy of the problem, with decisions being required as to what checks to perform, how and when to do the checking, and how to respond should an error be found; writing procedures to accomplish these functions is a difficult programming task. Also at fault is the unrealistic and overly simplistic view of data correctness embodied in most contemporary systems.

"Intelligent" data checking systems are required, which possess more extensive knowledge of the data base environment. They will need to understand the structure of the world which the data base models; the way the data base is used, and the relative importance of its various components; the sources of the errors that might occur and the costs of detecting them; and the patterns and rates of errors that actually do occur. Such a system would then be in a position to detect a wide range of errors, allocating its resources in a systematic fashion and responding appropriately to different error situations.

INTRODUCTION

It is a truism that any decision-making system is only as good as the data which it uses; this is especially true of computer-based information systems. Yet while the number and complexity of such information systems have been dramatically increasing in the last few years, supported by great enhancements in the technology of data base management systems, comparatively little has been done to assure the quality and reliability of the data on which these systems depend. Many computerized data bases in use today suffer from high error rates in the data they receive, and are consequently riddled with bad data. And with incorrect data, the most efficient and sophisticated system is well-nigh useless.

There are numerous potential sources of error in a computer data base. Some of these originate in the computer system itself, deriving from such causes as hardware failure or interfering concurrent users; however, these are generally secondary sources and can be controlled by existing technology. The major error problem lies in data that arrives at the computer already corrupted. The possible reasons for this corruption are manifold, including human error in the initial recording or formatting of the data; faulty transcription of the data, either by human or machine (e.g., OCR scanners); accidentally lost, forgotten, or delayed data; deliberately falsified or omitted data; and the like. It is also useful to include in our notion of erroneous data those cases where no error has occured in the transcription or transmission of the data, but rather where the data faithfully represent an illegal or impossible event. That is, the error is not in the data, but in the information it conveys.

In this paper, we consider the problem of detecting errors in data bases. We begin with a re-examination of the concept of data errors, and consider both the problems that they can cause and the difficulties that can arise from attempts to detect them. This leads us to consider the issues and problems of error detection, and the inadequacies of the current technology in this field. We proceed on the basis of this analysis to propose an alternative way of thinking about data integrity, an approach which has major implications for the design of error detection systems.

DATA ERRORS AND DATA INTEGRITY

It is worthwhile to re-examine the concept of error in the context of a data base. A data base is not just a collection of values; it serves as a model of some limited universe. At every point in time, the contents of the data base represent some configuration of that application world. Every such world is governed by some set of rules that determines the legitimacy or plausibility of its states, that specifies which configurations of

* This research was supported by the Advanced Research Projects Agency of the Department of Defense and was monitored by the Office of Naval Research under contract number N00014-75-0661.

the world are reasonable. Consequently, every correct version of the data base must obey these rules as well. If the values in the data base do not represent a legal configuration of the world, then there is an error in the data base.

In addition, every world has rules which do not constrain its instantaneous versions, but rather restrict the legitimate transitions between its valid configurations. Such rules are not violated by particular instances of the data base, by illegal transformations of the data base from one consistent version to another. For example, the rule that "salaries do not decrease" would be violated by a change to the data base which decreased some salary, though both the before and after states of the change might be internally consistent and legitimate.

The foregoing concept has been referred to as the "logical consistency" or "semantic integrity" of a data base.[1,3,4,5,7] This property is violated when the data base no longer reflects a legal world instance, or when a change is made to the data base that does not obey the constraints on world actions.

It is useful to consider two generalizations of the foregoing idea. First of all, many application domains are not governed exclusively by rules of a black-or-white character, which specify certain situations as perfectly legal and all others as totally illegitimate. Rather many worlds make extensive use of the notions of probability and likelihood. For example, it may not be impossible for an employee to get a 100% raise, but it is implausible. Therefore, we could not immediately classify data attesting to such a condition as being erroneous, but we would have to look at it askance; and should we note many such instances, our skepticism would begin to rise.

The second generalization is that errors are really just one kind of exceptional condition. Data that reflects situations that are in the norm can, in some sense, be said to have been anticipated, and so their occurrence requires no system response. However, unusual data, that either is faulty or represents a surprising turn of events, is noteworthy and demands special attention and response. Thus, any violation of the rules of a world model, whether caused by faulty data or by an illegal activity, requires detection.

We can identify several types of errors in a data base, which are of increasing complexity and difficulty to detect.

1. Most simply, an individual value which is inappropriate for the field which holds it. For example, the value may be of the wrong data type (e.g., a salary which is not numeric) or of the wrong magnitude (e.g., a salary less than $4000).[6]

2. An inconsistency between different fields of the same record. For example, an individual's salary may not be consistent with his job classification. Here we encounter the problem of localizing the error: though we know which record is faulty, we have to determine which of the two fields is the one causing the problem. We may have to draw upon additional information to resolve this.

3. An inconsistency between field(s) of one record and fields(s) of related record(s). For example, there might be a rule that no individual's salary may be greater than that of his manager. Should this rule be violated by the data base at some point, the error could only be localized to one of two possible offending records.

4. Some global pattern out of order in some set of records or in the data base as a whole. This would be a violation of some restriction, not on individual entities of the application domain, but on collections of them. These global patterns may involve aggregate functions (the average salary of all employees should not exceed $12,000), functionality relationships (every department has exactly one manager), and subset requirements (every manager is also an employee). These global pattern violations usually indicate not the presence of some particular faulty value, but rather of a general trend which violates expected norms. In these cases, it is often not the data that is wrong, but the events that they report, or sometimes even the the rules which define right and wrong in this environment.

5. Missing data. This notion includes blank fields, obsolete values (the new data is missing), entire records which are referenced but cannot be found, and lacking data which cannot be localized.

DATA ERRORS VERSUS DATA CHECKING

The hazards of allowing erroneous data into a data base hardly need belaboring. They include the obvious results of improperly executed operational activities and faulty decisions based on incorrect information. But bad data can also cause the malfunction of application programs that use the data base and can even degrade the performance of the data management software itself, sometimes to the point of failure; this occurs because programs frequently implicitly assume that the data which they manipulate are semantically reasonable and consequently satisfy various criteria. On a more systemic level, erroneous data can destroy the confidence of an organization's personnel in the entire information system, with a deleterious impact on morale; frequently the result is an atmosphere which fosters even higher error rates, due to negligence and disinterest.

While it is easy to recognize the dangers of allowing erroneous data into a data base, there are also potential hazards in attempting to prevent this eventuality from occurring. The major pitfall in this regard is an overzealous commitment to the notion of data correctness, whereby the error detection process becomes an end in itself. This condition results from a loss of perspective, wherein the actual dangers of the errors that do occur are not accurately assessed nor the costs of their detection weighed against the damage they can cause.

In reality, not all data errors are of equal significance in the context of a particular information system. Different parts of a data base are used for different purposes, and consequently have unequal degrees of importance; this ought to be recognized by the error detection system. Any aspect of the data base may be said to have both a "sensitivity" and an "impact" with respect to its being in error. For example, the salary field in a personnel file is very sensitive to error; any faulty value will give rise to an improper action (namely, the cutting of an incorrect salary check). On the other hand, the age field, if used primarily in projecting future manpower requirements, is comparatively insensitive; it would take many erroneous values to diminish the utility of the aggregate of the age field values. Yet the potential impact of the latter error situation may be much greater; a bad high level decision, in contrast to one inaccurate action. It would be appropriate, then, for a data checking system to expend its resources in proportion to the importance and severity of the errors it is trying to detect.

If the foregoing idea is not appreciated, a disproportionate amount of system resource may be invested in error checking, well beyond what it realistically deserves. This investment may manifest itself in the expense of constructing a powerful and "complete" error checker, or in the actual processor time allocated to this function. There may be more insidious side effects as well: over-emphasis on error detection may impair the performance of the data management system as a whole. Excessive timidity in the presence of possible errors can delay the entire decision-making process, or may even reduce the over-all functionality of the whole information system. On the other hand, an unwarranted over-confidence in a faultily performing error checking system can lead to a false level of confidence in a data base that may be in fact contaminated with much bad data.

CONVENTIONAL APPROACHES

The state-of-the-art in automatic error detection/correction has not been highly developed. Most data editing that is currently done is usually confined to the simplest validity checks, assuring that various fields are of the appropriate data types or are within specified ranges. The structure of most error systems is that they are comprised of a collection of hand-coded, special purpose procedures (written in assembly code or some conventional programming language), each of which is designed to monitor some particular transaction with the data base, and assure both that the transaction is legal and that it leaves the data base in a consistent state. These programs are generally entirely ad hoc, and follow no well-defined approach or methodology.[2]

This approach to error detection does not satisfactorily address the problem of complexity. Any data base that represents a real world system of interest is almost certain to be governed by a large and rich set of complex rules which delimit the legality of its data values. To reliably and effectively capture these rules in a disconnected set of procedures written in a conventional programming language is a task that strains the effective capability of contemporary programming technology.

In consequence, current data checking systems are frequently very expensive to build and, once built, are often highly unreliable. Furthermore, they are almost impossible to modify in an orderly and consistent way in order to meet new requirements, either in terms of evolving definitions of the errors to be detected or in modified characteristics of the operating environment.

Conventional methods of error detection usually check for error conditions on the occasion of every (primitive) update (insert, modify, delete) to the data base. This is expensive and can also lead to anomalous results. Consider for instance the restriction that no employee is to make more than his manager, and a series of transactions that increments everyone's salary by 8 percent. If an employee's raise is processed before his manager's, application of the test would compare a new salary with an old one and might raise a spurious flag, reflecting a transient condition in the data base.

In addition, current error systems are cumbersome, relying on primitive brute-force techniques to do the data checking; in general, they operate in a very inefficient manner. Partly this is a consequence of the complexity problem; the incorporation of any but the simplest techniques in the system structure described above might topple the entire structure. In another sense, this clumsiness is a result of the rigid and inflexible view of data correctness alluded to earlier. In this view, every datum is viewed as being either correct or incorrect, and all errors are assumed to be catastrophes of equal magnitude. There is no appreciation of the fact that while some fields must be error-free, others (because of the way they are used in the information system) can tolerate some measure of error; nor does it take into account the concept that the severity of an error might be measured in terms of its deviance from a legitimate value. Thus there is usually little relation between the importance of an error and the amount of resource expended to detect it.

Nor does the conventional system structure provide a systematic capacity for response to an error situation. Once the presence of an error has been detected, it is then necessary to localize the error and specify exactly which data value is at fault; in many cases, the state-of-the-art is incapable of doing this satisfactorily. After an error has been identified, there are several possible responses. The options include rejecting the erroneous data; allowing it into the data base, signalling its occurrence and/or marking it as questionable; putting it into a suspended status, pending the receipt of additional clarifying information; attempting automatic error correction. The choice of response should be determined by the importance of the error, the reliability of the error detection procedure, and the particulars of what causes the error. However, current systems are inflexible in this regard. They are especially weak in automatic error correction, relying on ad hoc techniques which can easily go astray.

All of these problems are greatly exacerbated in the context of large data bases with high data input rates. There the requirements of the data checking system can easily overwhelm the available system resources. These circumstances have resulted in data bases that are full of bad data despite extensive data checking, and whose utility is grossly restricted because of the unreliability of much of the data.

In some applications, the current technology is adequate, because of the simplicity of the world of application and the consequent limited range of possible data errors. However, the current state-of-the-art will not be able to meet the demands of data bases of increasing size, complexity, and sensitivity. As data bases are used to model ever larger and richer domains, and are relied on for more critical decisions, the need for reliable data will be ever more pressing and more difficult to satisfy.

AN ALTERNATIVE APPROACH

In view of the problems that have arisen as a result of a non-systematic approach to error detection, we propose the following basic principles to be adhered to in the design of error detection systems.

1. Expect errors, and be prepared to fail because of them in a "soft" manner. Do not design the kernel of the information system under the hypothesis that all data is correct, and then delegate to an error-checking subsystem the responsibility of bringing about that state of affairs. The goal of perfectly correct data is an unattainable one. We can minimize the presence of certain errors subject to various constraints, but cannot expect to eliminate them altogether.

2. Formulate the rules of the application world first; then relate them to the constructs of the data base; and then identify potential logical errors in terms of the data base transactions. Attempt to ensure the completeness and consistency of the world model before proceeding further.

3. Evaluate the importance of the various error types with respect to the decision process, considering both sensitivity and impact. Allocate the resources of the data checking system in line with this evaluation.

4. Anticipate the kinds of errors that may occur, identifying their sources, estimating their relative frequencies, and determining the costs of defecting them. Be prepared to adapt to changes in any of these factors: in the definitions of what constitutes an error; in patterns of actual error occurrence; in relative importance of errors; and in the costs of error detection. Learn from historical situations and detect emerging patterns as well.

We believe it is possible to construct an error-detection system in accordance with these principles, and are in fact currently engaged in such an effort. Below, we summarize the most salient features of the system design.

1. The system will be declarative, rather than procedural. That is, the rules governing the legitimacy of data values will not be implicitly embedded in the code of the procedures that perform data-checking, but will be stated as explicit assertions by an individual knowledgeable in the domain which the data base is modelling. The primitives used in the expression of these rules (called constraints) will be chosen to be naturally descriptive of the kinds of worlds most frequently represented in data base systems; thus a non-programmer would be able to describe the constraints directly, without programmer intervention.[1,3,4,5,7]

The declarative approach has numerous advantages over procedural techniques, besides ease of expression. Because the rules are all listed in a single place, it is possible to make modifications to them in a reliable and simple fashion. Since the procedure that uses the constraints to check the data is only written once, it is possible to verify its accuracy reliably and hence have confidence in its correct operation. In addition, the system (rather than an applications programmer) will bear the responsibility for determining and checking all the appropriate rules for a given transaction. Finally, it will be possible to examine the explicit constraints themselves, looking for incompleteness, redundancy, and inconsistency.

2. The constraints will do far more than express legal ranges of values for specific individual fields; they will describe rich structural aspects of the world in question, thus enabling far more sophisticated error checking than is currently done. In order to detect many kinds of errors of this sort, it is necessary for the checking program to possess a good deal of rich and complex "knowledge" of the domain in question. Conventional data base management facilities, and data editing programs that rely on them, do not have the capability to represent and utilize knowledge of the requisite form.

3. The occasions at which errors will be detected will correspond to "conceptual transactions" or "structured operations" with the data base[3,5]; these are appropriately selected sequences of data base transactions that form representations of real-world events. It is these complex transformations that actually occur in the world that the data base models, and so it is appropriate to check them (rather than each of their primitive constituents) for validity. This approach will

avoid many spurious situations and will facilitate suitable response to the detection of an error.

4. The system will be designed to operate independently of the actual data base system, and to reside on a remote processor. This processor will be dedicated to the task of data checking, but it will be able to communicate with the data base facility itself by means of a communication link. It will utilize the constraints which model the domain of the data base to examine data to be submitted to the data base; should it detect an error, the offending transaction can be identified and appropriately handled.

In order to rule on the validity of a transaction, the checking processor may need to inspect some of the values in the data base itself; it will obtain the items it needs by issuing a request for them to the data management system over the communication channel, receiving the results in the same way. As time goes on, the checking processor will build up a local version of those parts of the data base which it most frequently requests, thus obviating the need for much of the data transmission.

This strategy opens up several important possibilities. First of all, by detecting errors closer to the source of their occurrence, the opportunity for their timely correction is greatly enhanced; thus the overall performance of the information system is improved. Furthermore, the data checker can be made relatively independent of the actual data management system which is responsible for the data. Variations in the "back-end" data manager need only have a minor reflection in the operation of the "front-end" error detection processor. This is especially important in an environment where one conceptual data base may be distributed among several data management systems. A final potentiality is for distributed data checking, with multiple front-ends, each processing a separate stream of source data. This can address the problem of checking the correctness of large data bases with high input data rates.

5. The system will adopt a flexible view of the concept of error. While perfectly correct data is a laudable goal, in reality it is an unattainable one, and compromises must be effected in its pursuit. The system will make the necessary trade-offs, in the realm of efficiency versus accuracy, in a systematic fashion. Rather than swamping its resources with a futile and inappropriate effort to detect all errors, the system will concentrate on validating those items that require the highest levels of accuracy. Resources will be allocated to checking other fields based on their relative importance. The data base administrator will provide the system with the information regarding the comparative significance of various data items in the decision making process.

In deciding how to allocate its resources, the system will also consider the effectiveness of the various checks. It will have to determine the actual frequencies of various errors; combining this information with an estimate of the cost of detecting each of the errors in question and with a measure of the importance of the item being validated, the system will be able to proceed in an optimal fashion. The system will also be adaptive, automatically adjusting to changing patterns of errors.

6. The system will possess the degree of "world-knowledge" needed to process errors in an intelligent fashion. The first aspect of this is error localization, identifying exactly which data values are at fault. Once an error has been detected and localized, an appropriate response must be made. The range of such responses is great, and the one to choose may depend on numerous factors and, for a given error type, may even change over time. The system will be flexible enough to accommodate many possible responses, and will be in a position to select the right one.

The most ambitious of all responses is, of course, the automatic correction of the error in question, to restore the original value. The system will possess a facility for the data base administrator to provide a model of the error-making process in the system in question, which describes the loci where, and means by which, errors do occur. In those circumstances which the data base administrator identifies, this model can be utilized to reverse errors that do occur.

The ultimate goal of any error system should be error prevention: the identification of the sources of the errors that actually occur, and the instigation of remedies to forestall their further occurrence. The system will utilize the model of the error process, together with observed patterns of error, to pinpoint the origins of the most common errors and identify them to the data base administrator.

In order to achieve the capabilities just outlined, it will be necessary to utilize novel implementation techniques of a statistical character, that will enable the system to attain maximum data reliability subject to the constraints imposed by available resources. For example, the system could sample the incoming data in order to determine the actual rates of different transaction types and errors. If some errors are found to occur extremely infrequently, then those parts of the system used for their detection can be temporarily disabled. This may allow some erroneous values to slip by undetected, but this should be acceptable if the fields in question can tolerate the expected level of error. The sampling should be reactivated from time to time to ensure the constancy of the error rate. This approach results in application of resources where they are most needed. Other useful statistical information would include various summaries of the data base contents (in order to detect emerging global patterns) as well as patterns of error types and erroneous fields. These can be used to pinpoint the sources of the most common errors as well as indicate when an error is not in the transaction but in the master file itself.

To satisfactorily address the manifold demands of large and complex data bases, it will be necessary to rely on heuristic techniques that gain efficiency at the expense of perfect accuracy. For example, we might associate with various fields of the data base different levels of reliability, based on observed error patterns. These measures can help in localizing an error indicated by a data base conflict. Another idea would be to utilize concepts from "fuzzy logic," and abandon the notion of situations being only correct or incorrect. We might evaluate some predicate at a given time and find it to be "very true", so entirely satisfied that in all likelihood it would take a very long time for a normal series of transactions to make it turn false; we could then reasonably suspend the further checking of this predicate for a long time.

ERROR PREVENTION

Perhaps more important than these techniques which can be used to implement or facilitate error detection, are those measures that should be taken to prevent errors from occurring in the first place, or diminish their potential for harm if they do occur. Primary (and most obvious) of these is the adequate training of those who collect, record, and transmit data. But these individuals must also be provided with incentives to encourage accuracy in the submission or processing of data; someone who feels he derives no benefit from an information system is unlikely to expend much effort on its behalf. There are other "human factors" issues that can have enormous impact on the error rate. For example, the design of the forms on which data is recorded is a very important consideration, which when improperly done, can have disastrous consequences. Such questions as the layout of a form, the size and location of the different fields it contains, the redundancy of the information it carries, and the extent to which it is prefilled, all require careful thought.

The global structure of the information system will also impact the reliability of the data base. For example, it is important to provide multiple levels of protection, so that should an error get past one level of detection it will not immediately get into the data base and linger there forever. One mechanism to achieve this is a feedback system, whereby parts of the data base are directed to those responsible for (or familiar with) them, and then subjected to human review. Distributed data checking is another technique that can contribute to data reliability. It results in more timely error detection and more rapid correction of errors because of proximity of the detection to the source. It also makes for greater system efficiency, with the data base computer only checking for errors that cannot be caught at the source.

The structure of the files that actually comprise the data base also has an effect on the reliability of the data base. Some contemporary information systems are based on a single large file, consisting of a great number of identically structured records, each with many fields. Such a structure does not facilitate the prevention or detection of errors. Every transaction has potential access to all fields of a record and, should it go awry, can have unlimited consequences within the record. Thus, to prevent disastrous situations, all transactions require inspection and validation. A different kind of file structure can be more conducive to data correctness. For example, a multi-file structure wherein critical data is not stored together with less critical information enables us to concentrate our checking resources on transactions that manipulate the former. Similarly, a separation of stable, seldom changing data from that which is highly volatile can prevent erroneous transactions with the latter from influencing the former. Indeed, it may be appropriate to impose a multi-level structure on the data, for example by age. The first level might be the most recent data, not yet fully verified as to its accuracy; the second, the currently active data, into which new data is moved as it is validated; and the third, old seldom-used data, including statistical summaries. The record structure should also be carefully chosen to encourage intra-record checking, and to facilitate inter-record checking when it must be done.

CONCLUSION

In this paper, we have presented the framework of an approach to the construction of "intelligent" error detection systems. Further research is needed to formulate and develop the principles which underlie the advanced approach to error processing described above; having developed these concepts, it will be necessary to assure their viability and practicality by building systems that embody them, and use these systems in realistic problem environments. There are several major conceptual areas which require substantial development in the course of this research: the representational scheme for data base constraints; optimization techniques for efficient data checking; communication between a front-end processor and the back-end data base; measures of criticality and reliability of data, and the heuristics that make use of them; error correction as driven by a model of the error process. Nevertheless, this approach holds great promise for attaining the needed levels of reliability in the large and complex data bases of the future.

ABSTRACT

Large scale health data collection under Federal auspices is examined in this paper. The system planning for establishing the data base is intertwined with the vagaries and complexities of the Federal health administrative structure. This paper addresses the problem of how data can be structured in such a manner that it will give rise to maximum utility across the Federal bureaucracy. At present, minimum linkage between Federal agency data bases is possible. Establishment of linkages between different types of data collected is vital. In the Development of the data base design, careful considerations is given to the human element within the system structure. Mechanisms for human interface in the monitoring and control of data collection and processing are vital if the data is to be put to use.

The new opportunities that can be presented by large scale data collecting are explored briefly in this paper. The necessity for common coding systems and decisions as to storage of the data and form of recording are addressed. The data base is considered as the core element in an entire system design concept, which cuts across Federal, State and local levels.

INTRODUCTION

The Federal collection of health related data is continually expanding. This large scale data collection is intimately linked to the goals of many health programs. In most general terms the motivation behind these programs is to improve health care and lower costs. The amount of data collection and analysis necessary for the accomplishment of these goals is made feasible by computer technology. This paper deals with some aspects of the requirements of data systems to achieve programmatic goals. In particular, we indicate the framework and some of the planning and procedures for the data collected to be effectively transferred and used throughout the Federal health administration structure. Data bases that are set up can be used to achieve objectives under the jurisdiction of different departments only if they are well designed and easily accessible to all users. For this purpose appropriate technical considerations are insufficient. In terms of the entire system, there must be responsible people as checkpoints to review, pass on and act on the data collected. Such a simple question as the length and mode of storage of the large volume of data collected requires a full understanding of the possible uses of the data in the system. In view of the costs of the administrative structure and the burden of collection, structuring, processing and disseminating the data, a plan must be formulated to optimize possible data usage.

In this paper, we deal with the problems of a political and organizational nature within the health bureaucracy only from the point of view of the flow of data. However, this alone requires a framework for coordination and synthesis of activities and a network of responsible people to monitor and review data usage.

DATA BASE DEVELOPMENT

With the ever increasing involvement of the Federal government in the financing and regulation of the nation's health care, enormous fragmented bureaucracies, with numerous departments looking after specific aspects of health care, are being created. Under the Public Health Service alone, there are seven (7) separate agencies (See Table I) with different and overlapping responsibilities in areas of national health care. This expansion of the Federal bureaucracy has not been accompanied by the development of an organizational structure capable of coordinating the various components and, as a result, data collection activities are duplicated and health data systems are generated

with overlapping purposes. At the State and local level this duplication results in the imposition on local health agencies of an intolerable amount of redundant data collection and routing requirements. For example, Table II lists several data elements wh'ch Missouri State hospitals are required to collect for the different Federal, State and local (FSL) agencies listed in Columns 2 through 8. In almost all instances, the same data element is required by more than one agency and on a different form. Because of this duplication and the resulting burden on providers of health data, the health data users of Missouri are presently examining the possibility of entering into a Cooperative Health Statistics System* (CHSS) in which the users will define their needs, establish a "data broker" who will collect and aggregate data from all providers within the State and provide each user with needed data.

In order for the data collected within any specific region, such as in the Missouri region, to be useful on a national scale, an overall system must be designed which relates Federal, State and local data needs both in terms of basic sets of core data and the need for special data collection specific to a given area or activity. The entire system will only be of use if it is designed in such a way that necessary information can be retrieved from one source and linked with information from other sources. Data within the system must be in unit record form and the units must be of sufficient disaggregation to permit the study and analysis of variables affecting the supply and demand of health resources. Not all variables of interest can be maintained in a single base. Linkage between data bases will allow the integration of unit records; thus, information on manpower in hospitals could be combined with information on patient hospital stays. Linkage of such data bases will enable the health planner to quantitatively describe the health care system in order

* CHSS are Statewide systems funded in part by the National Center for Health Statistics/Department of Health, Education, and Welfare.

to plan for future allocation and development of resources.

It will also be possible to conduct many different types of studies and employ a variety of analytical techniques for monitoring of the nation's health services. For example, in Professional Standards Review Organization (PSRO) program data is collected from the hospital medical record. This involves abstracting from the record of each patient information such as diagnosis, age, length of stay, etc. Once a national program is under way and data is available on all discharges, it would be of interest to examine possible correlations involving environmental or demographic variables with PSRO data such as length of stay, frequency of diagnosis, morbidity and mortality. Since geographic and demographic information is not available from the PSRO data base, the ability to link with data bases generated by other programs such as the Health Resources Administration's (HRA's) Hospital Discharge Survey (HDS) and the Area Resource File (ARF) is necessary for conducting meaningful epidemiological studies.

DATA BASE DESIGN

In attempting to advance the health care services of our citizens, data collected has many roles to play. It can be used for monitoring, evaluation, information exchange, research and determination of policy. As such, we can expect a great deal of separate data collection and processing by the various government agencies. However, we expect a significant portion of the data elements in the separate data collections to overlap. The advantages of having a common coding system for the data elements and of structuring the elements into data bases which can be linked are self-evident. To achieve such a goal requires multiple planning in that the original work of the respective agencies must be collated, reviewed and restructured. The same holds true for the establishment of procedures and standards for data collection.

In structuring such a system, one must consider necessary features of the data base. The volume of data will be very great. In order to access and manipulate the data rapidly, the system must be modular. Separate files must be self-contained with respect to special topics. Thus, there can be a separate manpower file with geographical regions forming its subfiles. However, the file must contain crosslink indicators to all other relevant files and alternative classifications. If all of this is done, the data will be widely probed and unforeseen uses and requests will arise.

The data base design must be justified as an element of an information system. The criteria for rational design of information systems must be based upon the needs of the users in the performance of their activities. Information systems or services which are not designed on this basis will inevitably fail to meet user's needs. A logical first step in the analysis of the adequacy of existing systems and in the design and implementation of new ones, is the determination of the functions and activities of the potential users. This first step allows the determination of other needs.

The definition and enumeration of categories of use for better care includes:

- Policy, planning and program management and resolution at the Federal, State and local levels.
- Research at all national institutions.
- Application, i.e., the community which translates research results into practical applications.
- Implementation, i.e., those groups of individuals or organizations who are directly responsible for initiating health care actions.
- Dissemination, i.e., ensuring that the information is made known to those who may need it.

As an example, a health warning system may be set up as a major use of the data collected. The large amount of data collected will allow for the establishment of meaningful norms and expected deviations. It will be possible to use the data to establish baselines and look out for trends. Based on the deviations from established norms the impact of a given disease on an area could be determined.

In the massive collection of data the data elements must be standardized and organized into identically formatted records at the various source collection points. If this is not done, large processing costs will be incurred in attempting to use the data. However, these eminently practical procedures put a damper on the use of the data collected for creative investigation of medical questions. Let us consider an example. There is reason to believe, based on international evidence, that cancer of the colon is caused by either large meat consumption or low consumption of cereals.[1] This is established by showing the correlation between the incidence of cancer and meat consumption in 23 countries. The data are adjusted to eliminate differences in age distribution in the population. The possibility exists that it is not meat consumption, per se, but some other factor associated with meat consuming countries which gives rise to the correlation. A question worth answering in this regard is with respect to the United States population: "Does higher meat consumption appear to be a causitive factor in cancer?" To answer this question, it is necessary to obtain data from people whose environment and life styles are very similar except for their meat-eating habits. We can achieve our goals by carrying out physiological studies and comparing the hospitalization records of vegetarians with a socio-economically equivalent group of meat eaters. Here is where the catch is. This is not the sort of information that would be entered as part of the standard records collected on health care (and it should not be routinely collected). This means that a special effort must be made to obtain this information, most likely surveying the former patients for this one detail. However, the standard records that comprise the data base will, in our suggested record design, allow for a preliminary search to determine the target population for the survey. They will also contain most of the auxiliary information that is required; thus limiting the data collection needs. A very striking example is the case of the clinical trials which were planned to see whether people can voluntarily decrease their risk of heart disease by watching their diet carefully; in particular, whether reduction of cholesterol will have a significant effect on decreasing the risk of heart attack.[2] In attempting to carry out the clinical tests large sample sizes were needed in order to obtain a statistically valid analysis. The initial costs were expected to be 80 million dollars. Due to inflation and unanticipated costs, these trials will cost at least 200 million dollars. A large part of the cost is due to the large population sample that must be taken in order to assure that enough subjects within the sample will develop heart problems during the study period. If we consider the case where we have a large data base, we can choose the target population from out of our data base records and conduct a retrospective study. In this way, the information may be obtained at a much lower cost. Since retrospective studies are never as good as studies which are monitored from the start, another possibility is that the retrospective studies could be used to supplement clinical studies of a smaller scope; the combination of both types of studies will lend to greater validity of results. In addition, the retrospective study can be used to characterize the patient type who is more susceptible to a given type of disease and, in this way, allow for better clinical screening reducing the need for large samples in certain clinical studies. All of these possibilities exist. To what extent they can be implemented with the use of mass data collection depends on the proper planning and layout of the data elements to allow for such usages.

Within recent years the Federal Government has been heavily involved in efforts to standardize data sets based on hospital stay. In 1971, the Department of Health, Education, and Welfare (DHEW) examined the possibility of requiring a uniform set of data on all federally funded discharges from short stay, acute care hospitals. The Uniform Hospital Discharge Data Set (UHDDS)[3,4] was designed as the minimum data set, uniformly defined, capable of providing all users basic and comparable information on all hospital discharges. In 1972, the Uniform Hospital Abstract Form Subcommittee of the U.S. Committee on Vital and Health Statistics recommended the minimum basic data set. Minor modifications of this data set were made in 1974 for use in DHEW programs. The modified UHDDS with definitions is presented in Table III.

TABLE III—Uniform Hospital Discharge Data Set (UHDDS)

Person Identification
Each admission is to be reported by the patient's unique Social Security number.
Date of Birth
Sex
Race
Residence
Hospital Identification
The provider number assigned by the Medicare Program and used by Medicare and Medicaid in the hospital certification process.
Admission Date and Hour
Month, day, year and hour of admission
Discharge Date
Month, day and year of discharge
Attending Physician
This is the physician primarily responsible for the care of the patient from the beginning of this hospital episode.
Operating Physician
This is the physician who performed the principal procedure.
Diagnoses (Principal and Other)
Procedures (Principal and Other)
Disposition of Patient
a. Transferred to another short-term general hospital
b. Discharged or transferred to skilled nursing facility (SNF)
c. Discharged or transferred to an intermediate care facility (ICF)
d. Discharged or transferred to another institution
e. Discharged to home or self-care (routine discharge)
f. Discharged to home under care of an organized home health service.
g. Left against medical advice.
h. Died
Expected Principal Source of Payment
a. Self-pay
b. Workmen's compensation
c. Medicare
d. Medicaid
e. Other Government Payment (e.g., CHAMPUS)
(1) Title V
(2) Other
f. Blue Cross
g. Insurance Company
h. No charge (free, charity, special research, or teaching)

The long range goal is to have all users of the UHDDS, including PSROs (explained in Reference 5), claim payment agencies, State Cooperative Health Statistics Systems, discharge abstract services and planning agencies, receive these data through the use of a standard form and standard tape format. This approach would substantially reduce the data collection efforts within hospitals and provide all users with consistent, compatible data to be combined with data from other sources to meet total data needs.

At the Federal level several agencies have similar data requirements; however, at present there is no method of coordinating and linking these data bases for use by any agency. There is no reason, in principle, that one agency could not collect and disseminate all the required data. However, many different sub-agencies have their own mission and legislatively ordained functions to follow. As a result the entire array of independent requests for data from different agencies arises. The data collected under present conditions will form independent data bases which have a large amount of redundancy, but cannot be used in conjunction with other data bases in any simple manner. Incompatibility of the data files and data bases collected by different agencies will make it very costly to retrieve information with cross-agency applicability. The piecemeal specification of data bases is almost guaranteed to cause enormous duplication effort with resultant products of limited use. At the very least a general systems plan should be formulated to lower costs of collection, storage, software development for analysis and processing cost. Consider, for example, the computerized health resources information system known as the Area Resource File (ARF) which has been developed for the Bureau of Health Resources of DHEW. The County file unit identifier uses the Federal Information Processing Standards (FIPS) code for State and county locations. This sounds like an excellent means for standardization. However, in order to provide for the possibility of analysis of the data according to different ways of grouping counties, the following additional area identifiers are included:

1. State Economic Areas (SEAs) and Economic Subregions
2. Standard Metropolitan Statistical Areas (SMAs)
3. OBE Economic Areas
4. Federal Regions
5. Ranally Major and Minor Areas
6. DMI Place Sizes
7. Comprehensive Health Planning Areas
8. Professional Standards Review Organization Areas

With all of these identifiers only classifications which group whole county units are meaningful. In addition, the ARF is under revision with a contract out to restructure the basic file and add new elements. Among these new elements are further area identifiers such as the DHEW region code. It is easy to see how with time identifiers can keep on proliferating.

SYSTEM DESIGN CONSIDERATIONS

Since we must deal with many uncoordinated ongoing activities, the first requirement is to discover what present data collection and storing is related to health and what is planned for the future. Each of these activities must be evaluated in terms of its own mission and the potential meaningfulness of its interaction with other activities. Some of the factors which must be taken into consideration are:

1. *Collection of Data*
   Quality
   Reliability
   Duplication
   Meaningfulness of relationship to other data collection
   Cost
   Value
   Burden of collection on institutions.
2. *Processing of Data*
   Error checking
   Avoiding redundancy
   Assuring timeliness
   Ensuring availability and transferability
   Analysis of data
   Establishing norms and checking deviations
   Determining policy and operational impact
   Investigating linkage
   Determining level of usage of data

An approach to coordinating and making the collected information accessible through the system structure is by means of a hierarchical catalog. The catalog will contain information on all large data bases which involve interface uniformity. At the peak of the hierarchy are all the most generalized controlling data summaries, which may have a series of underlying data bases to support them. Thus, we might consider a possible chain of data bases each at a more detailed level:

- DHEW
- BQA
- Local PSRO
- Hospital
- Doctor (Patient)

Top level summarized catalog information may also refer to a segment of an independent data base with a different orientation. Thus the budget data of the Office of Management and Budget (OMB) summarizes all Federal funding of medical services. Another example would be analogous to the present computerized Program Review and Evaluation System of the Environmental Protection Agency (EPA). This program compiles in one location information on all monitoring programs operating throughout EPA. The control file can then be used as a starting point to identify and locate any specific monitoring operation. In our case the file would record all environmentally oriented data bases which have a health care impact.

The data base catalog at the top level would contain in its enumeration of data bases such information as the organization or agency and/or person in charge, the descriptors of the file structure, the sub-files (if any) that the data base derives from, the period covered, the area involved, and the major intended use.

At each succeeding level there will be a directory of the major segments into which that level is divided. Each "layer" performs its own set of operations and interfaces with levels above and below. Basic keys in each level allow for interfacing. The keys and links allow full reformulations of the data bases for special purposes, such as merging with another file. By keeping the data structure simple it allows for each creation of a new special purpose data bases with minimal programming. Note, the hierarchical classification and its tree structure refer only to the organization of the data bases themselves and not to the contents of the data bases. Insofar as possible, relational information should reside in the data itself or be explicit. It should not reside in the structure itself, for then two different data bases could not easily be combined.

A review of the present data gathering activities and existing data bases should lead to the definition of an overall system structure. All elements of this conceptual system must then be evaluated in terms of their aims and interactions with other parts of the system. The critique should lead to some degree of redesign with emphasis on factors such as the following:

- All data bases shall possess the flexibility to adapt to new requirements.
- The data base system shall be modular in nature in order to provide for future processing capabilities.
- The software support systems shall be:

(1) high-level language
(2) relatively machine independent

The data should have linkages to allow for the merging of subsets of different data bases. Planning must include flexibility which in the case of the data base means reserving unused pointers for future linked list expansions.

HUMAN INTERFACE WITH SYSTEM

A data base which covers a large segment of the population can give statistically valid answers to questions addressed to the data. For example, in the case of the elderly their insurance by Medicare ensures that most illnesses causing hospitalization will be recorded and reported. To the extent that their illness has been properly diagnosed, encoded and stored in the data base, one can obtain interesting profiles of the relative frequencies of major illnesses of the elderly. This information in turn can be distributed to local health planning agencies and used within the Federal Government to better determine resource allocation. However, these uses, as shown in our general analysis, depend on having responsible people scanning the data and taking action where necessary or passing the information to those responsible to act. There is no way of guaranteeing that proper action (or any action) is taken; however, in the design and description of human interactions which will insure that the large masses of data are reviewed and channeled to the proper agencies for appropriate action.

In terms of the data we wish to achieve compatibility and transferability of the data for use in the different agencies. The larger question we face is how to ensure that appropriate data will be used and shared and acted upon. This depends upon both the system and the people. Responsible and authoritative personnel in key positions can act as control points to spot unusual occurrences and optimize ordinary workflow. However, the fragmentation of the governmental health establishment (DHEW) makes meaningful flow of data difficult.[6] A coordinating and controlling body is therefore vital to support and expedite data transfer activities. In fact, DHEW requires a coordinating mechanism which will allow for review of all the data collecting needs and requirements of its various agencies.

Data input to the information system must reflect the realities affecting the providers of the data, i.e., physicians admissions officers, record librarians, fiscal intermediaries and patients. Requirements or requests for more data may not be relistic unless they bear directly on improving patient care and providing better health services.[6]

Information systems are often designed in the vacuum of the bureaucracy in a manner dictated by logic and efficiency. This approach is acceptable in the technological environment of the business world, but in the humanistic world of medicine, the patient-physician relationship determines and moderates the exchange and availability of various types of health data.

Concomitant with the input of data to the system is user access. Individuals must be able to determine where the data of interest resides within the system, who to go for access and how to use the information obtained. The overriding concern relevant to both input and access is confidentiality of the data—the protection of the physician-patient relationship from the potential abuse inherent in a massive system capable of linking various data sets into single comprehensive records.

As stated, we are dealing with sensitive medical data where human judgment is essential at all steps in the routing and processing of the data. Therefore, the controlling body will have to be supported by a large network of people sensitive to the needs of the medical community. At each point along the way these responsible persons will try to flag vital aspects of the data and bring it to the attention of those who might act upon it. It is essential that the individuals responsible for evaluating data have relevant backgrounds to make such evaluations. For example, as information comes into an organization and is analyzed by some statistical group whose function is to establish, maintain or review medical norms for various sections of the country, one of the people who looks over the work of the group must be familiar enough with norms and medicine so that if an unusual deviation occurs, he will alert the local medical authorities of such a development and appropriate action will be taken. This might be considered to be analogous to the Center for Disease Control's monitoring of potentially epidemic diseases on a national and regional basis. If someone at a higher level notices a long term range increase in the incidence of a given disease, unless he is in the position to initiate action, the data will merely be published in some official bulletin and set to rest in a convenient archive. It is important that throughout the system there are checkpoint people who make sure that when data is important, it is routed, flagged and given high priority; when it is not important they will suggest the removal of data from the system that need not be collected. What this amounts to is that with the planning of the hardware and collection network there also must be planned a software network of people, so that not only is the normal flow of data expedited in the ordinary manner, but action outside of the normal flow can be taken.

SUMMARY AND CONCLUSION

Once established, the system could provide health planners, epidemiologists and other researchers with the means to undertake studies of a type and magnitude not heretofore possible. For example, PSRO activities will result in the establishment of a national data base containing unit record discharge data on all Federal discharges from short term acute care hospitals across the nation. The ability to link this health data geographically with data contained in the Environmental Protection Agency and Department of Labor or other Federal data bases on industrial pollutant levels would allow epidemiological studies of the relationship of pollutants to hospitalization, disease etiology, frequency of surgical procedures, etc.

Linkage of hospital utilization data with the geographically coded Area Resource File data bases containing facility and manpower data could provide information over time on trends in manpower and facility availability relative to hospital utilization; providing health planners with the means to predict the need of any given area in the country and make appropriate recommendations for future facility construction and health manpower allocation.

Once established with the Federal health system, the utilization of an information system capable of linking data from many sources is limitless. However, the system is only as good as the people running it. It is essential that all along the flow of data through the system that human checkpoints be established to monitor and appropriately act upon the output of the system.

Data base processor technology

by DONALD R. ANDERSON
Sperry Univac Defense Systems Division
St. Paul, Minnesota

ABSTRACT

The ability to achieve significant amounts of mass memory has not been matched with a capability for processing data stored within the mass memory. The concept of a dedicated data base processor that would implement microprogrammed data base primitives with high speed microprocessor technology appears to be a plausible means of obtaining higher performance data base processing systems. The premise of this concept is that simple operations that manipulate data base information can be included in a separate, simply structured processor that operates in parallel with the central system. In doing so, parallel execution benefits are realized that could lead to higher system performance levels.

The technology that supports the dedicated data base processor concept, system architectural considerations, the application of the concept to both distributed and centralized systems, and areas of needed research are described in this paper.

INTRODUCTION

Memory technology developments are providing an increasing number of alternatives for achieving significantly large amounts of system storage at differing levels of performance and cost. These alternatives presume conventional system architectures which are not optimized to permit higher performance levels based upon the parallel processing that is felt to be inherent to data base processing problems. Newer memory devices, Charge Coupled Devices (CCD) and Bubble memory, are taking their places along with improved disk capabilities and the newer cartridge units to provide for storage of 10^9 bits or better but these memory technologies seem deficient in that while they extend the system mass memory capacity, they do not provide additional system processing ability.

This paper describes the concept of a Data Base Processor (DBP) which specializes data base processing functions within a processor that is closely associated with mass memory. These processing functions are normally time-shared on the central processors with other user functions. The data base processing concept recognizes that a system containing significant mass memory has a dominant part of its resources expended toward processing mass memory data and that specializing data base processing functions in a separate and independent processor could yield substantially improved system performance.

THE DBP CONCEPT

There are many data processing applications where the data processing system is designed to process information stored on mass storage devices in the form of a regularly structured data base. These applications differ from command/control or process control in that significant amounts of data move to/from mass storage devices in the normal processes that occur during system operations. Data base systems also have less stringent real-time (i.e., second versus millisecond response times) requirements than the process control or command/control systems.

In applications where data base operations predominate it appears reasonable and profitable to consider an alternative to conventional system architecture to provide more balance between lower-level mass memory access/processing operations and data base information manipulations to achieve higher system performance. The DBP architectural concept is to move a subset of the overall data base processing away from central processing facilities into a processor that is intimately associated with the mass memory upon which the data base is stored (Figure 1) and which has only high-level function characteristics (instructions) for data base processing. In effect, a parallel processing architecture is created in which memory access/processing operations are performed in parallel with central processing operations.

The advantage of the DBP architectural concept can be illustrated by considering the processing of rèlational data base information. In a conventional architecture, relation content processing is performed by the central processor and intuitively, there are instances where the entire relation content is not needed, especially where decisionary processes that select or reject data are involved (as in the case of linked files). The access to, movement of, and subsequent examination of the relation content represent unnecessary sys-

MASS MEMORY
CONVENTIONAL ARCHITECTURE
VS
DISTRIBUTED DATA BASE PROCESSING

Figure 1—Distributed data base processing concept

tem overhead if the end-object desired is not in the relation accessed. A data base query, for example, that builds a list of all employees who are female would require, in a conventional architecture, the movement of an entire relation content into the central processor even though only part of the relation is needed in order to establish the desired list. Contrastingly, in the postulated DBP architecture concept where the processing of the relation content occurs away from the central processor, the only information that is provided to the central processor is that which is the result of processing the relation data. This reduces central processor loading allowing more central processor time for further processing of the file information.

Linked files are another example where the DBP architecture concept would provide higher performance. With linked files the desired information is accessed through a series of files each of which contains information that, in effect, points to or links to succeeding information. Ultimately the decision process links to the end-object desired. In a conventional architecture each succeeding file must be moved into the central processor for examination, which requires physical movement of the file into the central processor, synchronization with concurrently executing tasks, binding the data to the process which examines the file data, and then initiating access to the succeeding file should one be desired. With the DBP architecture concept, most of this could be eliminated by performing the search and decision process within the DBP.

Conceptually, the DBP is a semi-independent, simply structured, special-purpose processing unit that operates under high-level control of the central processor. The DBP can be interconnected with a central processor in any of several ways discussed later and is interfaced with mass memory as dictated by the mass memory interface characteristics. The DBP contains data base processing primitives to which it is directed by the central system. When executing its own program, the DBP operates independently of the central system, accessing and using mass memory facilities as directed by its internal program. The DBP contains its own independent buffering facilities for holding data base information to be processed and is programmed as a special-purpose microprogrammed processor with separate microprograms implementing high level processing functions.

DBP TECHNOLOGY FACTORS

There are four technology factors which support specializing data base processing functions: Distributed Processing, Data Base Languages, Microprocessors, and Mass Memory Technology. Each of these factors contributes to the overall concept, but none completely provides a total solution. When supplemented with additional research, however, these factors indicate feasibility of the DBP concept.

Distributed processing

Functionally distributed processing principles seem applicable to the DBP concept. Microprogrammed data base processing functions are separate and independent processes executing in specialized processing facilities[1] (i.e., functional distribution).

Data base languages

High level data base processing languages form a uniform and consistent method of expression through which data base processing problems are solved. The syntax and semantics of these languages incorporate subprocesses which, when partitioned, resemble primitive functions that could exist as microprogammed processes in a data base processor.

Microprocessors

Economical integrated processing logic is available at very attractive performance levels.[2] Many special purpose functions can be implemented with significantly improved execution times.[3]

Mass memory technology

Through magnetics, CCD,[4] and Bubble[5] memory, mass memories of greater than 10^{11} bits may be built. An intelligent memory which would combine on-chip processing with semiconductor logic would extend to the data base processor concept.

SYSTEM ARCHITECTURE CONSIDERATIONS

Distributed and centralized systems

The data base processing concept applies to both distributed and centralized processing systems. The implementation may differ with the architecture into which it is merged, however, the basic principles of the idea remain unchanged. A distributed system is a system of independent computers interconnected with a mechanism for information transfer between the independent computers which may be a packet switched communications network or a specialized ring structure.[6,7] A centralized system is a conventional unit computer or multiprocessor system whose cental processor facilities are not physically dispersed. Remote terminals may be located away from the central processor in a centralized system.

The architecture principles of the data base processing concept that apply to both distributed and centralized systems are the at-location processing of data base information which lessens the central processor overhead and the implementation of a system-parallel data base processing capability. In a network distributed system, communications loading would also be lessened.

In distributed systems where the communications network utilizes common carrier lines (50 kb/sec line interconnections, for example) the DBP could interface with a central processor which would provide it with the high level commands (Figure 2). The central processor in this instance provides the necessary interfaces with the network protocol, the translation of requests from users into DBP commands, the translation of DBP responses into network format, and the return of the network formatted data to the user. In instances where the interconnecting network is a special or dedicated structure (Figure 3) or where it is desirable that the DBP directly interface with the network, the DBP would interpret protocols and multi-user data base inquiries in addition to the retrieval and manipulation of the data base information.

Memory hierarchies

The practical achievement of a significant mass memory is governed by economics. The most plausible and practical way of implementing a mass memory today is through a combination of technologies which implies a hierarchy of mass memory storage and the ability to control the movement of information between hierarchy levels.[8] The DBP, if it is assumed to be used with a hierarchical mass memory system, must provide for information movement between various levels of the hierarchy and for handling interfaces unique to the different mass memory devices used.

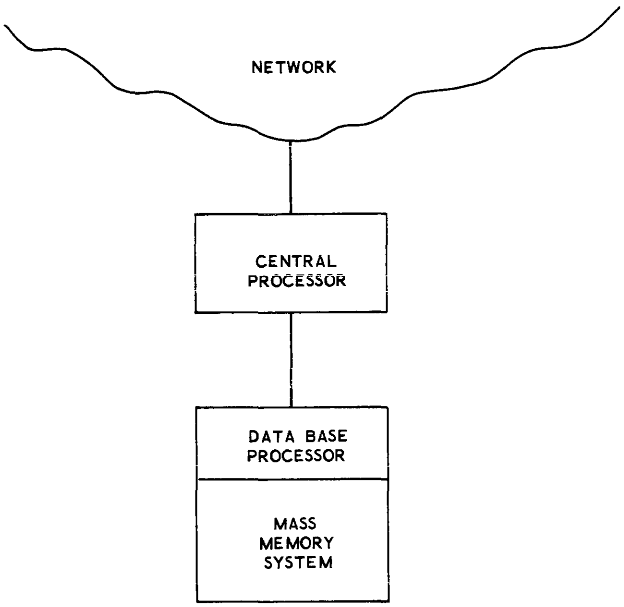

Figure 2—DBP network interconnection through host

DBP-hardware interfaces

The general architecture design of the DBP must accommodate three classes of hardware interfaces—network, central processor, and mass memory—in order to be applicable to a wide variety of system architectures. In the network system, when the DBP assumes

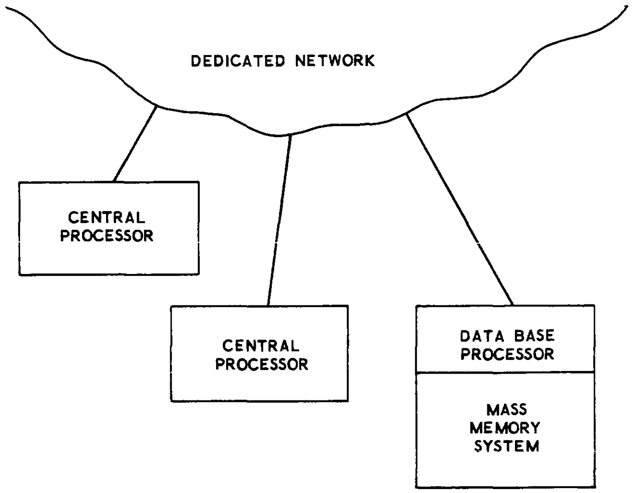

Figure 3—Direct DBP network interconnection

a host-equivalent role it must also assume the interface responsibilities that a host assumes. This includes physical hardware interfaces (serial, parallel, rates, coding format, control signals) and the ability to act as a receptor/transmitter and interpreter of message control (protocol) information. The network interface problem appears to dictate a multi-form network interface module that can be used for interfacing with either special purpose interconnects or general purpose networks. Different versions of this module would provide a standard internal DBP interface.

Two classes of central processor interfaces are needed in the DBP architecture: I/O channel and DMA. The I/O channel interface seems to be the most important considering the general philosophy of the DBP architectural concept. However, a DMA capability coupled with suitable memory protection could provide a means of common memory communication between the DBP processes and the general data management processes which are performed by the central processor. The I/O channel interface should be capable of handling multiple users, either as a multiplexed single channel, or as separate physical I/O channels multiplexed internally within the DBP. The DMA interface with the central processor should incorporate memory protection controlled by the central processor. This is especially needed when virtual environments are provided by the central processor.

Future mass memory technologies that can be expected to be used with the DBP are block organized; discs, MNOS BORAM, CCD and Bubble memory devices, magnetic tapes, magnetic cartridges, etc. The DBP architecture must be able to accommodate, through interface modules, different mass memory interfaces. In the case of some mass memory technology, disc technology in particular, the interface module could be identical to the central processor interface module. Support of the mass memory interface through microprogramming appears to be a requirement.

DBP ARCHITECTURE REQUIREMENTS

The DBP system requirements form a general bound for the DBP design. In a sense, the DBP extends data base management to a parallel processing environment in which one of the processors is specialized for independently processing data base information.

Modular structure

The DBP should be organized in modular fashion (Figure 4) in order to accommodate different interfaces and be usable in different system architectures.

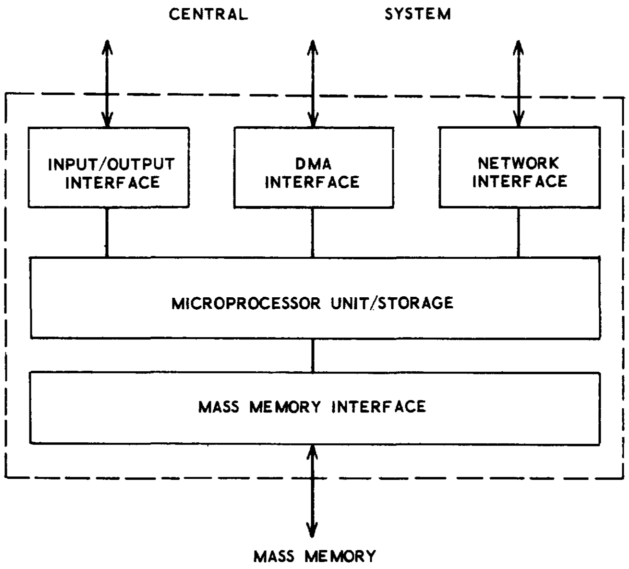

Figure 4—DBP modular structure

Primitives

The DBP shall implement microprogrammed primitive functions that can be used by the operating system or data management system for processing of file data concurrent with central system operations.

DBP-internal processing

The DBP shall be capable of independently processing data stored on mass memory or in its own internal memory.

Multi-operation processing

The DBP shall be capable of performing a limited number of operations concurrently to permit efficient usage of the DBP where interfaced with mass memory with significant latency times.

Memory hierarchy

The DBP shall contain the necessary interfaces and control programs to support a mass memory hierarchy and to transfer information between hierarchy levels.

Rate/format matching

The DBP shall provide the buffering/processing required to match mass memory intrinsic speeds and formats to central system transfer capacities and formats.

MAJOR DBP ELEMENTS

The DBP system architectural concept uses specialized, independent microprocessing logic to perform data base processing operations. The elements needed to implement the DBP modular structure are described in preliminary fashion to indicate hardware technology that could be used.

Processing element

The DBP processing element will be a 16-bit, high speed (200 ns cycle time), microprogrammed unit with separate micromemory and buffer storage. Internally the processing element will be an asynchronous bussed structure.

Buffer storage

The DBP will have a word organized, high speed buffer memory (4,096 words) for command storage, intermediate storage of file data, and rate matching between mass memory and central system interfaces.

Input/output interfaces

The DBP will have both byte and word parallel I/O interface modules capable of multiplexed and nonmultiplexed operations.

Mass memory interfaces

The DBP will support wide word (in excess of the DBP internal word width), narrow word (less than DBP internal word width), and serial mass memory interfaces.

DISTRIBUTED DATA BASE SOFTWARE DESIGN

Implementation of the DBP concept requires rethinking of the major system software elements. The DBP concept is intended to relieve conventional system processors of their workload and in doing so, modifications of existing software structure must be anticipated. At this time, three software-related problem areas have been identified. These are the modified operating system software structure, the definition and design of microprogrammed primitives, and user control of the primitive operations.

Operating system software/DBP interfaces

A simplified diagram of a conventionl data base management software structure is shown in Figure 5. Conventionally, the operating system interfaces directly with secondary storage on which the data base is stored to move data between the secondary storage and the system buffer allocated in the computer main memory. User programs and the Data Base Management System do not interface with secondary storage but with the system buffers.

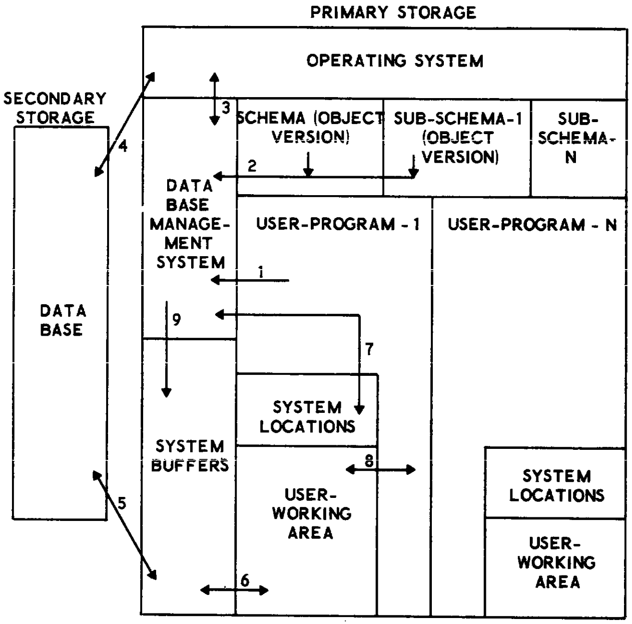

Figure 5—Conventional DBM software structure

Incorporation of processing capabilities within the secondary storage poses questions of which software elements should directly relate with and access the data base. The existence of processing primitives at the data base in effect causes the user program to transcend the primary store-secondary store interface; i.e., the execution of a user program takes place in two places with possibly intervening software elements that do not necessarily permit direct communication between concurrently executing parts. The enumerated paths provide a depiction of the operations which transpire in the conventional software structure:

"1" a call for data by the user program
"2" DBMS supplements the call arguments with schema information
"3" DBMS requests I/O operations from the Operating System (OS)
"4" The OS interacts with secondary storage
"5" The OS transfers data between secondary storage and system buffers
"6" DBMS transfers data between system buffers and the program working area
"7" DBMS provides status information to the calling program
"8" Data in program's working area manipulated as required using host language
"9" DBMS administers the system buffers

Primitives implemented in a data base processor would modify the DBM software structure (Figure 6). In this proposed structure, operations would:

"1" a call for process execution by the user pro-

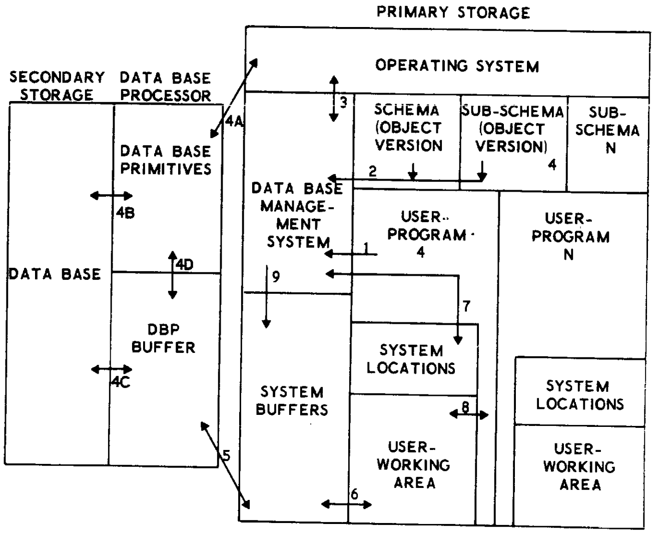

Figure 6—Modified DBM software structure

gram. This extends the original structure concept by including the capability of the user program to request a process to be executed and relying on the DBMS to formulate and control the requested process. Previously this was limited to a call for *data* which eventually was manipulated by the user program.

“2” DBMS supplements the call arguments with schema information.

“3” DBMS requests I/O operations from the Operating System (OS). In this operation, modifications may have to be made to expand the I/O function to include a differentiation between DBP function commands to be sent to the DBP (or status information requested from the DBP) and normal buffered data transfers.

“4A” The OS interacts with the DBP. The DBP acts as the OS/DBMS agent to perform, through execution of primitives, the operation requested.

“4B” The DBP interacts with the secondary storage to perform, in association with its internal storage, the operation requested.

“4C” The data base information is transferred from secondary storage to the DBP buffer for processing and returned to secondary storage should it be required.

“4D” The DBP accesses its internal storage in operating on the data base information.

“5” The OS transfers data between the DBP Buffer and the System Buffer. To the OS no change should be apparent during this step. The secondary store/DBP would appear as a buffered secondary storage system.

“6”–“9” No major changes apparent in these operations.

The DBMS, rather than the OS, software design would be impacted the most by inclusion of DBP primitives. These impacts would center heavily on including capabilities to operate a concurrently executing process in parallel with user program execution. The overall DBMS control strategy and methods definitely require further research.

Definition of microprogrammed primitives

The intent of the DBP is to provide improved system performance through the use of microprogrammed primitives. The definition of the primitive operations to be performed is difficult. User program needs, DBMS needs, and the practical capabilities that can be incorporated into hardware all impact the primitive function definition. Considerations in defining the primitive function set include:

General purpose vs special purpose

A truly general purpose set of primitives that benefit all possible user programs is probably unattainable given realistic development resources. A totally special purpose primitive function capability, on the other hand, would create an unnecessary burden on many users because they would be required to develop, or modify for use, the basic operations needed to interface with secondary storage. The eventual solution would appear to be a compromise between these extremes implementing a selected set of general purpose primitives that would be useful in many user applications and supplementing that general purpose set with a user capability for creating special purpose functions that are of immediate and direct benefit.

Dynamic vs static primitive function sets

Dynamically changing machine instructions (primitives) that make multiple usage of the same logical operation codes create system state management difficulties. Dynamic primitive function sets are desirable in processing environments that presumably service many different users. Environments which tend to be application-static do not appear to require dynamic function sets.

Direct HOL vs machine level operations

Direct implementation of DML (or other data base languages) elements through microprogramming represents an approach to the design of the primitive function set. At the other extreme, the primitive function set could be defined to encompass the functionality of conventional machine instructions. The necessary properties of the primitive function set seem to be to provide the user the freedoms of high level code, but also allow him, at some time during the system development and design process, machine level specification of the primitive processes.

Data base management vs file processing

Data Base Management is the organization and management of the system of information rather than the manipulating and processing of data base information subsets (File processing). User programs are most probably concerned with the latter, whereas the Data Base Management System is concerned with the former. Neither should be neglected in the definition of the primitive function set. The DBMS, in managing large data bases with a significant number of uniquely identified information elements, encounters difficulties analogous to the difficulties encountered by user programs, namely movement of files between mass storage and primary storage, processing of those files, etc.

Mixed language primitives

A choice exists between defining primitives which are total process entities (i.e., single user statement, single process) and defining user-apparent primitives that are a mixture of interpreted language statements and microprogrammed processes. The mixed-language primitive approach supports standardized primitives but still retains primitive customization capabilities.

Standardized relations

Standard file manipulation relations have been defined for file processing. These include cartesian product, union, intersection, projection, diadic restriction, monodic restriction, join, composition, permutation, computation, difference, inversion, and ordering and are representative of standardized functions that would form the basis of a primitive function set. Other standardized relations for moving data between hierarchies should also be considered.

User control of primitive operations

There are two kinds of users of the DBP. One is the application user represented by the user programs in the machine. The other is the systems programmer who is represented by the DBMS/OS software. DBP primitives should support both users. How these users control data base processing operations through primitives depends to a large extent on the kind of computer system operating environment they are operating in. In very specialized systems where the applications code and the system software are part of an integrated design, it is possible to have application user programs directly command and sequence primitive operations. In general purpose systems where predesigned operating systems and data base management software exist, control responsibilities would probably be relinquished to the DBMS. The specific choice of how the user controls primitives remains a function of the operating environment.

A common problem that will be encountered by both kinds of users will be the control of parallel execution. The DBP, as an independent processor, represents a specialized computation resource which can operate in parallel with other processors. Computation results from the DBP must be merged with program main stream which requires that methods of controlling parallel processes be established. To some extent these methods have been researched for multiprocessors. At the applications user level, however, DML languages have as yet no provision for invoking, staticizing, or merging parallel processes. At the system user level, the DBMS will require modifications such that utilization of a parallel processing capability is possible.

SUMMARY

The DBP concept has been depicted as a promising architectural approach for building higher performance data base processing systems. Intuition indicates, however, that higher performance will not be attainable without expending effort in system research. Research is recommended in areas of DBMS, OS, and system organization to define strategy, functional design, and to evaluate primitives:

Strategy analysis

The fundamental objective of the DBP architecture is higher performance in the processing of data base information. Key to the attainment of this objective is the apportionment of data base processing functions between hardware (the DBP) and software (DBM/OS). Apportionment decisions are most appropriately based upon well defined system strategies formulated knowing the performance impacts of different strategy alternatives. Conventional system strategy and organization can be expected to be modified but intensive examination of the modified strategy is needed in order to make apportionment decisions. Available technology will impact apportionment decisions.

Functional design

Once apportionment decisions have been made, the functional design of a DBP should be investigated. In this design, DBP interfaces, architecture, technology, and primitive functions require specification in concert with the specification of the functional interfaces with the companion central system. Use of primitives and identification of modified central system software and hardware require description.

Environmental primitive evaluation

Primitives, once defined, require evaluation for performance and functional capability. Laboratory implementation of primitives with a modified current system seem relevant to establish practicality and to provide a first approximation to attainable performance.

Integrity aspects of a shared data base

by EDUARDO B. FERNANDEZ and RITA C. SUMMERS
IBM Los Angeles Scientific Center
Los Angeles, California

ABSTRACT

A simple model is formulated to represent integrity constraints and to describe the evaluation and enforcement of these constraints in a shared data base environment. The proposed model is applied to define the integrity facilities of a relational data base. This data base consists of a set of base relations, which are presented to the user through application-oriented views. These views are basically joins or projections of the base relations, and the data base is accessed through a language which by referring to predefined views, makes explicit the intentions of application programs. The types of integrity rules incorporated in this system, their description, their evaluation, and the propagation of changes to views into the shared data base, are discussed.

INTRODUCTION

Information protection, i.e., the prevention of illegal disclosure, modification, or destruction, and of invalid modification, of the contents of the data base, is one of the most critical problems of data base systems. For this effect, the data base should include an *authorization system* to prevent illegal access to the information, and an *integrity system* to prevent some types of inconsistencies, introduced by errors of the users or their application programs. By enforcing semantic restrictions on the information, it is possible to insure that the contents of the data base are at least plausible, if not correct, and that no inconsistencies exist between related information.

An integrity system for a data base consists of a set of *assertions* about the contents of the data base (expressed in some suitable language), a *validation mechanism* that checks changes to the data base for compliance with the integrity assertions, and an *enforcement mechanism* that performs some predefined actions upon detecting that one or more of the integrity assertions have been violated. In those systems where users have access to a shared data base through views,[3,17] the integrity system should also contain specifications about how changes are reflected to the shared data.[13]

Typical integrity assertions are statements such as: "Salaries must be positive." "Salaries must be nondecreasing," "Student numbers must be present in enrollment lists." Present commercial systems have only basic capabilities to define and enforce these types of statements,[9] and more advanced integrity checking is left to the application programs. In large shared data bases, it is clear that preserving integrity should be a system function, not left to the individual applications.

A model for the functions of an integrity system is presented in this paper (second section), which describes the structure of the integrity constraints, their evaluation, and their enforcement. This model is applied in the following sections to define an integrity system for a shared relational data base described in previous papers.[11,18] The third section contains a brief description of this data base, the type of integrity assertions included in it, the association of these assertions with data objects, the way of describing the assertions, and their evaluation. The use of compile-time actions to prepare integrity checking, and the effect of changes to the data base through views, are considered. The fourth section compares this approach to other proposals, while a final section provides some conclusions.

A MODEL FOR INTEGRITY

A simple model for integrity is now presented, which can accommodate most of the features found in recent discussions of integrity characteristics.[4,9,10,12,13,17] It is described in terms of a relational model of data,[5] and it is used to guide the selection of integrity features for a relational data base. However, a substantial part of the subsequent development could be applied to other logical models of data as well.

Integrity rules

An *integrity rule* is the 5-tuple (o_l,t_k,p_q,c_n,e_m), where o_l is the *data object* to which the rule applies, t_k is an *access type* which indicates for what type of data base access the rule will be invoked, p_q is an *assertion* stating a semantic constraint which must be true for an occurrence of the object o_l, c_n is a predicate expressing a *condition* which must be true in order for p_q to apply to o_l, and e_m is an *enforcement type* that specifies the action that will be taken by the system if p_q is not true.

For specific systems it may be convenient not to separate the five components of the rules; for example t_k and c_n could be combined to specify a condition for application of p_q, or c_n could be part of p_q.[10,17] Also, in most cases the t_k's are a small and predefined set, and the specification for t_k need not be explicit. However, it is important for conceptual clarity in the design of the integrity system, to separate these components as independent units.

As an illustration let us consider a student data base where record type or relation STUDENT contains the fields NAME, ADDRESS, COURSE, and GRADE. An integrity rule for object STUDENT. GRADE could contain an assertion p_q such as "Grades must be 'A' or 'B' or 'C' or 'D' or 'F'." This assertion would be enforced whenever some access actions involving field GRADE, specified by t_k, are performed; for example if t_k indicates "update, insert," then validation of new values for field GRADE will be performed. However, if a condition c_n is specified, for example: "When COURSE$\neq$'123A'," the validation test will only be applied for those tuples where the COURSE field value is not '123A'. An enforcement type specification could indicate "log and record invalid tuple(s) in INVALID," indicating that on violation of the assertion the name of the program, time of day, etc., will be logged and the tuple or tuples not satisfying the assertion will be stored in a special table called INVALID.

In a system containing many interobject constraints, each of them involving several objects, a more convenient definition for an integrity rule would replace object o_l by a set of objects to which the assertion applies. However, most of the interobject constraints found in practical systems involve only two data objects, such as "Enrolled students must be registered students." In this case, it suffices with splitting the constraint into two constraints of the form indicated earlier, and associating each constraint with each object. In the example, we obtain two assertions: "The set of enrolled students is included in the set of registered students," associated with object "enrolled students," and "The set of registered students includes the set of enrolled students," associated with object "registered students."

In a relational system the objects o_l are either domains or relations. In those data base systems which do not have domains as separate entities,[18] domain constraints are replaced by constraints associated with *field types*, where a field type is a prototype for fields that carries a set of attributes that apply to all the fields based on the corresponding type. The integrity constraints associated with a given type apply similarly to all the fields based on the type. Relation constraints include interrelation between fields or constraints that apply to specific fields in the relation.

There is sometimes a rather fine line between an integrity rule and an access rule. An access rule was described in References 11 and 19 as a tuple (S_i,o_l,t_k,p_q,e_m), where S_i is a subject or requesting entity, and all the other terms are the same as in integrity rules but with a different interpretation. There, o_l is the object accessible to S_i; the type of access authorized to S_l for o_l is given by t_k, and it is only granted if predicated p_q is true. Finally, e_m specifies an action to be performed by the system if an illegal access is attempted. As either access or integrity rules include predicates, application of an integrity rule can depend on the identity of the user, and an access rule can depend on data values. However, access can be decided in some cases by looking only at the names of the requested objects, while integrity control depends always on the contents of the objects involved. Further, the access types t_k specified in an integrity rule always refer to access that modifies the data base, while access control refers to any type of access, including just inspection of the contents of some data unit. Notice also that access rules do not include conditions for their application, but every access must be validated by the system.

Validation of integrity rules

Integrity assertions can be classified into a few basic categories[9,19,13] which correspond to specifications of range, sets of permitted values, format, uniqueness of some value, non-missing values for a field, new vs. old values (transition assertions in Reference 10), and interfield assertions. Validity tests for these categories can be symbolically described as follows.

(a) Update validity test.

Let v be a new value for a field f_i, corresponding to domain or type F_h, which is part of relation R_j. Then, the validity condition is

$$\begin{aligned} &\text{is-valid } (v,f_i,R_j) \rightleftarrows \\ &\qquad \text{for } P=\{p_q \mid (o_l=F_h \vee R_j) \wedge (t_k=\text{`update'}) \\ &\qquad\qquad \wedge (c_n=\text{`true'})\}, \\ &\qquad\qquad P(v)=\text{`true'}. \end{aligned}$$

This test establishes that all the predicates of the integrity rules that apply to object o_l and for which their condition predicates are true must be satisfied, in order for the new tuple including the changed value v to be acceptable. The object o_l is taken to be either the field type for f_i or the relation including f_i, since either of these can contain assertions relevant to f_i.

(b) Insertion/deletion validity test.

Let $(v_1,v_2,\ldots,v_z)$ be a tuple to be inserted into or to be deleted from relation R_j, and that specifies values for fields $f_1, f_2, \ldots f_z$, respectively, corresponding to domains $F_1, F_2, \ldots, F_z$, respectively.

Now the validity condition is

$$\begin{aligned}&\text{is-valid } ((v_1, v_2, \ldots, v_z), (f_1, f_2, \ldots, f_z), R_j) \rightleftharpoons \\ &\quad \text{for } P_i = \{p_q \mid (o_l = F_i \vee R_j) \wedge (t_k = \text{'insert' (delete)}) \\ &\qquad\qquad\qquad\qquad \wedge (c_n = \text{'true'})\} \\ &\qquad\qquad\qquad\quad P_i(v_i) = \text{'true'},\ 1 \leq i \leq k.\end{aligned}$$

These validation tests assume that the assertions are associated with all the relevant fields. For example an assertion "Field f_1 must be a subset of field f_2" would also imply the assertion "f_2 includes f_1".

When users have access to the shared data base through application-oriented views,[3,17,18] it is necessary to have special *reflection rules* which specify how changes to the views are reflected to the shared data base. The resultant tuples, which are tuples of the base relations, must then be validated as above.

A reflection rule has the general structure (v_i, o_l, t_k), where v_i is the view to which the rule applies, o_l is a data object, and t_k an access type (which for fields can be 'null' or 'update', and for relations can be 'null', 'insert', or 'delete'). A rule of this type specifies that for view v_i, a change of type t_k to object o_l in the view results in a corresponding change on o_l in the shared data base.

The following example illustrates the reflection rule mechanism. Let $v_1(f_1, f_2, f_3, f_4, f_5)$ be a view including fields $f_1, \ldots, f_5$, and formed by the join of relations R_1, R_2, and R_3, such that $f_1, f_2 \in R_1$, $f_2, f_3 \in R_2$, $f_3, f_4, f_5 \in R_3$ (that is, f_2 and f_3 are the joining fields). Let the following reflection rules be defined $(v_1, f_1, \text{update})$, $(v_1, f_3, \text{update})$, $(v_1, f_4, \text{update})$, $(v_1, R_1, \text{insert})$, $(v_1, R_3, \text{insert})$. Updates through v_1 are then reflected as follows: update f_1 in R_1, update f_3 in R_2 and R_3, update f_4 in R_3. Integrity constraints referring to the fields of the base relations can now be applied. Insertions through v_1 are reflected as: insert tuple in R_1, insert tuple in R_3 (subject to any integrity constraints affecting R_1 and R_3). Notice that if we had an additional reflection rule such as $(v_1, f_2, \text{update})$, then updates to both f_1 and f_2 are effectively insertions into R_1 and must be reflected as such. Also if the views are formed with projections of some of the relations, then some of the reflected tuples will have unspecified fields, and may thus violate integrity constraints that prescribe specified values for given fields.

FUNCTIONAL SPECIFICATIONS FOR AN INTEGRITY SYSTEM FOR A SHARED DATA BASE

The model of the previous section includes most of the features which are of importance in a practical system. It is used in this section to define an integrity system for a shared data base proposed in previous papers,[11,18] The data description language[19] is used to present the functional capabilities of the system. A mechanism to support these functions is given in the fourth section of this paper.

The data base system

This data base consists of a set of base relations (or *Data Base Structures*), which are presented to the end users through application-oriented views. These views, or *templates*, are basically joins and/or projections of the base relations, constructed for specific purposes. The data base is accessed through an extended high-level language, which, by referring to predefined templates, allows the user programs to manipulate data base elements as any other program variable. The organization of this data base lends itself very well to apply to it an authorization model,[11] which, due to the fact that the extended language makes program data intentions manifest, can be enforced partially at compile time. Even those access decisions which are data-dependent and cannot be enforced at compile time can be prepared at this time, thus decreasing validation overhead at execution time.

The model of data described in Reference 18 uses four kinds of data objects: templates, data base structures, fields, and types. (The term *type* replaces the term *field type* used in earlier papers.) The DB structures constitute the shared system view of the data base, and they are composed of one or more fields. Types, which carry attributes, serve as prototypes for fields. A template is an aggregate (typically a join) of DB structures that is constructed for a specific purpose. A template includes a *defining expression*, which indicates which DB structures participate in its construction and how they are combined. An application program views the data base as a set of templates. The terms DB structure and template will be used in two senses: as structural entities or definitions, and as sets of occurrences of those entities.

Four basic roles for users are contemplated in this system—data base administrators (DBA) define and maintain the shared DB structures and their integrity and authorization rules; data base designers build templates to perform specific functions; application programmers use the predefined templates to write application programs; application users invoke their authorized programs to perform specific actions on the data base.

A data description language for this data base has been proposed in Reference 19, where its functions, use, and syntax are presented in some detail. As its syntax is simple and almost self-explanatory we shall use this language in our examples without further explanations. We are not concerned here with syntactical details and the use of this language is purely to illustrate the functional capabilities of the system.

Integrity rules

Integrity rules can be associated with both types and DB structures. They can be given as part of the object declaration or as independent rules. A rule associated with a type automatically applies to all fields based on that type. The goal is to simplify the descriptive tasks—if a rule is specified for a type, it need not be written for all the fields based on that type. DB-structure rules, enhanced by the relevant type rules, are the basic integrity rules for the shared data base. In addition, the template's defining expression provides criteria for new occurrences created through that template.

An integrity rule can contain references to either built-in functions or procedures provided by an installation. These latter are data base procedures in the sense of the CODASYL DDL report,[4] or formulary procedures,[16] and should be carefully certified. Data base procedures also play a role in the enforcement of integrity and security. Both integrity rules and access rules include an enforcement type, which specifies the name of another system object called an *action*. Some action names are built-in (for example LOG, NOTIFY_SECURITY_OFFICER); other actions are defined by ACTION declarations, which can specify procedure names.

The following are examples of type declarations including integrity assertions:

```
DECLARE EMPNO TYPE WHERE (*>10000 &
*<100000); DECLARE STATUS_CODE TYPE
     FIXED BINARY WHERE (*<100);
```

The declarations for EMPNO and STATUS_CODE specify ranges of admissible values. (The asterisk is used in place of the type or component name.)

The declaration of a DB structure specifies the fields of the structure (by reference to types) and integrity rules. The following are examples of DB-structure declarations:

```
DECLARE 1 SUPPLIER DBSTRUCTURE
  WHERE(NUMBER¬=MISSING),
  2 NUMBER LIKE SUPPLIER_NUMBER,
  2 NAME LIKE BUSINESS_NAME,
  2 STATUS LIKE STATUS_CODE,
  2 CITY;

DECLARE 1 PART DBSTRUCTURE WHERE
(NUMBER¬=MISSING),
  2 NUMBER LIKE PART_NUMBER,
  2 NAME,
  2 COLOR,
  2 WEIGHT;

DECLARE 1 SP DBSTRUCTURE,
  2 SPKEY,
    3 S_NO LIKE SUPPLIER_NUMBER,
    3 P_NO LIKE PART_NUMBER
  2 QUANTITY;
```

SUPPLIER is a DB structure with four fields. The value of SUPPLIER. NUMBER is required; that is, it cannot be undefined (denoted by MISSING in this particular syntax). LIKE indicates correspondence between fields and types, i.e., NUMBER must obey the integrity rules of the type SUPPLIER_NUMBER, CITY of the CITY type, etc. Uniqueness requirements, and integrity rules that involve DB structures other than the object of the rule, are discussed in the fourth section of this paper.

The previous examples expressed integrity assertions as part of the object's declaration. If there is more than one rule for an object, if the rule is complex, or if more dynamic integrity assertions are required, separate statements can be used. The following rule, for example, states that an attempt to set STUDENT NAME to MISSING causes the entire occurrence of STUDENT to be deleted. DELETE is a built-in action.

```
STUDENT IS CONSISTENT WHERE(NAME¬=
        MISSING) ENFORCE(DELETE);
```

The following rule states the requirement of no A's in a specific course:

```
ENROLLMENT IS CONSISTENT WHERE
   (GRADE¬='A') ENFORCE(LOG)
      WHEN(CN='CS123A');
```

The WHEN expression is evaluated first and determines if the WHERE expression is to be evaluated. Unqualified names on the left side of comparisons in the expressions are implicitly qualified by the object name. Reference is to the new value of the occurrence, unless the old value is explicitly specified, as in

```
WHERE(COUNT>OLDVALUE(COUNT))
```

Integrity expressions may be specified in three ways: WHERE, WHERE SOME, and WHERE NONE. The meaning of each form is given in a later section. SOME can be used, for example, to express the requirement that CITY must be an element of CITYVAL, as in

```
CITY IS CONSISTENT WHERE SOME
       (CITY=CITYVAL);
```

To require that PART.NAME be unique, we write,

```
PART IS CONSISTENT
  WHERE NONE(NAME=OLDVALUE
  (NAME));
```

However, this last constraint is awkward, and could be simplified by introducing the concept of uniqueness in the DDL (see for example Reference 10).

Actions

The concept of an *action* provides a generalized way of making events contingent on the state of the data base system. Logging, report generation and various periodic activities are declared as actions. Logging of data accesses is a valuable security tool if the content of the log can be dynamically controlled and if access to the log itself is also controlled. (We refer here to selective logging as opposed to complete journalling that is done for recovery purposes.) Actions also provide a way to start and stop the gathering of statistics or performance measurements.

An action is specified as either (1) a procedure invocation, or (2) combinations of other actions, declared or built-in. It can have initiating conditions specified in the form of a WHEN expression, or can be initiated as enforcement of an access or integrity rule. Built-in actions execute with the rights of the system. Administrator-defined actions execute with the rights of the DBA application and the user class of the definer.[11] The WHEN expression can refer to system data only. For example, to initiate an action whenever a new part is added to the data base

```
DECLARE NEW PART ACTION(LOG,PROC
  (P1))
WHEN (REQUEST.OBJECT='PART' &
  REQUEST.ACCESS='ALLOCATE');
```

In the example above, LOG is a built-in ACTION. P1 is a procedure declared by the administrator, and REQUEST is a system DB structure. The REQUEST and SYSTEM data values are available to the procedure; it can use any other data base items accessible to its application and user class.

There exist some problems associated with the use of actions, not all of which have satisfactory solutions until now. Some of these problems are:

(i) integrity violations within actions, which could result in a never-ending sequence of actions invoking actions;

(ii) name resolution at the moment of invocation of the procedures in the actions;

(iii) access rights of the invoked actions.

A simple, although somewhat unsophisticated solution for (iii) is given in this section. Problem (ii) is discussed later.

Updates through views

From the viewpoint of an application program, all modification of the data base occurs through templates. From the viewpoint of the system as a whole, all modification is effected through changes to DB structures. One of the functions of the view mechanism is to provide the transition from a template-expressed change to an unambiguous DB-structure change. Many problems arise in this context, not all of which have been solved.[6] It is clear, however, that the system's basic integrity rules apply to DB structures. The template definition can place additional constraints on changes made through that template.

A template, like a DB structure, is a structure that can also be viewed as a relation or table. A template can join two or more DB structures, eliminate rows and columns of the resulting table, and permute and rename columns. For example, using the data base definitions, the following template joins SUPPLIER and PART, using SP as intermediate. It also deletes the fields NUMBER and STATUS from SUPPLIER and all fields but NAME from PART, renames CITY to PLACE, and reorders the remaining fields.

```
DECLARE 1 PARTSLOC TEMPLATE
  WHERE (SUPPLIER.NUMBER=SP.S_NO
    & SP.P_NO=PART.NUMBER),
  2 SUPPLIER,
    3 PLACE LIKE CITY,
    3 NAME,
  2 PART,
    3 NAME;
```

The WHERE expression could have been extended by, for example,

```
& SUPPLIER.CITY¬='LONDON'
```

to eliminate rows or occurrences. If a template involves only a single DB structure, and does not select rows, no WHERE expression is needed.

If two fields compared in the WHERE expression are not based on the same type, the template designer receives a warning; if the two cannot legally be compared (according to PL/I rules), the template is rejected. When two fields with unlike attributes are compared, conversion takes place. Attributes may appear on field names in the template; if they do, conversion from or to the attributes of the type will occur when data is accessed.

The template has a *visible* aspect (the portion that appears in the declaration below the defining expression) and a *hidden* aspect (all other fields of the participating DB structures). A program can use only the visible aspect; access and integrity rules can also refer to hidden fields. The user who defines a template must have READ NAME access to all objects whose names appear in the template.[11]

To summarize the definition of a template, it is a projection (not purged of duplicates) and permutation of a subset of the cartesian product of the DB structures named in the defining expression and in the visible aspect. The subset is specified by the defining expression, the projection by the fields appearing in the visible aspect, and the permutation by the order in which the fields appear.

Each template represents a specific intent with respect to data base access. Not all templates are intended to be used for changing the data base, for example. Those that *are* have attributes that limit the kinds of changes that can be made through the template and that resolve any ambiguities about how the change is made.

The UPDATE attribute can appear on template fields. ALLOCATE and FREE are attributes of the template. Allocation of a template by a program, folowing by setting of field value means: "ensure that an occurrence with this value exists in the data base". This could possibly require adding occurrences to more than one DB structure. The ALLOCATE attribute can limit which DB structures will be affected, as in the following attribute for the PARTSLOC template

```
ALLOCATE(SP)
```

which does not allow occurrences of SUPPLIER or PART to be allocated, but only of SP. If there existed no occurrence of SUPPLIER with the NAME value of the new template occurrence, the ALLOCATE would be rejected and an error condition raised. A template with no ALLOCATE attribute cannot be used for allocating. The FREE attribute allows FREE operations to be performed on a template and resolves any ambiguities about which DB-structure occurrences are to be deleted. For example, the program statement

```
FREE PARTSLOC;
```

could be implemented by deleting occurrences of any of three DB structures. The template attribute

```
FREE(SP)
```

specifies which DB structure is intended.

The UPDATE attribute specifies that a template or a template field can be updated, and may also specify propagation of the update to other (possibly hidden) fields of the template. For example, the following template, which is used for changing a part number, updates PART (its source DB structure) and also SP.P_NO, which is compared for equality with PART. NUMBER in the defining expression.

```
DECLARE 1 CHGPN TEMPLATE WHERE
(PART.NUMBER=SP.P_NO),
  2 PART,
    3 NAME,
    3 NUMBER UPDATE(EQUAL);
```

The template's defining expression acts as an integrity rule, since all updates made through the template must satisfy the expression. (Updates need not satisfy the application program selection expression, however).

The UPDATE, ALLOCATE, and FREE attributes specify what can be done through a template, regardless of application or user class, i.e., they implicitly define reflection rules. Access rules further constrain use of the template in specific contexts. A more general mechanism to specify reflection rules could be constructed by the use of actions.

AN INTEGRITY MECHANISM

General aspects

It is clear that a mechanism to perform validation and enforcement of the integrity assertions discussed earlier will involve a good increase in overhead with respect to a system not providing these functions. It is then important to define a mechanism able to support the desired functions at the lowest possible cost. The cost function to be minimized will be the amount of CPU time involved in validating the assertions, and it will be shown that the data base architecture under consideration provides a convenient environment for efficient evaluation of integrity constraints. As it has been pointed out by several authors,[12,14,15] the way in which the data base is structured has a significant effect on the validation effort as well as on the type of inconsistencies that can occur. However, neither the model described here nor this data base have anything special to offer in this respect, and the performance implications of data base structuring will not be considered.

Evaluation and enforcement of integrity rules

As indicated by Florentin,[12] a basic condition to have an effective validation system is a user interface consisting of preformatted transactions. This is the case in this data base, where all manipulations on the data base are made through predefined templates. The prespecified structure of the template makes it possible to validate integrity assertions in a systematic and disciplined way.

Any change to the data base must satisfy both the template's defining expression and all integrity rules for all the DB structures that are changed. The defining expression is first evaluated on the new template occurrence, and the change is rejected if the expression is false.

Integrity rules associated with a DB structure can involve fields in other DB structures. For example, values of one field may be required to be a subset of the values of another. The concept of an *integrity template* is introduced to define how these rules are evaluated when the DB structure is updated. There are three interpretations of the integrity template, corresponding to WHERE, WHERE SOME, and WHERE NONE.[12] Assume a new or changed occurrence of a DB structure DBI, with a new value of dbi. For each integrity rule that has DBI as an object, we consider a WHEN-template whose defining expression is (DBI= dbi & when-expr). If the WHEN-template is empty, the rule is ignored. For each category of WHERE, we consider an integrity template that is the cartesian product of all DB structures appearing in the effective integrity expression (which is the AND of the remaining rules), selected for (DBI=dbi). Then, depending on the category, we require that the effective integrity expression be

(1) true for all occurrences (WHERE)
(2) true for at least one occurrence (SOME), or
(3) true for no occurrence (NONE) of the integrity template.

Changed occurrences become a part of the shared data base when unlocking occurs. During the interval between update and unlocking, violations of certain types of integrity rules may exist, but these are seen only by the process making the changes.

As the data manipulation language used in this system makes explicit the data actions of application programs, it is possible to determine at compile time exactly what the program is intending to do with respect to the data base. This allows to generate code at this time to evaluate and to enforce access rules.[7,11] In a similar way, code can be generated to evaluate integrity rules. In effect, by looking at the type of access of the program with respect to a given data object o_l, it is possible to decide by looking at the t_k of the integrity rules for o_l, which of these rules apply to the given program. The conditions for the relevant rules will normally only be able to be evaluated at execution time since they are usually data dependent, and the same is true for the predicates p_q. However, as the data objects which have to be retrieved to evaluate these predicates are known at compile time, code can be generated for their efficient access. At the same time, code to perform any enforcement action can be generated. Problems with name resolution in the procedures that can be present in p_q, c_n, or e_m, can be decided if compile-time actions include flow of control analysis.[1] Naturally, compiled programs become sensitive to changes in the relevant integrity rules, which result in recompilation of all the programs where they are used.

All this early processing permits considerable reduction in the overhead necessary to perform access control and integrity checking at execution time. For systems where even this overhead is excessive, integrity rules can be evaluated periodically rather than at every modification of the data object. This can be done easily in this system by defining an action to be an integrity check, and giving that action an appropriate WHEN condition. For example,

DECLARE A1 ACTION (INTEGRITY(PART))
WHEN(SYSTEM.TIME='0000'):

As in this system file descriptions are external to application programs, it is possible to use as a mechanism for enforcement a strategy similar to the one proposed in Reference 8, where "surveillance routines" are attached to files where given conditions should be enforced. The only difference is, that instead of these routines being attached by the execution supervisor to the application programs accessing the file, they are attached at compile time.

DBA facilities

A fundamental requirement of an integrity system is to provide a convenient interface for the data base administrator, to permit an easy, consistent, and efficient way of defining and maintaining integrity rules. The data description language presented here in distributed form has been designed to be simple and complete. The integrity rules are themselves stored together with all other data definitions, access rules, action declarations, etc. using the same mechanism as the data files of the shared data base.[19] In other words, integrity rules and all other data descriptions are data base structures and constitute a "data base about the data base," which incorporates the information usually associated with data dictionaries/directories.[20] Some of the integrity rules therefore, could refer to the consistency of the relations storing integrity rules. Also, information about which programs are affected by changes to a given integrity rule should be part of this facility.

RELATED WORK

The separation between the logical and physical aspects of a data base makes it possible to define high-level integrity systems which can be analyzed for consistency and completeness. This has resulted in several approaches to integrity.[2,3,4,9,10,12,13,14,15] It is then important to compare our results to these to put things in perspective.

With respect to integrity, the CODASYL DDL[4] provides the CHECK clause, which can specify either ranges of values, expressed in literals, or the name of a data base procedure. The value range is only one of many types of required integrity constraints; and the procedure invocation mechanism allows integrity requirements to be buried in procedural code, as they are buried in application code in today's data base systems. Such a mechanism has to be provided, but as a last resort after more explicit ways of expressing integrity have been exhausted.

A comprehensive treatment of integrity is given by Stonebraker[17] in describing the INGRES system, in which an integrity assertion is stated as one or more range statements, plus an integrity qualification. The range statements define a cartesian product, and the qualification is true or false for each tuple in that product. This is equivalent to our integrity template, but the lack of a WHEN specification causes rather awkward qualifications. For example, the rule that everyone in the toy department must make more than $8000 is expressed in INGRES as

RANGE OF E IS EMPLOYEE
INTEGRITY E.SALARY>8000 or E.DEPT≠'toy'

as opposed to our

```
EMPLOYEE IS CONSISTENT WHERE
        (SALARY>8000)
   ENFORCE WHEN (DEPT='TOY');
```

Another important relational data base is the SEQUEL system,[2,3] whose integrity aspects are discussed in References 2 and 10. The functional specifications of the integrity subsystem of SEQUEL are in general consistent with the approach presented here. The concept of condition in their integrity rules is imbedded in the assertions. The concept of action is present in their "failure actions," which define how the system responds to integrity violations. Update through views is discussed separately from integrity.[3] The view concept of the SEQUEL system allows the subschema to define joins (as well as other structures) and to convert between units (such as dollars and lire). The template differs from the SEQUEL view primarily in the handling of changes to the data base. A template is the concrete representation of a specific intent regarding use of the data base. Rather than being defined by the casual user of a query language, it is designed by a professional application designer and installed by a DBA.[18] Therefore, rather than applying the "uniqueness rule" of Reference 3 (that a change to a view is permitted only if there is a unique change to the underlying base relations that will result in the view change), we allow the template's definition to choose one of several possible changes, or to disallow a unique change. In any case, it is clear that a system like SEQUEL is compatible with this latter approach, i.e., it would be possible to have data base administrators and application designers building views for casual users.

Florentin[12] has studied integrity from a more theoretical point of view, stressing the value of predicate calculus in defining and evaluating integrity conditions. However, his cost function for the calculation of integrity constraints is based on the number of sequential file searches instead of minimization of CPU time as in our case. Graves has given a very complete discussion of the functions needed in any data description language for integrity purposes.[13] Our concept of condition, and the delayed assertions of Reference 10 are found in his specifications. The syntax of his DDL is COBOL-oriented while our syntax is PL/I-oriented, however most of his concepts are consistent with our approach. He was also the first one considering update effects an integrity problem. Hammer and McLeod[14] have provided a detailed discussion of the nature of integrity constraints; however, they do not consider the problem of updates through views or the evaluation of the constraints. Their work is of great value to define the descriptive aspects of integrity constraints and the functional capabilities of the supporting system.

CONCLUSIONS

A model of the functions of an integrity system for a shared data base has been proposed. Such a model is valuable to guide the design of the functional specifications of integrity systems for specific data bases. The model includes not only the characterization of integrity constraints but also the handling of updates to the data base through views, which is considered here as an important aspect for preserving the semantic integrity of the information stored in the data base. The model puts together different aspects of integrity, which until now have only been partially present in specific proposals.

A relational shared data base presented in earlier papers[18] is then shown to represent a very convenient embodiment of the integrity model. The particular characteristics of this data base, i.e., use of an extended high level language for data manipulation, direct reference to the data base variables, view interface for end users, use of compile-time actions, provide an environment in which the definition, evaluation, and enforcement of integrity constraints can be performed with relatively low overhead, with respect to systems incorporating similar functions.

Designing optimal data structures

by LARRY CLOUGH, WILLIAM D. HASEMAN and YUK HO SO
Carnegie-Mellon University
Pittsburgh, Pennsylvania

ABSTRACT

This paper is concerned with developing a methodology for designing optimal network data base structures. The model uses as an input the logical description of the files and existing network structures which are to compose the new network structure, along with a list of the functional dependencies of each file. From this input, a canonical plex structure is generated which contains all the known data and its relationships in a non-redundant form. This canonical form can be modified by adding additional sets and indexing schemes which can improve the retrieval efficiencies at the cost of additional storage. Given the set of queries or data requests and their relative importance, an operations research model can develop an optimal data structure which minimizes a multiple objective cost function. A methodology is then proposed for loading this optimal structure as well as for detecting when a reorganization or new network structure is necessary.

INTRODUCTION

In the past few years there has been a great deal of research directed toward the development of generalized data base management systems. The major objective of this research was to develop systems which could (1) eliminate redundant data, (2) store all data in one centralized data base, and (3) store not only the data but also the *relationships* between the data. This need to express relationships between data was the impetus for the work which led to the development of the CODASYL DBTG report of 1971.[1-4] Part of this need grew out of the fact that when several files were combined to form a data base and therefore redundant data was removed (i.e., social security numbers existed in more than one file), some mechanisms or relationships needed to be created to represent that information (i.e., something needed to be created to link together those files). In the terminology of the CODASYL report this relationship is called a set. A set consists of an owner-member relationship which is always a one-to-many relationship.

A second research effort which has been concerned with this question of relationships among data are the proponents of the relational approach,[5-11] which was nurtured by E. F. Codd of IBM San Jose Lab. In this approach the data is viewed as a set of tables where all the data contained within a row of that table (tuple) is related. This approach leaves the redundant data in the data base, at least at the logical level, and allows the user to join together various tables of data using the known relationships between the tables. The early work demonstrated that some of the required operators were not valid unless the tables were in a specified or normalized form. The process of converting raw data into the third normal form involves removing repeating groups (such as arrays) as well as removing various functional dependencies. These functional dependencies are indeed some of the relationships between data that the CODASYL report was concerned with representing.

A third research effort in this area has been the work being performed in the file conversion area.[14-36] This work, though preliminary in nature, has been concerned with developing techniques for converting data from one file structure to another. Most of these processes involve defining the input file (source file) and the output file (target file) through the use of a data description language. The programmer then defines the actual conversion process which is then performed to convert the source to the target file.

The objective of this paper is to combine the knowledge gained by the aforementioned research to develop a methodology for automatically designing and loading optimal data base structures. Since the CODASYL approach is currently the accepted generalized data base system, the data structures to be generated will be network or plex structures, which are supported using the set concept. This is not meant to exclude the relational approach in that Bonczek, Haseman and Whinston[12] have demonstrated that a network can be used to store a relational data base and Clough and Haseman[13] have proven that the network approach is an efficient method for storing relational data bases.

It will be assumed that the data to be stored within this optimal data base will consist initially of either a number of networks and/or COBOL files and each will be described using a common data description language. The COBOL file structure is the most common file structure currently being used and most other file structures are a subset of it. It will also be assumed that all functional dependencies are known for each file involved. In order to generate an optimal data structure the list of queries or data requests and their importance must also be known.

OPTIMAL DATA BASE DESIGN

This section of the paper will be concerned with converting the logical description of the input files and networks into a logical description of the optimal network. This entire section will be concerned with only the data description language (logical description) and the data requests (queries) for the resulting data base, and not with the actual data files. This approach of first manipulating the data description language without involving the actual data appears to be a unique idea.

The drawing shown in Figure 1 demonstrates the processes which are discussed in this first section of the paper. The first stage of the design involved (1) developing a data description language (DDL) to describe the input files and their associated functional dependencies and (2) converting those existing networks into hierarchical file structures, so they will be consistent with the COBOL-like files. The DDL which has been developed is an extension to the GPLAN DDL,[3] which is consistent with the DDL proposed by the CODASYL DBTG report. The process involved with converting an already existing network into a group of COBOL-like files is discussed in the third section of this paper.

The primary reason for converting all existing data structures into a hierarchical file is because the second stage can consistently convert each of these files into a normalized form. To first convert a COBOL file into an unnormalized relation the repeating groups must be eliminated and a set of keys for each relationship must be determined using the functional dependencies. The process of converting the unnormalized relations to normalized relationships has been discussed by Codd et al.[5] This is discussed later.

The third stage of the project is concerned with developing a canonical plex (network) structure from the given set of normalized relations. This canonical form contains all the data and all of its known relation-

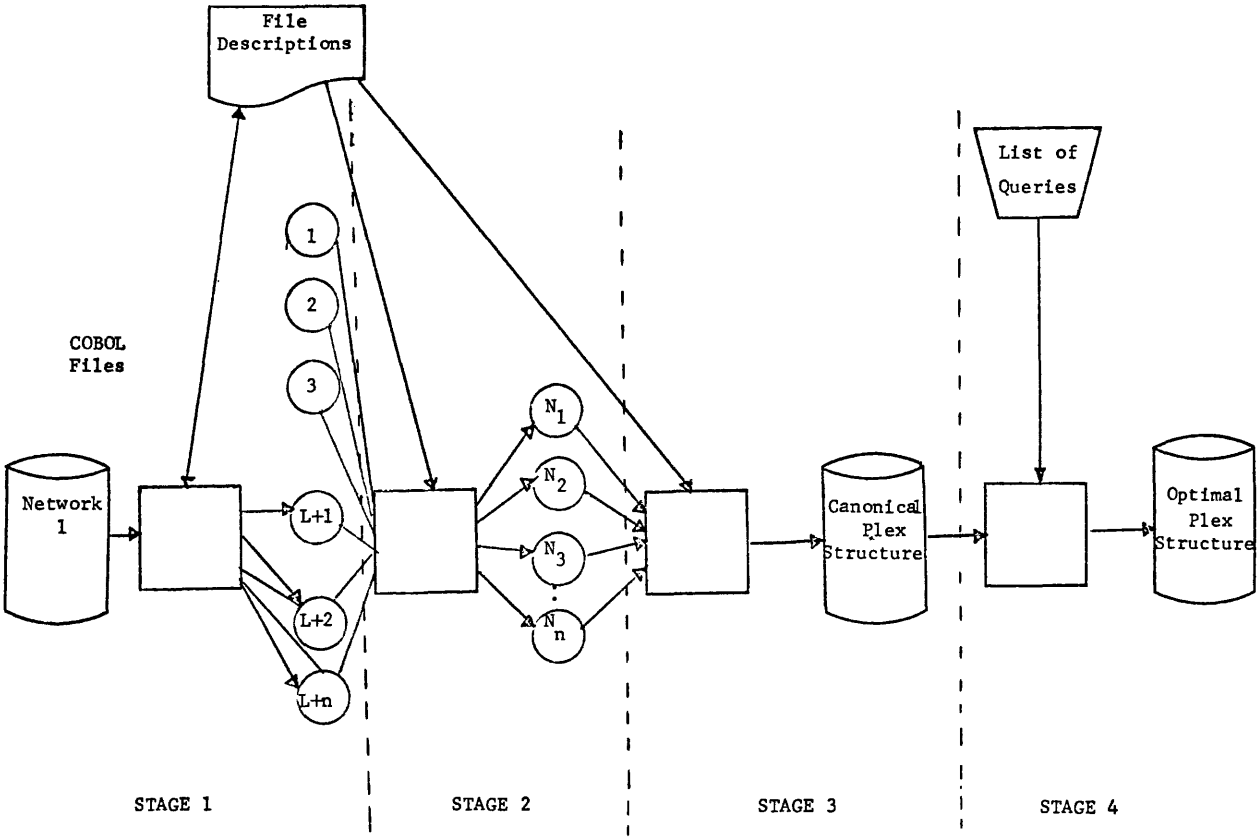

Figure 1—Structure of the data base design

ships. In the context of the relational terminology, this structure can support a relationally complete language.[12] This structure has the network properties of containing no redundant data and no extra set relationships. Since this structure will support any requests for data, this canonical structure could be viewed as being the ideal structure if the types of data requests (queries) are unknown. This structure may also be ideal if the types of data requests are dynamically changing. The discussion in a later section presents some of the operators required to form this canonical structure along with preliminary algorithm for forming the actual structure.

The fourth stage of the project involves trying to optimize this canonical structure in order to answer a given set of queries more efficiently. Various techniques such as adding additional sets or links, creating indexed sets and look-up tables, and splitting apart various relations can possibly increase access efficiencies at the cost of increasing structure costs. The preliminary model presented later looks at how these options can be evaluated in terms of an operations research type of model. This model is concerned with the methodology behind developing criteria for optimal network structures. It is clear that the optimal structure must be an outgrowth of the canonical form to be feasible, however the amount of optimizing must depend on the tradeoffs between access time and mass storage demands.

The following then is a more detailed discussion of the four stages which compose the first phase of the project.

STEP 1—CONVERTING A NETWORK INTO TREES

In order to facilitate the restructuring process, we have chosen the tree representation as the starting data structure for the source files. Since some source files may have network structures, it is necessary to convert them into the corresponding tree structures. In this section we shall investigate preliminarily into this restructuring problem.

The assumed criterion in decomposing the network is to create the least number of trees required to encompass all the data relationships in the network. Thus, the order in which the records are selected as roots plays an important role in the restructuring process. We shall provide in the following the criteria we use in selecting roots in the tree creating process. First, the definitions for the indegree and outdegree are given.

Definition: The indegree of a record x, denoted id(x), is the number of times that x appears as a member of a set relation in the network.

Definition: The outdegree of a record x, denoted od(x), is the number of times that x appears as an owner of a set relation in the network.

The selection criteria

(i) Records with outdegree zero will not be used as roots.
(ii) For all other records, group them according to their indegrees.
(iii) Rank the groups in ascending order of indegrees.
(iv) Rank the records within each group in descending order of outdegree.

An example of the selection criterion is shown in Figure 2.

Notations:

(1) N={(a, b) : record a is the owner and record b the member of a set relation in the network}

Thus, the data relationships in the network are completely described by N which can be constructed from the DDL description of the network.

(2) R is a set of records rank-ordered with respect to their desirability as roots using the criteria described above.

(3) T_i={(a, b) : (a, b) is a set relation, with owner record a and member records b, in tree i}
TN_i={x : x is a record in tree i}
V_i={x : x is a record to be further expanded in tree i}

The Tree Structuring Algorithm:

```
(1) i=1
(2) If N is empty, then stop.
(3) r=POP (R)*.
    (r is to be used as the root of the next tree to be built)
(4) $TN_i$={r}; $V_i$={r}; T={ }
(5) k=POP($V_i$)
(6) A={(k,y) : (k,y)$\epsilon$N and y$\notin$$TN_i$}
    $T_i$=$T_i$ UA
    (For all y, if y is not already a record in the tree, add all set relations (k,y) in N to $T_i$)
```

	indegree	outdegree
A	0	3
B	1	3
C	2	0
D	1	2
E	1	1
F	3	0
G	1	0

Ranked candidate roots:
(A, B, D, E)

Figure 2—Example of selection criteria

* x = POP(L)
(i) x is the first element in L if L is an ordered list. If L is an unordered set, then x can be any element in L.
(ii) x will be deleted from L.

(7) $N=N-A$
(Delete the set relations, which have been accounted for in the tree structure, from the network data base)
(8) $TN_i=TN_i \cup RANGE\ (A)$**.
(Add the newly attached records to TN_i)
(9) $V_i=V_i \cup \{x:x \in RANGE\ (A) \text{ and } od(x)>0\}$
(For all newly attached records, if their outdegrees are not zero, that is, if they are expandable, add the records to V_i)
(10) If V_i is not empty, then go to (5)
(11) $i=i+1$.
(12) Go to (2).

The example in Figure 3 demonstrates how the network structure shown in Figure 2 would be converted into a group of tree structures using the restructuring algorithm. In this example four COBOL files could be used to demonstrate the designed network structure. It should be reinforced that only the DDL for the new files is being generated, and the actual data is not being converted.

STEP 2—NORMALIZING HIERARCHICAL FILES

C. Delobel[10] has developed a rigorous theory of data in an information system which supports the relational model. He derives the essential aspects of the relational model from the concept of an elementary functional relation between two sets of attributes in an information system. These elementary functional relations define the data structure. All possible relations in the system may be derived from them by use of the join and projection operators. Delobel shows how an elementary set of functional relations may be derived from an arbitrary consistent set of relations. He also addresses the problem of decomposing a collection of data into a set of smaller units which are determined by a set of elementary functional relations and a set of user-supplied constraints upon such decomposition. Delobel presents algorithms for performing these operations.

Bernstein, Swenson, and Tsichritis present a similar approach to defining data structure.[37] They show how a rigorous and simple relational description of data relationships form the functional dependencies. They use a *constructive* approach and show that relations may be synthesized from functional dependencies *algorithmically.*

Functional relations are many-to-one relationships among attributes; owner-coupled sets are one-to-many relationships among records. Can the synthesis of relations from functional relations be used to produce an optimum network structure? A transformation between a relational description of data and an owner-coupled set network description is not simple because of the different modes in which information is stored in the two models of data structure.

(1) Order is used to store information essentially in an owner-coupled-set.

(2) Relationships among data items are stored both in the set structure and in the conjunction of data-items in a record.

(3) The data-item/data-item-value distinction does not capture the domain/attribute value distinction which is present in the relational model.

(4) Owner-coupled-sets are named, and that name contains essential information. Codd has shown that if owner-coupled-sets are treated as analogues of functional relations, spurious information may be created by such associations (see "the connection trap"[6]). For example, there may be more than one owner-coupled-set relationship between two records. A processor which is traversing the network must be sophisticated enough to choose which relationship is appropriate. A relational processor may be more naive because any relationship which it derives will be meaningful if the initial set of functional relations is consistent.

There are three functions which owner-coupled-sets may serve in a network implementation:

(1) elimination of redundant data;

(2) expression of elementary relationships between two records;

(3) improvement of access speed by expression of transitive relationships—i.e., composition of elementary relationships.

Few of the previous objections apply to the conversion of COBOL files into relational form. A COBOL file is very similar to an unnormalized relation. The main difference is that it may have a limit upon the number of occurrences of a repeating group. So it may be transformed almost directly into an unnormalized relation and then normalized. The only significant problem is in determining the primary keys of the unnormalized relations.

Delobel[37] has shown how we may derive a set of elementary functional relations from an initial set, and

** RANGE(M) = {y:M is a set of ordered pairs and (x,y) εM, V x}

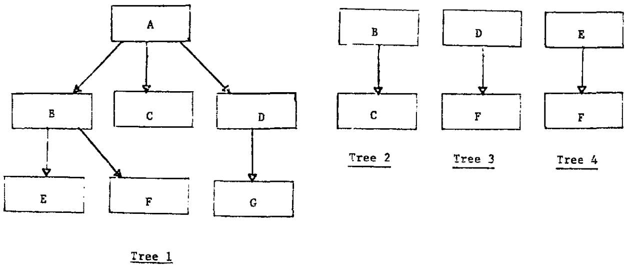

Figure 3

from that elementary set determine a key for a relation. The initial set of functional relationships must either be specified in advance or determined from the set structure of the initial files.

STEP 3—BUILDING A CANONICAL NETWORK FROM RELATIONS

In this section, we shall look into the restructuring problem in consolidating a collection of normalized relations into a network data base. The present stage of the restructuring work is to build a base network structure which will preserve all the data relationships presented in the relations. By creating a network, the data interdependencies across relations are explicitly recognized. This is done by joining the relations on their common domains. Thus, all common domains are represented only once in the network. However, further optimization of the network, such as the splitting of records for efficient accesses or storage savings purposes, will be presented in stage 4.

Three functions used in the restructuring model are described. They are SPLIT, MERGE, and JOIN.

(a) SPLIT

SPLIT is used to extract a specified attribute group from a given relation and to create the linkage (set relation(s)) between the two split parts. First, some notations used will be described.

R: the relation to be split.

D_R: the attribute domain set of R.

E: the attribute group to be extracted from R.

$E' = D_R - E$

$R' = R[E']$ (the projection of R on E').

SPLIT (R, E): the SPLIT function.

Depending on the functional relationship between E and E', three types of splitting might be resulted:

(1) If E uniquely determines E', then create a set relation with owner record E' and member record E.

(2) If E' uniquely determines E, then create a set relation with owner record E and member record E'.

(3) If E and E' assumes a many-to-many relationship, then create a dummy record EE' and two set relations, one with owner record E and member record EE' and one with owner record E' and member record EE'.

(b) MERGE

The function of MERGE is to combine two sets of occurrences of the same record type. The occurrences probably differ in the number and types of set relation pointers. Thus, by MERGING, the occurrences will have a compatible set of pointers.

$MERGE(M_1,M_2)$: the MERGE function where M_1 and M_2 are two sets of record occurrences for the record type M. M_1 is to be merged into M_2.

m: the record occurrence indicator (i.e., without considering the set pointers).

m_1: the record occurrence, with indicator m, in M_1 (m_1 includes all set pointers pertaining to M_1)

m_2: the record occurrence, with indicator m, in M_2.

The process:

(1) for all m, $m \epsilon (M_1 \cap M_2)$, add all pointers in m_1 to m_2.

(2) for all m, $m \epsilon (M_1 - M_2)$, add m_1 to M_2 and attach null pointers to m_1.

(3) for all m, $m \epsilon (M_2 - M_1)$ attach null pointers to m_2 for all owner pointers pertaining to M_1.

An example is shown in Figure 4 of two records being merged.

(c) JOIN

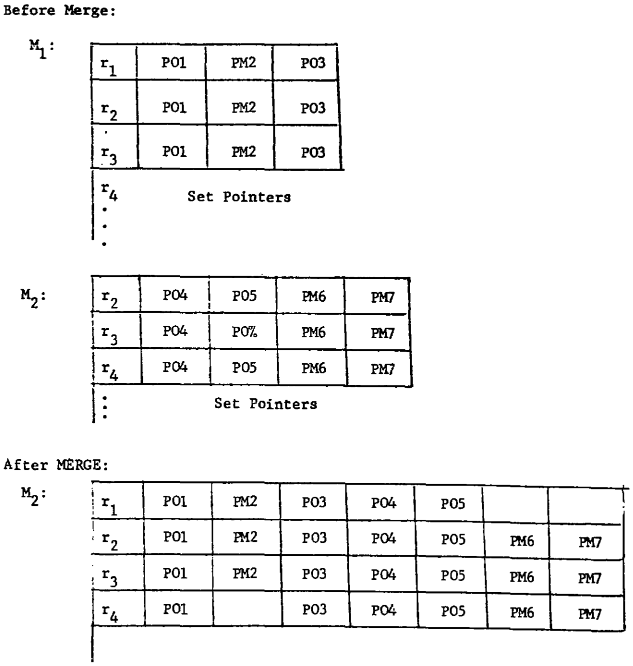
There are two portions of the JOIN operation: (1) to extract a specified attribute group from a given relation; and (2) to merge the extracted group into one already outstanding in the network. Therefore, the function of JOIN is to connect two or more relations on their common attributes.

JOIN (M_1, R): the function

M_1: the attribute group to be extracted and merged into M_2.

R: the relation from which M_1 is extracted.

M_2: the outstanding attribute group with the same type as M_1.



Before Merge:

M_1:

r_1	PO1	PM2	PO3
r_2	PO1	PM2	PO3
r_3	PO1	PM2	PO3

r_4 Set Pointers

M_2:

r_2	PO4	PO5	PM6	PM7
r_3	PO4	PO%	PM6	PM7
r_4	PO4	PO5	PM6	PM7

Set Pointers

After MERGE:

M_2:

r_1	PO1	PM2	PO3	PO4	PO5		
r_2	PO1	PM2	PO3	PO4	PO5	PM6	PM7
r_3	PO1	PM2	PO3	PO4	PO5	PM6	PM7
r_4	PO1		PO3	PO4	PO5	PM6	PM7

Figure 4

The process:

(1) SPLIT (M_1, R).
(2) MERGE (M_1, M_2).

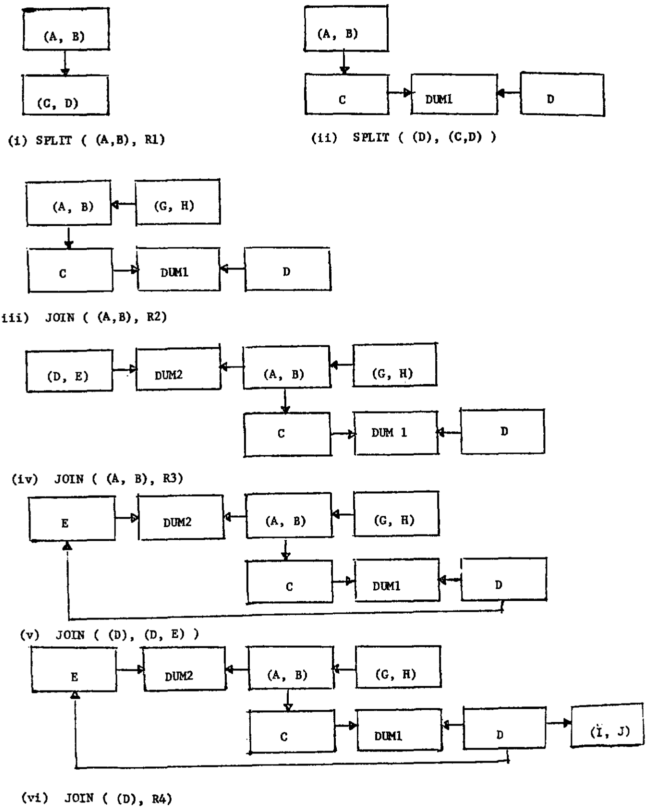
Notation:

C_i: the set of common attribute groups in relation i.
N: the set of attribute groups in the network.

The network generating algorithm:

```
(1)  Number the relations $R_i$, $i=1, 2, \ldots, n$.
(2)  Determine $C_i$ for each $R_i$.
(3)  $N=\{\ \}$.
(4)  $i=1$.
(5)  If $C_i$ is empty, then go to (11)
(6)  Select and then delete an attribute $G_1$ from $C_i$.
(7)  If $G_1=D_{R_i}$ then (i) if $G_1 \epsilon N$,
                                 then MERGE ($G_1$, $G_2$)
                                 else add $G_1$ to N.
                           (ii) go to (11).
(8)  If $G_1 \epsilon N$, then JOIN ($G_1$, $R_i$)
                     else SPLIT ($G_1$, $R_i$).
(8a) $N=(N-\{R_i\})U\{G_1, G_1'\}$
(9)  $R_i=R_i[G_1]$.
(10) Go to (5).
(11) $i=i+1$.
(12) If $i>n$, then stop.
(13) Go to (5).
```

Given the following set of relations and the following assumptions on functional relationships, the network shown in Figure 5 demonstrates the use of this algorithm.



(i) SPLIT ((A,B), R1)

(ii) SPLIT ((D), (C,D))

(iii) JOIN ((A,B), R2)

(iv) JOIN ((A, B), R3)

(v) JOIN ((D), (D, E))

(vi) JOIN ((D), R4)

Figure 5

Relations:

R1(A, B, C, D)	C1={(A,B), D}
R2(A, B, G, H)	C2={(A,B)}
R3(A, B, D, E)	C3={(A,B), D}
R4(D, I, J)	C4={(D)}

Assumptions on functional relationships:

(1) $(A,B) \leftarrow (C,D)$
(2) $C \not\rightarrow D \ \Lambda\ D \not\rightarrow C$
(3) $(A,B) \rightarrow (G,H)$
(4) $(A,B) \not\rightarrow (D,E)\ \Lambda\ (D,E) \not\rightarrow (A,B)$
(5) $E \rightarrow D$
(6) $(I,J) \rightarrow D$

STEP 4—DESIGNING OPTIMAL PLEX STRUCTURES

In order to develop an optimal plex structure it is necessary to investigate what effect the addition of extra sets or access methods will have on the canonical plex structure. In order to evaluate these methods, the demands or queries to be placed on the data structure must be known. Since it is likely that some queries will occur more often than others, it is also nice to know a measure of the frequency with which the query will be asked. For example:

LIST CITY FOR STATE='INDIANA' .03%
LIST NAME FOR CITY= 'INDIANAPOLIS' AND STATE= 'INDIANA' .05%

Once this information is obtained it is possible to identify where the various techniques for decreasing access time may be applied. Initially there appear to be four possible alternatives:

(a) split an existing record
(b) create a new path which bypasses record occurrence
(c) use the CALC option to locate a member directly
(d) use the dynamic pointer to create an inverted structure.

Although other alternatives might exist, this preliminary look will only consider these four techniques.

The format of the queries determines which nodes in the canonical plex structure are to be considered for the optimizing functions. For example, the following query:

LIST POPULATION FOR STATE='INDIANA' AND CITY='LAFAYETTE'.

would suggest that the structure shown in Figure 6 might be a candidate for splitting as well as for using the CALC option. In order to evaluate the increase (or decrease) in core requirements for selecting either or both of these options and the decrease in access time it is necessary to make some assumptions about implementation techniques and size of fields.

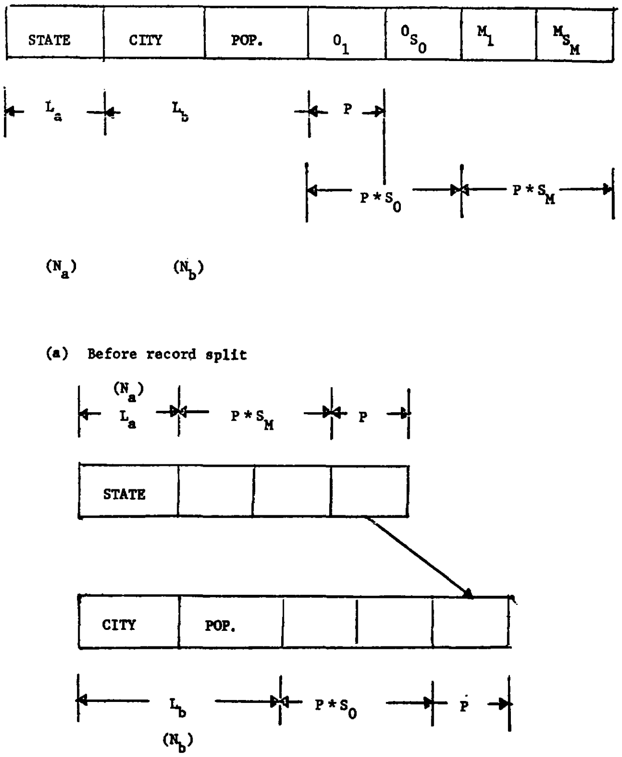
Assumption 1. The canonical plex structure is implemented using a doubly linked list structure, when data and pointers are stored together.

Let:

N_a Number of distinct values for variable STATE
N_b Number of state-city combinations
L_a Length (bytes) of STATE field
L_b Length (bytes) of CITY and POPULATION field
S_0 Number of sets existing record is an owner of.
S_m Number of sets existing record is a member of.
P Length (bytes) for each set of pointers.
c Storage requirements before split.
c′ Storage requirements after split
$\Delta c = c' - c$ Change in storage requirements

The drawing in Figure 6 demonstrates each of these variables. In order to calculate the storage requirements, the following equation can be used to determine core requirements before (c) and after (c′) splitting the record:

$$c = Nb(La + Lb + P^*S_0 + P^*S_m)$$
$$c' = Na(La + P^*(S_m + 1)) + Nb(Lb + P^*(S_0 + 1))$$



(a) Before record split

(b) After record split

Figure 6—Splitting a record

$$\Delta c = c' - c$$
$$\Delta c = La(Na - Nb) + P^*S_m(Na - Nb) + P^*(Na + Nb)$$

where the value of Δc will be the increase (decrease) in number of bytes of storage required to store the record if it is split. It will normally be assumed that this will always be an increase, but for some situations it might possibly be a decrease.

In order to determine the change in access time (Δt) some assumptions will have to be made.

Assumption 2. If the doubly linked list structure is used to locate a single record, it will require looking at one-half the record occurrences on the average.

Assumption 3. The access time T is proportional to the number of records accessed.

Let:

t Records accessed before split
t′ Records accessed after split
$\Delta t = t' - t$ Change in records accessed
$T = wk\Delta t$ Change in access time
w Percent of time specific query requested

Then:

$$t = N_b/2$$
$$t' = N_a/2 + N_b/2N_a$$
$$\Delta t = 1/2(N_a - N_b + N_b/N_a)$$
$$T = wk/2(N_a - N_b + N_b/N_a)$$

This sort of process can be repeated for each of the other possible optimizing alternatives in order to develop the necessary data for the following model.

Let:

$x_i = 1$ if optimization alternative i is selected
0 otherwise for i = 1, 2, . . .
c_{max} = Maximum additional storage available
W_c = Dollar cost per additional bytes of storage
W_t = Dollar cost per additional second of access time
T_{max} = Maximum access time permitted
Δc_i = Change in storage requirements for alternative i
T_i = Change in weighted access time for alternative i

Model:

min $W_c\Delta cx + W_tTx$ minimize total costs

s.t. $\sum_{t=1}^{L} c_ix_i \leq c_{max}$ memory constraints

$\sum_{i=1}^{L} T_ix_i \leq T_{max}$ access time constraints

$x_i \geq 0$
$x_i \leq 1$
x_i integer

where the solution to the problem is those alternatives for which $x_i = 1$ are selected and all others are rejected. The problem of applying multiple options to one record are handled as follows: (See Figure 6)

x_1—split record
x_2—form CALC for STATE
x_3—split and form CALC for State

Using this technique more variables will be generated, however, all intersections can be handled using a linear formulation.

Although this rudimentary model needs further extension, it does propose an approach to solving the question of an optimal network data structure. All of the variables in the model with exception of the weights are included in the proposed data description language which describes the input data files. The selection of the weights, particularly W_t, allows the designer some flexibility to investigate different alternatives. Although the solution to this proposed problem for a large data base may be formidable, it doesn't appear to be totally out of the question.

AUTOMATED DATA LOADING

The second phase of the project involves the development of the methodology for automating and even optimizing the process of loading the data from the specified source files into the optimal plex structure. The initial premise is that the work being done by Ramirez[23] will lead to techniques for generating the code necessary to convert the source file into the target file in a process similar to that shown in Figure 1. Since the input files are initially defined by the data description language and the output of the first phase of the project is a DDL for the target structure, the only missing link will be this code which directs the file conversion. It will be during this second phase that the actual data files will be handled in this data base loading problem.

AUTOMATED RESTRUCTURING

As should be noted in the description of phase 1 of the project, the input files can include existing network structures. The reason for extending the model to include these was to allow for the model to restructure existing data bases. It is clear such an event is necessary when new data items and records are to be added; however, it should also seem clear that if the set of queries or data requests changes significantly, a new set of x_i might be appropriate. The work in this phase will look at extending the model to include the costs of restructuring, so that it can predict at what point the query batch has changed significantly to economically justify reorganizing the logical data structure.

It appears that if no new data is to be added, that the canonical structure will be the same, and only the x_i's will change. It also appears that the loading program might be able to take advantage of this fact and try to minimize the amount of data which has to be physically reloaded. It would appear that this technique would offer a viable solution to the future requirements of a dynamically restructuring data base.

CONCLUSION

The work described in this paper's relevance can be summarized in three areas:

(1) the development of a criterion for "optimal" network structures, using a multidimension objective function;

(2) proposing a methodology of automating the process of designing structures for large data bases;

(3) an attempt to use the work of the CODASYL and relational approaches in a constructive rather than a destructive manner.

As the research on the automation of data loading and restructuring is completed, it is felt that this methodology will lead to great advances in the data base management area.

REGIS—A relational information system with graphics and statistics

by J. D. JOYCE and N. N. OLIVER
General Motors Corporation
Warren, Michigan

ABSTRACT

While the relational data management model has been known for some time, it has yet to be proven that such systems can perform efficiently in an industrial environment. This paper describes user experience with and the external highlights of the RElational General Information System (REGIS) which is currently being used within General Motors. This data analysis system combines the features of relational information handling along with graphical, interactive and statistical capabilities. REGIS provides the flexibility of handling unforeseen queries and enables the user to interactively analyze his data by entering commands from terminals. Its use does not require any conventional programming effort. It is possible to interface to user written functions if the need arises.

INTRODUCTION

Although the relational data management approach has been known for some time,[1,2] it has yet to be proven that such systems can perform effectively in an industrial environment. These new concepts have been implemented in the REGIS (formerly RDMS[3,4,5]) relational data management system. This paper describes the highlights of and user experience with this system which is currently being used within the General Motors Corporation.

The **RE**lational **G**eneral **I**nformation **S**ystem (REGIS) is an interactive (conversational) system designed to provide convenient, powerful and flexible information manipulation facilities for information storage, retrieval and analysis. This is an area where long range data management system requirements have been poorly met.[6] Its main power is in its ability to handle unplanned queries and enables the user to utilize intermediate results to determine the future course of his analysis. An emphasis is placed on providing a view of data in which the relationships are easily understandable and easily manipulated to derive new relationships. Of particular importance is the capability to handle groups (sets) of information. This is different from handling one record at a time such as in the CODASYL Data Base Task Group approach.[7] With each REGIS command information may be extracted from a whole set or from the interaction of sets of information.

Capabilities are integrated into the system for those users whose main interests are to use flexible graphical tools to view their data. Other users may want to place an emphasis on statistical analysis of data. REGIS contains elementary statistical programs and planned interfaces to make reasonably smooth transitions between REGIS and advanced statistical packages. The user can prepare his data for analysis utilizing the (relational) data management facilities, analyze it with the statistical operators and plot the results all within one package. Some users have found that the integration of these three broad capabilities in one package is the most useful feature. It is also recognized that other classes of applications will have particular needs for special functions. REGIS provides a simple interface to such functions.

Extensive performance monitoring tools have been installed in REGIS. These will be used primarily by system implementors to measure and assess the effects of new algorithms and any improvement in the existing ones.

SYSTEM OVERVIEW

Figure 1 gives an overview of the major components of the system. The central part of the system consists of the relational information handling capabilities. The graphics part of the system consists of some built-in facilities which will operate on dial-up typewriter or alphanumeric CRT terminals and an integral link to the SIMON graph plotting system. (See the SIMON command description in the Appendix for information about this interactive graphics system.) The SIMON capabilities are invoked with a REGIS command just like any other REGIS facilities. The statistics component includes a number of built-in functions as well as interfaces to other statistical systems. An interface is planned for a general purpose statistical package, a Monte Carlo Simulation system,[8] and a "snowflakes" package. This "snowflakes" (circle diagrams) package is a graphical technique for "browsing" through multivariate data as is indicated in a portion of Reference 9.

REGIS is designed primarily for an interactive mode in which the user can extract and analyze information and make new analyses based on the information which he has just learned. Thus by continuous refinement of the information analyzed, a user can proceed to conclusions by procedures or data dependent methods which might not be evident in the beginning. The user has available a variety of commands which are interpreted as they are entered at a computer terminal. See the Appendix for description of some of the commands, or the Examples section which illustrates their use. The tools of the REGIS system are intended to serve applications where all the queries cannot be defined ahead of time to fully serve an application.

REGIS is available to any user having access to a typewriter or CRT terminal. It runs on an IBM 370/168 computer under the TSS operating system.[10]

USER VIEWS OF DATA AND RELATIONAL SYSTEM

The users view of a relational data handling system is markedly influenced by the approach and terminology by which this subject is introduced to him. Some of the precise terms of relational theory are simply not appropriate to use with potential users. The user must be approached with simple terminology and meaningful explanations of the concepts and ideas involved. It was determined that potential users, including experienced mathematicians, were decidedly turned off by the terms 'ntuple' and 'domain', for example. Replacement of these terms by 'row' and 'column' greatly expedited the communications with new users. This naturally leads into a users view of his data as being made up of simple rectangular tables of rows and columns.

Figure 2

Data views

The ability of the user to relate views of data to simple rectangular tabular representations provides a common starting point for a wide spectrum of users. Tables were a common denominator for representing data before the advent of computers and continue to be a common representation of data. From these simple concepts, it is relatively easy to lead new users thoughts into understanding that in addition to a table being a repository or collection of data it also represents relationships among the data items in that table. These relationships may be referred to as attributes, or properties of items in the table. Figure 2 shows an example of such a relationship where each person whose name is given in the first column is described by the attributes of social security number, sex and birthdate.

Figure 3 shows another type of relationship which is also contained in a simple table. This example shows a relationship in which the two objects represented by STUDENT and CLASS columns are tied together by the attribute GRADE. The attribute of GRADE does not solely describe either the STUDENT or the CLASS but rather describes the connection (relationship) between the two objects. Other types of relationships could be shown, but the key point, however, is that each relationship can be expressed in a simple tabular form.

After a user has expressed part of his information in a table, it is a natural extension to view his entire data base as a collection of unique groups of data. Additionally, our users view the tables as being related to one another through various common elements of the tables.

STUDENT	GRADE	CLASS
JONES	A	BIOLOGY
SMITH	C	PHYSICS
JONES	B	CHEMISTRY
ADAMS	D	ENGLISH
MARTIN	B	PHYSICS
ADAMS	B	CHEMISTRY
ADAMS	A	PHYSICS

Figure 3

Two observations can be made here from dealing with users in introducing the concepts of relational data bases. The first observation is that users who have been doing computer processing of some of their data have been molded by the computer tools previously available. One impact of this is that users attempt to cram all their relationships into a single table by highly coded representations and replication of data. This has undesirable side effects relating to updating and deletion. Another impact is that significant related data has been ignored in many applications simply because of the lack of facilities to handle multiple relationships. The second observation is that the users find this view of data somewhat simpler than the mechanics of hierarchies or networks. This probably arises from both the backgrounds of the users and the fact that relational implementations generally provide a higher level interface to the data than do the data base packages which require the user to know about the networks and hierarchies.

Relational system views

Once the user has established his external views of the data, his views of the system are much simplified, providing that one can reasonably stay clear of confusing or ominous terminology. The applications to which relational data base techniques are applied tend to be those which the user is examining, condensing, extracting new relationships or insights from groups of data rather than examining or updating individual pieces of data. This acclimates the user to thinking in terms of operations which operate on tables of information. The tables are actually sets of information and the user is frequently applying operators whose foundation is set theory. The user can learn from simple examples about the functions performed by the relational operators. Thus the system appears as a new set of tools to solve his problems quicker and easier. The aura of mystique about relational ideas has been removed and we can move on to the problems of making the systems useful and practical.

APPLICATION EXPERIENCES

Some highlights of feedback from actual applications of a working relational data base manager will be presented here. One application involved personnel data where the information was primarily names, text, codes and dates. One of the areas in this application where the new operators proved to be very useful was in input data validation. By looking at large clumps of data and grouping items together in various ways, many errors either in spelling or in erroneous manual coding of data were isolated. These validation procedures were not carried out before by special programs because of the programming effort required to write and debug computer programs. The relational operations further came into play by making it easy to examine relationships between tables and isolating unusual items for further examination.

It was recognized by the implementors that data handling, whether relational or otherwise, was not an end in itself. Graphical facilities to see data and a reasonable complement of statistics to massage data were an integral part of the design. Feedback from our users indicated that these features which could have been built into many conventional data base packages (and have been in some cases) were sometimes more valuable than the relational power available. The ability to perform aggregate operations (grouping combined with arithmetic functions), joining tables together, subsetting, and selecting items from one table based on criteria from another table have proved to be the most valuable operations to date. Another application consisting mainly of numerical data for an experimental engineering program on noise reduction in new equipment made particularly heavy use of the aggregate functions and the selection of items from one table based on criteria in another table. It is also evident that higher language levels are desirable provided that they can be implemented without significantly increasing the complexity of the language.

EXAMPLES OF DATA QUERIES AND ANALYSIS

Two examples are included to give a flavor of how REGIS is being used at General Motors. (Commands and keywords are shown in capital letters while the set and column names are shown in lower case letters.)

The first example deals with the information in the relationship (or table or set) entitled "failures." This set with its labelled columns is represented as:

```
failures (fail# faildate failtime operator machine#
failtype severity fixdate)
```

The question in the first example is: "Do certain machine operators show a propensity to having particular types of failures when they are operating the machines?"

```
opfail=PROJECTION failures operator failtype
op=AGGREGATE opfail operator COUNT cntop
op=SUBSET op WHERE cntop GE 10
optypes=AGGREGATE opfail operator failtype
  COUNT cntfail
counts=optypes JOIN op operator
COLUMN counts percent FLOAT
counts=counts COMPUTE cntfail * 100 INTO
  percent
counts=counts COMPUTE percent / cntop
result IS SUBSET counts WHERE percent GT
  35.0
```

The PROJECTION command in the first line simply extracts from the source set those columns of interest.

The AGGREGATE command in the second line groups the rows by operator and counts how many rows of failure data are associated with each operator. Now if the user knows that a number of the operators have had only a few failures he might wish to eliminate those operators from further analysis. This is done in the third line with the SUBSET command which selects only those operators who have had 10 or more failures. The next use of the AGGREGATE command in the fourth line groups the rows of failures based on unique combinations of operators and failure types. At the same time this command counts the number of rows in each combination and stores these counts in the column entitled "cntfail." The JOIN command in the fifth line combines the data relationships in the two sets "optypes" and "op." The results of this command are that the operators who had less than 10 failures are eliminated from further consideration and the counts of each operator by failure type and the total number of failures for each operator are stored in adjacent columns. The next three commands (sixth through eighth lines) generate a column for a percent value and compute each failure type as a percent of all the failures for each operator. The SUBSET command in the last line singles out those operators who have an abnormally high percentage of failures of any particular type.

This procedure is one arbitrary solution to a general question. Other solutions could have taken into account absolute numbers of failures by operator and type. Other possibilities include looking at deviations from averages or generating some data which could be plotted to show some deviations from trends.

The next example illustrates use of some of the statistics and graphics procedures. The input data consists of one set with only two columns. A set on quality control data contains the supplier column and the measured hardness of the material in each of a sample of parts in the second column. The set is represented as follows:

qcdata (supplier, hardness)

The desired analysis is stated as follows: "Obtain statistics about the hardness data, then fit a weibull curve and plot a comparison of the raw distribution to a generated weibull curve to give a visual indication of the closeness of fit."

```
stats=STATISTICS qcdata
tempset=PROJECTION qcdata hardness SORT
wb=WEIBFIT tempset
wbcurve=CURVE wb
DEFAULT INTERVALS 12
rawdata=DISTRIBUTION qcdata hardness 100
  BY 5
comb=wbcurve COMBINE rawdata
SIMON comb
GRAPH frequency VS hardness
ADDGRAPH yhardness VS xhardness
```

The STATISTICS command in the first line stores in the "stats" set statistics about all the numeric columns in the "qcdata" set (in this case only the hardness column). The PROJECTION command in the second line sorts the hardness data in preparation for the weibull fit command which follows. After the weibull parameters are generated (third line) a curve containing 100 points will be generated with the CURVE command in the fourth line. The next two commands set up the parameters for and generate a distribution of the raw data. The COMBINE command (seventh line) merely puts the data for the two curves in one set in preparation for the graph plotting command which must have all its data in one set. The SIMON command brings the user into a graph plotting system which permits the use of any of the SIMON commands to overlay curves, label axes, add titles, add legends, etc. The GRAPH and ADDGRAPH commands in the last two lines of the example illustrate the commands necessary to plot two curves on the same graph.

For more information about the command language see the Appendix.

PERFORMANCE MONITORING

REGIS contains automatic performance monitoring facilities which continuously record various phases of its performance for the usual purposes of locating inefficiencies and predicting performance (cost and response time) as a function of command sequences and data base sizes. In addition, command sequences are monitored to determine whether certain commands should be restructured in simpler or more powerful relational commands for the user. Since there is a wide variety of applications and users with diverse backgrounds, the data concerning performance and distribution and usage of commands in user environments will also be useful to designers of data base hardware and firmware which incorporate relational operations. The monitoring information collected is stored in normal REGIS sets and thus can be later analyzed utilizing this data analysis package.

CONCLUSIONS

The development of a relational data base implementation has resulted in a worthwhile tool for a wide variety of applications. The new relational concepts are practical in a problem solving environment for industrial applications. Concern over efficiency of such a generalized approach is still justified. However, use of the system does eliminate the traditional specialized programming effort. We feel that this savings has greatly offset any execution inefficiencies in this general purpose package. It is also clear from the performance monitoring data that substantial improvements in efficiency can be made. Improved sorting and searching capabilities will make such systems economically applicable to even wider classes of applications.

Simple views of the data to be handled and the commands for manipulating the data have been very attractive to users. A manual explaining the concepts in simple terms and augmented with a few examples has been sufficient for a number of users to make effective use of the system without any training or consultation. The ability to carry out unplanned queries and data reduction interactively (either via local or remote dialup terminals) has been valuable to users. A type of macro facility in which a knowledgeable user prepackages command sequences for other less knowledgeable users has been useful in those applications where sequences are often repeated. User acceptance of the system was greatly encouraged by the provision of a comprehensive variety of graphical and statistical analysis capabilities as supplements to the relational data handling facilities.

APPENDIX—COMMAND LANGUAGE

The REGIS command language is a non-procedural[11] relational algebraic language believed to encompass the most useful relational functions. Commands have the following general format:

$$\text{[set } \left\{\begin{matrix}\text{IS}\\ =\end{matrix}\right\} \text{ [set]] KEYWORD [parameter...]}$$

(Notation explanation: Uppercase words denote a keyword that must appear as shown; items contained within square brackets [ ] are optional; items followed by the ellipses ... may be used once or more; multiple items stacked and enclosed in braces { } represent alternatives for a choice of one item.)

This command language operates in any one of two modes depending on the leftmost word of the command: Either it is a command name in which case it is usually a control command and the results are displayed at the terminal, or it is a set name in which case a new (or old) set is used to store the results of the specific operation. Varying number of options (if any) can be specified in the parameter field of each command.

Examples:

COMMANDS FROM set
LIST set
set=SUBSET set
set IS set1 UNION set2

The syntax and brief description of the most useful commands follows. For additional information see Reference 12.

COLUMN set column [type]

The COLUMN command adds a new column with the specified name to the specified set.

ADDROW set rowvalues ... $END

This command adds row(s) to the specified set.

$$\text{COMMANDS } \left\{\begin{matrix}\text{TO}\\ \text{FROM}\end{matrix}\right\} \text{ file}$$

COMMANDS enables the user to store and/or execute more than one command at a time. It is a convenient facility through which a long sequence of commands can be executed by entering only one command.

SPECIAL name setin setout

The SPECIAL command allows the user to execute any program which he has previously created. Thus the user is able to add to the REGIS package extra capabilities tailored to his specific needs. (For example: a report generator.)

$$\text{BARCHART set column} \left[\text{minimum} \left[\left\{\begin{matrix}\text{TO maximum}\\ \text{BY increment}\end{matrix}\right\}\right]\right]$$

BARCHART produces a horizontal bar chart of the values in a specified range of one column of a set.

SIMON set

This command invokes the SIMON PLOTTING SYSTEM to obtain graphs of REGIS data. This simple graphics system, developed at General Motors Research Laboratories, enables the user to produce good formatted graphs of data stored in any REGIS set. The user can restyle the graph via SIMON interactive commands. The graph is generated on the TEKTRONIX storage tube terminal while hardcopies can be generated on CALCOMP plotters or SC4060 film recorders.

REVISE set column [#[TO #]] WITH newvalue [increment]

REVISE enables replacing a specified range of column values in a set with a constant and optional increment.

resultset=PROJECTION set columns ... [ETC]
[SORT [WEED] [DESCENDING]]

The specified columns of the source set are copied to the resultset. If the SORT option is specified then the resultset is sorted on these columns.

resultset=SUBSET set

$$\left[\left\{\begin{array}{l}\text{\# [TO \#]}\\ \text{WHERE Compare} \left\{\begin{matrix}\text{AND}\\ \text{OR}\end{matrix}\right\} \text{Compare] ...}\\ \text{SAMPLE samplevalue}\end{array}\right\}\right]$$

The Compare syntax is: columna Operator $\left\{\begin{matrix}\text{columnb}\\ \text{value}\end{matrix}\right\}$

Operator can be any of the following: =or EQ; ≥=or NE; >or GT; >=or GE; <or LT; <=or LE. ¬

SUBSET places rows of set into resultset. The WHERE clause compares values from columna to either values in columnb or a constant value. The comparison conditions can be nested in multiple levels.

$$\text{rset=set COMPUTE} \begin{Bmatrix}\text{columna}\\ \text{value}\end{Bmatrix} \text{Operator} \begin{Bmatrix}\text{columnb}\\ \text{value}\end{Bmatrix}$$
[INTO columnc]

Operator can be any of the logical operators described with the SUBSET command and also any of the following: + (plus) : − (minus) ;* (multiply) ; /(divide) ; EXP; REM or TRUNC.

This command performs the arithmetic operation on all elements of the specified columns. The arithmetic operation between each value of columna and the corresponding value of columnb, or constant values, is performed and the result is placed in columnc.

resultset=AGGREGATE set columns ... [COUNT column] [SUM columns ...] [AVERAGE columns ...] [MINIMUM columns ...] [MAXIMUM columns ...]

The source set is subdivided into groups based on distinct combinations of values for the specified columns. One row for each group is placed in the resultset. A count, sum, average, minimum and maximum of the consolidated columns can be optionally obtained.

resultset=STATISTICS set [column ...]

This command calculates values such as: minimum, average, maximum, sum, standard deviation etc.

$$\text{rset=set1} \left\{\begin{matrix}\text{UNION}\\ \text{INTERSECTION}\\ \text{XOR}\\ \text{DIFFERENCE}\\ \text{JOIN}\\ \text{COMPOSITION}\end{matrix}\right\} \begin{matrix}\text{set2 [cols1...}\\ \text{[MATCH cols2...]]}\end{matrix}$$

The UNION and XOR commands place in rset rows from set1 and set2; UNION places all rows of set1 and all rows of set2 which are different in the matching columns into rset; XOR places only those rows of either set which are not in both sets into rset. Rows are compared on the basis of named columns from set1 matched up with the named columns from set2. The INTERSECTION (DIFFERENCE) commands place in rset rows from set1 when the specified columns of the row in set1 match (do not match) those of set2. The JOIN and COMPOSITION commands place in rset combinations of rows whose specified columns match. JOIN places all columns of set1 and set2 in rset. COMPOSITION, on the other hand, excludes the matched columns.

$$\begin{matrix}\text{resultset=SELECTION set1 [FOR column1a]}\\ \text{WHERE column 1b} \begin{Bmatrix}\text{EQANYOF}\\ \text{EQALLOF}\end{Bmatrix} \begin{matrix}\text{column2}\\ \text{IN set2}\end{matrix}\end{matrix}$$

For the EQANYOF option, this command places in resultset those rows of set1 for which the value of column1b is equal to any value of column2 in set2. The EQALLOF option partitions the rows of set1 into groups, one group for each distinct value in column1a. If the values of column1b for a group include all the different values of column2 in set2, then that entire group of rows is placed in resultset.

ACKNOWLEDGMENTS

We wish to acknowledge the contributions of Kevin Whitney to the original experimentation, design and implementation of the system. Others who contributed to the design and implementation include Karen Nielsen, Steve Holland and Dick Rawson. We would also like to thank G. G. Dodd for his support of this project and advice during the course of its development.

Query-by-example—Operations on hierarchical data bases

by MOSHÉ M. ZLOOF
IBM Thomas J. Watson Research Center
Yorktown Heights, New York

ABSTRACT

Query-by-Example is a high level non-procedural data base language which provides the end user with a simplified unified interface for *querying, updating, defining,* and *maintaining,* the data base, as well as imbedding various *integrity* and *authority* constraints. When querying the data base the user fills in, through a keyboard display, an example of a possible answer in a skeleton of the logical structure of the data base. As demonstrated in previous work, when the data base is relational, skeleton tables are used. In this paper, we show that the Query-by-Example operations are in fact independent of the structure of the data base. In particular, we demonstrate that if the view at the user interface level is hierarchical, the query is again accomplished by filling-in an example of a possible answer, but, in this case, a skeleton of the hierarchy is utilized. It is, also, shown how the user can map a relational view into a hierarchical view and vice versa, formulating queries that involve both views simultaneously. Finally, a linear version of Query-by-Example is made available for situations where a display facility is unavailable.

INTRODUCTION

Query-by-Example is a high level non-procedural data base language which provides the end user with a simplified unified interface for *querying, updating, defining,* and *maintaining* the data-base, as well as embedding various *integrity* and *authority* constraints. When querying the data base the user fills in, through a keyboard display, an example of a possible answer in a skeleton of the logical structure of the data base. Our main philosophy behind Query-by-Example was to allow the user to learn very little to get started, and keep the number of objects and concepts that has to subsequently be learned, to cover the whole language, at a minimum. And in fact, the results of various behavioral tests conducted in our labs to teach non-programmers the Query-by-Example language[5] showed that in less than three hours the users could ask quite complicated queries as powerful as first order predicate calculus.

Initially, Query-by-Example was started as a query language for relational model of the data base[1,2] as was introduced by E. F. Codd[10,12] but since then it was extended to a whole data base language with facilities to update, define, and maintain the data-base;[3,14] however, to keep the simplicity of the language intact, most of the operations used for querying the data base are kept in use for updating, defining, and maintaining that data base, thus providing the user with only *one* unified interface. For that reason we did not feel it is necessary to change the name of the language for the other modes of operations, such as Define-by-Example or Update-by-Example etc., since the same Query-by-Example operations are also used for these modes.

In this paper we introduce Query-by-Example operations on a hierarchical view of the data base (view being what the user sees at the user interface level, independently of its underlying model—for example, a hierarchical view can be built on top of a relational model of the data). Here a query is again formulated by filling in an example of a possible answer through a keyboard display, but in this case a skeleton of the hierarchical structure is utilized. It is also shown how the user can map a hierarchical view of the data into a relational view and vice versa. This implies that the Query-by-Example operations are independent of the view of the data base be it relational, hierarchical, network, or any combination of the three.

The reason why the user should be given the options to view the data base in the above three different ways are as follows:

—It is sometimes more intuitive for the user to view part of his data base as a hierarchical tree (such as an organizational chart), although the underlying model may be relational.

—Although we are of the opinion, as are many others, that the relational approach which was proposed by Codd, will in the future be implemented on large-scale systems, the current large-scale implementations, however, are primarily hierarchical or network.

Therefore, given a currently standing hierarchical data base model (such as IMS) with a programmer who is already trained to work with such a hierarchical structure, it would be advantageous to be able to replace current procedural data languages (such as DL/1 or GIS) by a high level non-procedural language (such as Query-by-Example) that operates on the *same* hierarchical views of the data base.

While the procedural language programmer *must* have knowledge of the hierarchical structure and access paths of the data base in order to 'navigate' through the tree paths, the Query-by-Example user is only required to have knowledge of the data base structure. The transformation of a non-procedural Query-by-Example statement into a procedure in a lower level language is done by the system through a proper interpreter.

The last reason is that of enhancing performance. If in a given system performance is a major factor, one can enhance it by letting the user view the data base as a hierarchy. Once he is aware that certain paths are more efficient than others, the user may have some control over the performance of the system even though the language is still non-procedural.

A summary of the basic concepts of Query-by-Example as they apply to a relational view of the data base is presented in the second section of this paper. In addition, a linear version is introduced for situations where a display facility is unavailable. In the third section, we introduce Query-by-Example operations on a hierarchical view of the data base. Section four is a combination of the basic concepts of the second and third sections, such that the user can formulate a query concerning both relational and hierarchical views simultaneously. It is also shown how the user can map one view into another. In the fifth section, we comment on how the user can participate in enhancing the performance of the system.

SUMMARY OF THE MAIN FEATURES OF QUERY-BY-EXAMPLE

When dealing with a relational data base, the user basically formulates his query by *filling in* skeleton tables with an example of a possible answer through a keyboard display. In fact, to get started on the system, the user need only distinguish between the following two entities:

1. The 'example element' (variable) which must be underlined and
2. The 'constant element' which should not be underlined.

In addition, the function denoted by 'P.' stands for 'print': the user inserts 'P.' before any data he wishes to be outputted.

A relation is basically a table, and an example of such a table is the employee relation given in Figure 1.

EMP	NAME	SALARY	MANAGER	DEPARTMENT
	ANDERSON	8K	SMITH	TOY
	MORGAN	10K	LEE	COSMETICS

Figure 1—Employee relation

As in Reference 1, the concepts of Query-by-Example are introduced through illustrations of queries and their answers. The queries are drawn from the following relations which are a part of a department store data base.

—EMP (NAME, SAL, MGR, DEPT)

—SALES (DEPT, ITEM)

—SUPPLY (SUPPLIER, ITEM)

—TYPE (ITEM, COLOR, SIZE)

The EMP Table specifies the name, salary, manager, and department of each employee.

The SALES Table is a listing of the items sold by departments.

The SUPPLY Table is a listing of the items supplied by suppliers.

The TYPE Table describes each item by color and size. A sample of the above data base is shown in Figure 2. At this point we are assuming that these tables are made available to the user upon calling them by name.

Actually, in a current implemented prototype,[13] the sequence of user operations in constructing a query is as follows:

EMP	NAME	SALARY	MGR	DEPT
	JONES	8K	SMITH	HOUSEHOLE
	ANDERSON	6K	MURPHY	TOY
	MORGAN	10K	LEE	COSMETICS
	LEWIS	12K	LONG	STATIONARY
	NELSON	6K	MURPHY	TOY
	HOFFMAN	16K	MORGAN	COSMETICS
	LONG	7K	MORGAN	COSMETICS
	MURPHY	8K	SMITH	HOUSEHOLD
	SMITH	12K	HOFFMAN	STATIONARY
	HENRY	9K	SMITH	TOY

SALES	DEPARTMENT	ITEM
	STATIONARY	DISH
	HOUSEHOLD	PEN
	STATIONARY	PENCIL
	COSMETICS	LIPSTICK
	TOY	PEN
	TOY	PENCIL
	TOY	INK
	COSMETICS	PERFUME
	STATIONARY	INK
	HOUSEHOLD	DISH
	STATIONARY	PEN
	HARDWARE	INK

SUPPLY	ITEM	SUPPLIER
	PEN	PARKER
	PENCIL	BIC
	INK	PARKER
	PERFUME	REVLON
	INK	BIC
	DISH	DUPONT
	LIPSTICK	REVLON
	DISH	BIC
	PEN	REVLON
	PENCIL	PARKER

TYPE	ITEM	COLOR	SIZE
	DISH	WHITE	M
	LIPSTICK	RED	L
	PERFUME	WHITE	L
	PEN	GREEN	S
	PENCIL	BLUE	M
	INK	GREEN	L
	INK	BLUE	S
	PENCIL	RED	L
	PENCIL	BLUE	L

Figure 2—Sample data base

The user is initially presented with a display with a blank skeleton table in which he enters through a keyboard, the appropriate table name in the table name field. Upon pressing a function key, the column names are automatically filled in by the system. If needed, a different function key will create additional blank skeleton tables etc. After having on the screen all the required skeletons with their column names, the user proceeds to fill in these tables with elements to satisfy the stipulation of the query. For more details, please see Reference 13.

Let us now proceed with query examples.

Examples:

Q1. Print the red items.

The user fills in the TYPE Table in the following manner.

TYPE	ITEM	COLOR	SIZE
	P.PEN	RED	

Explanations:

Since the query is concerned with red items, RED is a constant element and is, therefore, not underlined. On the other hand, the underlined element PEN is the example element and is entered as an example of a possible answer. Actually, a pen may not necessarily be an element of the data base and can be substituted by DRESS, WATER, or a variable X without altering the meaning of the query. One of the reasons we are using an example element is that it gives us the freedom to use an entity which is partially variable and partially constant (such as PEN, meaning: Print the red items that start with the letter P). Also, for the above simple query, one can dispose of the example element PEN altogether, entering only 'P.'. The SIZE Column can be left blank or filled in with an example element.

Considering the sample data base, the answer to Q1. is:

ITEM
LIPSTICK PENCIL

For cases where a display is not available, a linear version of Query-by-Example, which is a straight forward mapping of the tabular version, is also available, and Q1 in linear form will be written as follows:

Q1. TYPE (ITEM :P.PEN,COLOR :RED)

Q2. Find the department(s) that sell(s) an item(s) supplied by the supplier Parker.

Here the user fills in both the SALES and the SUPPLY Tables as follows.

SALES	DEPT	ITEM
	P.TOY	PEN

SUPPLY	ITEM	SUPPLIER
	PEN	PARKER

ANS:

DEPT
HOUSEHOLD TOY STATIONARY HARDWARE

Explanation:

The example element PEN (linking variable) is included in both tables, implying if an item is sold by the department in question, that same item has to be supplied by Parker.

In linear form Q2 will be written as follows:

Q2. SALES (DEPT :P.TOY,ITEM :PEN)
SUPPLY (ITEM :PEN,SUPPLIER :PARKER)

If the user wishes to retrieve information from two or more tables in the form of a new relation (table), he first sets up a skeleton of the required table by specifying its attributes, and then fills in this skeleton table with linking elements. The assignment of a name to the new relation being outputted is optional. This is illustrated in the next query.

Q3. List the departments and their corresponding suppliers.

SALES	DEPT	ITEM
	TOY	PEN

SUPPLY	ITEM	SUPPLIER
	PEN	BIC

DEPT	SUPPLIER
P.TOY	P.BIC

Explanation:

Here the user groups the two columns DEPT and SUPPLIER to form a skeleton of a table (which may or may not be identified by name). The example element PEN appearing in both the SALES and the SUPPLY tables indicates a natural join on the common domain ITEM.

Q3 in linear form:

Q3. SALES (DEPT :TOY,ITEM :PEN)
SUPPLY (ITEM :PEN,SUPPLIER :BIC)
(DEPT :P.TOY,SUPPLIER :P.BIC)

If the user wishes to save an intermediate relation, which he created from columns of existing ones, for use in subsequent queries, he must assign a name to this relation and precede it by the command 'SAVE.'.

Q4. Create an intermediate table DEPT-SUPP such that it contains all the departments and their corresponding suppliers.

SALES	DEPT	ITEM
	TOY	PEN

SUPPLY	ITEM	SUPPLIER
	PEN	BIC

SAVE. DEPT-SUPP.	DEPT	SUPPLIER
	TOY	BIC

Explanation:

The 'SAVE.' command will save this intermediate relation DEPT-SUPP. The user can now call this table by name and query it in the usual manner. A 'P.' in front of TOY & BIC would cause the system to print out the data (in addition to saving it), which would be the same as the table outputted in Q3. A second command, 'REMOVE.', is used in the same manner as 'SAVE.' to dispose of intermediate relations when no longer required.*

Q4 in linear version:

Q4. SALES(DEPT:TOY,ITEM:PEN)
SUPPLY(ITEM:PEN,SUPPLIER:BIC)
SAVE.DEPT-SUPP(DEPT:TOY,SUPPLIER:BIC)

Q5. Find the name(s) of any employee(s) who earns more than his (their) manager(s).

EMP	NAME	SAL	MGR	DEPT
	P.JONES	>10K	HARRIS	
	HARRIS	10K		

ANS:

NAME
LEWIS HOFFMAN

Explanation:

If HARRIS is an example of such a manager and if HARRIS earns 10K (as an example) then JONES is an example of an employee who earns more than 10K (indicated by the comparison operator "greater than", or ">"), and therefore more than his manager. It should be noted that the order of the rows is immaterial.

The above examples briefly demonstrate the concepts of Query-by-Example. For more details and for reformulation of the queries in predicate calculus, see Reference 1.

Q5 in linear version:

Q5. EMP (NAME:P.JONES,SAL:>10K,MGR:HARRIS)
EMP(NAME:HARRIS,SAL:10K)

OPERATIONS ON HIERARCHICAL STRUCTURES

In this section we assume that the user is familiar with the hierarchical data base model and views the data as a collection of logical hierarchical structures. He formulates his queries by filling in skeletons of the structure of the logical data base through a keyboard display with an example of a possible answer. These skeletons are initially displayed on the screen by entering their name, in much the same manner that skeleton tables are displayed in the case of a relational view.

The Query-by-Example operations are again introduced through illustrative examples, and a linear version of these examples is given for cases where a display facility is unavailable.

Let us consider a sample hierarchical data base taken from "An Introduction to Data Base Systems" by C. Date.[15] Figure 3 illustrates the various data base record types of an educational system whose function is to run a number of training courses. Each course is offered at a number of different locations.

—For each course: course number (unique), course title, course description, details of prerequisite courses (if any), and details of all offerings (past and planned)

—For each prerequisite course for a given course: course number and title

—For each offering of a given course: date, location, format (for example, duration, full-time or half-time), details of all teachers, and details of all students

—For each teacher of a given offering: employee number and name

—For each student on a given offering: employee number, name, and grade

As shown in Figure 3, there are five types of segment: COURSE, PREREQ, OFFERING, TEACHER, and STUDENT, each one consisting of the field types indicated. COURSE is the root segment type; the others are dependent segment types. Each dependent

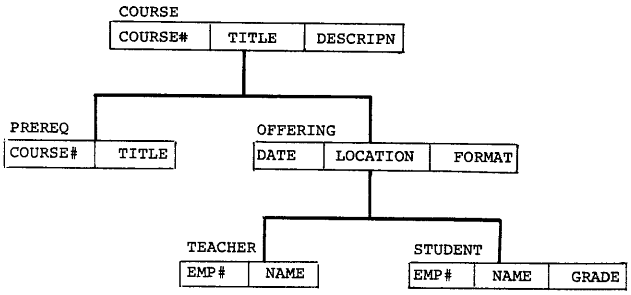

Figure 3—The education data base record type

* The 'SAVE.' & 'REMOVE.' commands were not included in the original version of Query-by-Example. They will be added to the revised version which will be published soon.[14]

has a parent—for example, the parent of TEACHER (and STUDENT) is OFFERING. Similarly, each parent has at least one child—COURSE, for example, has two.

Figure 4 illustrates specific instances (occurrences) of the data base. For example, COURSE M23 has three OFFERING occurrences, in Oslo, Dublin and Madrid. Madrid's OFFERING, in turn, has three STUDENT and one TEACHER occurrences.

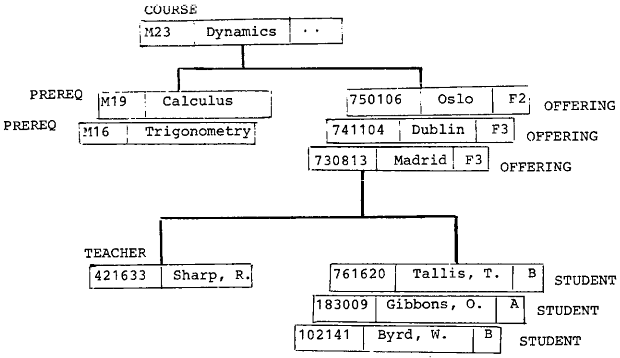

Figure 4—Sample occurrence for the education data base

We now proceed with examples of queries on this data base, some of which are also taken from Reference 15.

Q6. Get the dates of all the OFFERING occurrences where the location is Stockholm.

The user fills in the skeleton of the logical data base as follows:

COURSE

COURSE #	TITLE	DESCRIPTION

OFFERING

DATE	LOCATION	FORMAT
P.	STOCKHOLM	

Explanation:

Since there are no conditions on the COURSE fields, they are either left blank or filled in with example elements (underlined); the same is true of the DATE and the FORMAT fields in the OFFERING segment. STOCKHOLM is, therefore, the only specified constant element. The function 'P.' under the DATE field indicates that we want the dates to be printed out.

Linear version:

Q6. COURSE
COURSE;OFFERING(DATE:P. ,LOCATION: STOCKHOLM)

Explanation:

The segment name COURSE in the first row specifies the root of the logical data base. The segment name COURSE in the second row followed by a semicolon indicates that COURSE is a parent (not necessarily the immediate parent) of the OFFERING segment. The condition Stockholm Location and the function 'P.' are specified in the parentheses. It should be pointed out that since the system has the knowledge of the logical data base, in this case it is sufficient to simply put the query in the following short form.

OFFERING(DATE:P. ,LOCATION:STOCKHOLM)

The system will be able to trace the OFFERING segment to its parent segment. We originally specified the COURSE segment for clarity, so that the user will get the feel for the hierarchical tree.

Q7. List the names of all the students who achieved grade A where the offering location is Stockholm.

COURSE

COURSE #	TITLE	DESCRIPTION

OFFERING

DATE	LOCATION	FORMAT
	STOCKHOLM	

STUDENT

EMP #	NAME	GRADE
	P.ED	A

Linear version:

Q7. COURSE

COURSE ;OFFERING(LOCATION: STOCKHOLM)
OFFERING;STUDENT(NAME:P.ED,GRADE: A)

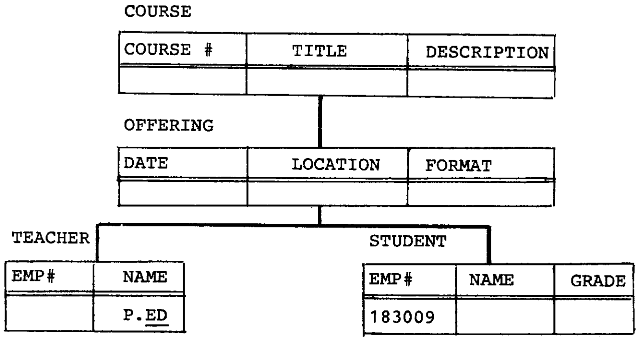
It should be noted that the sequence of the rows is immaterial. Furthermore, as the above examples illustrate, in this language, whether in the graphical or in the linear form, the user simply has to state *what* he requires to be retrieved; he does not have to be concerned with particular hierarchical sequences or hierarchical paths of the data base. In a procedural language, on the other hand, the user has to be concerned with hierarchical sequences of the data base, so that he can 'navigate' through the tree paths. As an example, let us reformulate this query in a simplified version of the DL/1 Language, which is the data sublanguage for IMS.

Q7 in DL/1 is classified as a *sequential retrieval with a conditional segment search argument* (SSA).

```
        GU  COURSE
            OFFERING
              (LOCATION='STOCKHOLM')
            STUDENT     (GRADE='A')
    NSA GN  STUDENT     (GRADE='A')
        go to NSA
```

Here the user has to be familiar with the IMS search paths in order to structure the query accordingly. In the cases where the search is forward, the formulation of the query is relatively easy; however, it becomes much more complex when a backward search path is required. One can say that here "the user is forced to devote time and effort to solving problems which are introduced by the model and are not intrinsic to the questions being asked."[15]

Q8. Get the teacher's name of an offering (of any course) attended by student 183009.



COURSE

COURSE #	TITLE	DESCRIPTION

OFFERING

DATE	LOCATION	FORMAT

TEACHER

EMP#	NAME
	P.ED

STUDENT

EMP#	NAME	GRADE
183009		

Explanation:

Here the STUDENT occurrence (EMP# 183009) and the required TEACHER occurrence *must* be linked to the same OFFERING occurrence. This link is indicated by a line connecting the three segments and can be thought of as having two relations, OFFERING-STUDENT relation and OFFERING-TEACHER relation, linked by example elements as follows.

OFFERING			TEACHER	
DATE	LOCATION	FORMAT	EMP#	NAME
x	y	z		P.ED

OFFERING			STUDENT		
DATE	LOCATION	FORMAT	EMP#	NAME	GRADE
x	y	z	183009		

Note that the *x y z* links indicate that the TEACHER and the STUDENT have the same parent OFFERING.

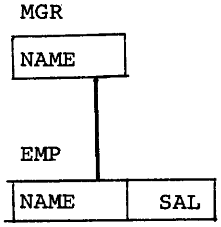
Q8 in DL/1 is classified as *use of command code F* query.

```
       GU   COURSE
    NO GN   OFFERING
       GNP  STUDENT(EMP#='183009')
       if not found go to NO
       GNP  TEACHER*F
```

Explanation:

In IMS, certain command codes are introduced to give the language more flexibility for such cases as when the user wants to search the path *backwards*. Q8 is an example of such a case. If we used GET NEXT WITHIN PARENT (GNP) TEACHER (without the code "*F"), the answer would be "segment not found", since the search would be in a *forward* direction and teachers precede students in the hierarchical sequence. What is required is a means of stepping *backwards* under the current parent and this is accomplished by the code "*F".

When we wish to relate segment occurrences to two or more occurrences of the same parent we have to qualify these parents accordingly. This is illustrated in the next example. Consider the following data base.



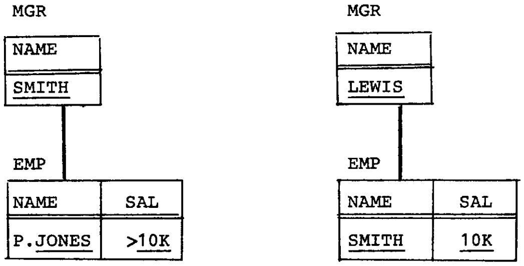
MGR

NAME

EMP

NAME	SAL

Q9. List the employees' names who earn more than their managers (same as Q5.).



MGR

NAME
SMITH

EMP

NAME	SAL
P.JONES	>10K

MGR

NAME
LEWIS

EMP

NAME	SAL
SMITH	10K

Explanation:

Here a separate skeleton is used for each occurrence of the MGR. The line connecting SMITH and JONES indicates that SMITH is JONES' manager. In order to find SMITH's salary we have to search for SMITH in an occurrence of the EMP segment; however, SMITH in the EMP segment has a manager of his own (say LEWIS) as indicated by the connecting line.

Linear version:

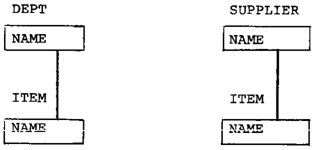
```
Q9.                  MGR(NAME:SMITH)
   MGR(NAME:SMITH);EMP(NAME:P.JONES,
                       SAL:>10K)
                     MGR(NAME:LEWIS)
   MGR(NAME:LEWIS);EMP(NAME:SMITH,
                       SAL:10K)
```

Explanation:

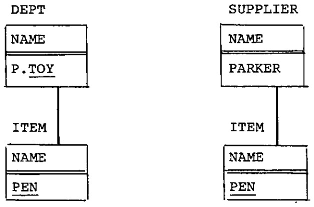
The manager qualified by the name SMITH is the parent of the employee whose name we wish to be printed out, and the manager qualified by the name LEWIS is the parent of the employee SMITH.

Note that here we cannot dispose of parent qualifications, without which the system will not be able to relate an employee to his manager.

The next query is an example of relating two different Logical data bases. Consider the following two data bases.



Q10. List the department names that sell items supplied by Parker (same as Q2.).

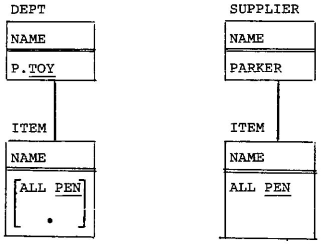


Linear version:

```
Q10.         DEPT(NAME:P.TOY)
       DEPT;ITEM(NAME:PEN)
             SUPPLIER(NAME:PARKER)
   SUPPLIER;ITEM(NAME:PEN)
```

We will end this section by a query that requires universal quantification.

Q11. List the department(s), each of which, sells *all* the items supplied by Parker.



For more details see Reference 1.

Linear version:

```
Q11.          SUPPLIER(NAME:PARKER)
    SUPPLIER;ITEM(NAME:ALL PEN)
              DEPT(NAME:P.TOY)
        DEPT;ITEM(NAME:[ALL PEN,.])
```

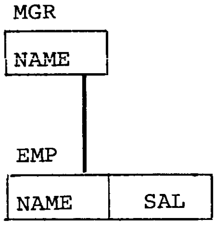
MAPPINGS

In this section we demonstrate how the user can map a hierarchical (H) view to a relational (R) view and vice versa. An example of a query involving both views simultaneously is given.

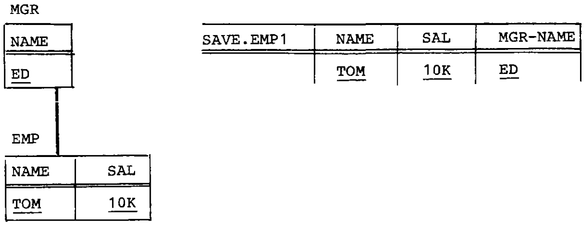
a. Mapping a hierarchical to a relational view

(H→R)

Consider the following data base.



Q12. Convert the above data base to a relation called EMP1 and save it.



Linear version:

```
Q12.      MGR(NAME:ED)
    MGR;EMP(NAME:TOM,SAL:10K)
          SAVE.EMP1(NAME:TOM,SAL:10K,
                    MGR-NAME:ED)
```

If we just want a printout in the form of a relation, without being concerned with saving it, we fill in the following skeleton.

NAME	SAL	MGR-NAME
P.TOM	P.10K	P.ED

Linear version:

(NAME:P.TOM,SAL:10K,MGR-NAME:P.ED)

This is consistent with the examples in Q3 and Q4.

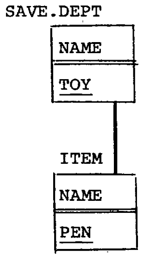
b. Mapping a relational view into a hierarchy

(R→H)

Consider the SALES relation in Figure 2.

Q13. Construct and save a hierarchical view from the SALES relation, where the root segment is DEPT.

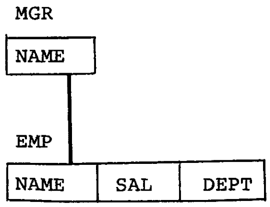
SALES	DEPT	ITEM
	TOY	PEN



Linear version:

Q13. SALES(DEPT:TOY,ITEM:PEN)
SAVE.DEPT(NAME:TOY)
DEPT;ITEM(NAME:PEN)

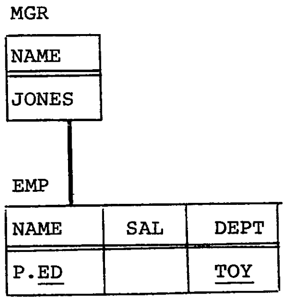
Consider the following data base which combines hierarchical and relational views.



SALES	DEPT	ITEM

The following query is formulated using both views simultaneously.

Q14. Find the employees who are managed by Jones and work in a department that sells pens.



SALES	DEPT	ITEM
	TOY	PEN

Linear version:

Q14. MGR(NAME:JONES)
MGR;EMP(NAME:P.ED,DEPT:TOY)
SALES(DEPT:TOY,ITEM:PEN)

PERFORMANCE CONSIDERATIONS

Where the performance of the system is a major factor, and it is particularly so when the data base is large, one can improve the performance by making the user cognizant of the fact that certain paths are more efficient than others; this will probably encourage him to use a more efficient approach. For example, take the TYPE relation that has ITEM and COLOR as column names and consider the following two queries.

Q15. Find the red items.

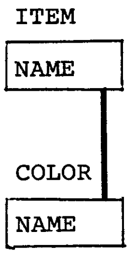
TYPE	ITEM	COLOR
	P.	RED

Q16. Find the colors of ink.

TYPE	ITEM	COLOR
	INK	P.

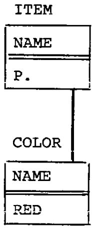
The above two queries are completely symmetric (which is, of course, one of the merits of the relational approach).

We now view the above data base as hierarchical with the ITEM segment as the root.

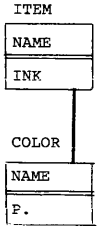


Q15 and Q16 will look as follows.

Q15.



Q16.



If the user is told that queries involving an "upward" search path, such as Q15, are less efficient than queries requiring a "downward" search path, such as Q16, he will then try to keep the number of queries formulated in the form of Q15 to a minimum. If many queries inevitably involve the same upward path, he may improve the performance by constructing another logical data base which is the inverse of the first, thus diverting the search to a downward path.

This is just a simple example of how the user can participate in the performance. It remains to be seen whether this concept can be generalized to a practical size data base, involving queries of a practical complexity.

CONCLUSIONS AND REMARKS

In this paper we demonstrated that Query-by-Example operations are independent of the view of the data base.

The feature of printing-out part of the data (such as, 'only one element' or 'the first five') is yet to be embedded in Query-by-Example. At present the 'P.' operator means 'print all the elements'. It may be possible to specify the number of elements to be printed out following the 'P.'. Example: 'P.(1)PEN' will print out one item, and 'P.(5)PEN' will print the first five items, etc.

The feature of ordering the outputted set is also not as yet included in Query-by-Example.

ACKNOWLEDGMENTS

To Peter deJong I am most grateful for his helpful discussions, suggestions, and interest throughout the preparation of this paper.

I also wish to thank my wife Rosy for correcting the manuscript and for many helpful suggestions.

A virtual memory system for a relational associative processor

by S. A. SCHUSTER, E. A. OZKARAHAN and K. C. SMITH
University of Toronto
Toronto, Ontario, Canada

ABSTRACT

The Relational Associative Processor (RAP) is an experimental "backend" cellular processor for implementing data base management systems. RAP is particularly well suited to supporting Codd's relational model of data. The capacity of a RAP device implemented with current IC and memory technology can be estimated to contain 10^8 to 10^9 bits of associatively processable data. Because many data bases are larger, a virtual memory environment for RAP has been proposed and its performance simulated. The environment incorporates conventional memories for bulk storage and a single RAP processor—both controlled by a general purpose front-end computer. The system requires that the entire relational data base be divided into pages of size equal to one RAP cell memory. A buffer memory is added to RAP to permit the overlap of paging with processing. It has been found that user environments containing small relations or queries exhibiting either long processing times relative to paging requirements or some "locality" (defined as the degree to which sequences of queries reference some relations more than others) can efficiently page data between large data bases and data base machines without significant losses in performance.

INTRODUCTION

The relational model of data is an important approach to data base management because it presents its user with a simple, consistent, and operationally complete view of data.[1] However, its high-level user-oriented view creates serious problems for efficient generalized implementation on conventional hardware. We briefly review the relational model and a special purpose peripheral processor called RAP which is designed to provide high performance relational data base operations.[2–4] A small prototype version of RAP is being implemented at the University of Toronto. This paper concentrates on the problem of using RAP to support large relational data base applications. To do this, we propose several architectural extensions and a software support system to create a virtual memory environment for a RAP processor. A model of the virtual memory environment has been simulated and the results are presented and analyzed.[5]

THE RELATIONAL ASSOCIATIVE PROCESSOR "RAP"

A relation can be viewed as a table whose rows contain data about a set of similar entities. The table's or relation's name identifies the set of entities being described and the column headings are the names of the attributes which are used to describe the characteristics of each entity. Each row contains an n-tuple of values—one for each attribute—which uniquely describe each entity. The set of values that can be taken by an attribute is called a domain. A relational data base is composed of a collection of time-varying relations that may change because of modifications, insertions, and deletions. Several relations can be interrelated through common domains to formulate complex queries.

The Relational Associative Processor (RAP) is an experimental "backend" non-numeric processor designed to efficiently implement data base management systems. Its architecture and instruction set is particularly well suited for supporting the relational model of data. In addition, recent research indicates that RAP is sufficiently generalized to support set-oriented hierarchical and network views of data. This paper concentrates on RAP's relational aspects.

RAP architecture is based on the observation that relational operations of search, retrieval, statistical computation, and update are inherently associative and set-oriented. The basic organization of RAP is shown in Figure 1. The design incorporates an array (i.e., parallel set) of circularly connected associative cellular processors which are driven by a central controller and statistical processor. A RAP instruction is a data base operation which is executed by each cell in parallel directly on the cell's memory. Each cell is composed of a microprocessor and a sequential circulating memory (e.g., a track of a drum or disk, CCD's, bubble memories, etc.). The rows of a relation are stored as blocks of data on one or more cell memories. The RAP data structure allows rows to be duplicated.

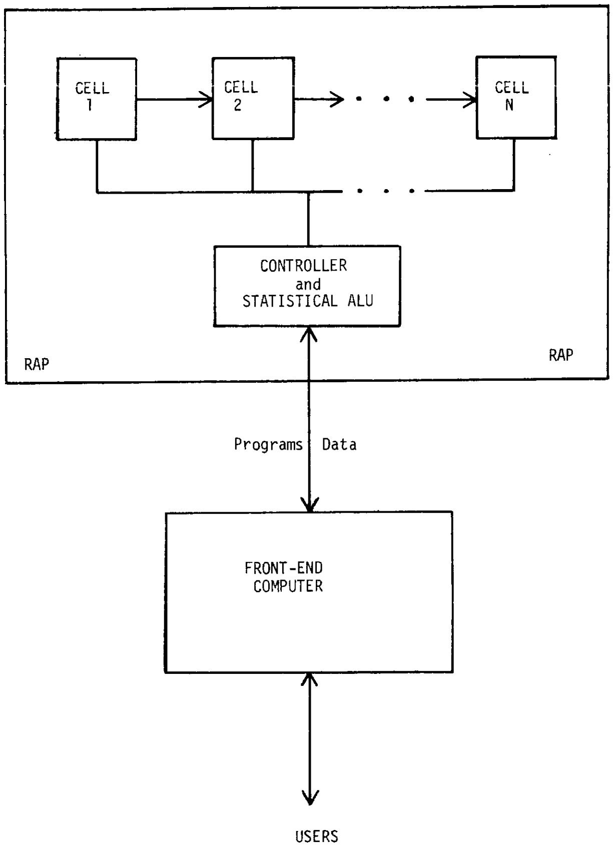

Figure 1—Basic organization of RAP architecture

Relational queries can often be constructed from just a few RAP primitives and often only a single RAP primitive is required. The RAP system is designed to execute its most important instructions within one parallel rotation of the cell memories. Because operations are accomplished in parallel on the entire storage, RAP is an effective associative processor providing significant search and manipulation efficiencies. That is, RAP accomplishes relational data base management without complex data structures and software aids such as inverted lists and hashing for multi-key searching required in conventional systems. This is especially important for applications which have extensive update activity. The extra indices and ordering requirements must be maintained whenever an update occurs in a conventional data base system. In RAP, only the relation itself has to change and this is accomplished directly on the data without having to move any portion of the data base to the front-end processor.

An analytical model was constructed which compared the performances of RAP to a conventional data base management system.[4,6] The model considered resident data bases for RAP and fast access paths in the form of inverted lists for the conventional system. The results showed that significant gains in query execution speed can be achieved by the RAP architecture over the conventional system even if it uses fixed-head disk memories. The model includes queries of the form: simple Boolean selection retrievals or updates, retrievals including statistical criteria in the query qualification, and retrievals involving implicit joins. This study indicates that, under many circumstances, on-line retrieval and updates of large data bases may only be possible with the aid of RAP-like systems.

The concept of providing large scale associative processors and memories for data base management are also currently being explored by others.[7-10] These devices are generally referred to as "data base machines". Most of the discussion to follow may also be applicable to the general theory of data base machines.

The maximum capacity of a single data base machine implemented with current IC and memory technology can be estimated to contain from 10^8 to 10^9 bits of associatively processable data.[4] Data compression, of course, should be exploited. This capacity may be sufficient for many applications but there are others which require larger storage. The costs of data base machines may not permit them to be casually duplicated when larger storage is required. This then raises the question as to what architectural extensions and software techniques can be explored to efficiently extend the address space of RAP-like data base machines. A virtual memory system for RAP is proposed which incorporates conventional disk memories for bulk storage and a single RAP processor—both controlled by a front-end general purpose computer.

RAP ARCHITECTURE FOR LARGE RELATIONAL DATA BASES

The need for the virtual memory system arises when the data base is larger than RAP memory capacity. However, it is assumed that all the pages for a query can be contained within RAP memory. This assumption is reasonable in light of the expected memory capacity for RAP (10^8 to 10^9 bits). For applications requiring very large relations, partitioning of large relations into smaller ones containing the same columns may be required. This would require a user to create a sequence of tasks to process several subqueries over the smaller relations and assemble or interrelate their results.

The proposed virtual memory system requires that the entire data base be divided into fixed size pages equal to the capacity of one cell. A page contains rows from only one relation. Each page has a unique identification. Therefore, the set of rows for a complete relation can be specified by indicating the pages that contain the rows.

The extensions to RAP architecture for implementing a virtual memory system are displayed in Figure 2. In this configuration, the front-end general purpose computer contains a virtual memory monitor and acts as an I/O interface for paging data between conventional bulk memories (e.g., direct access secondary memory devices) and RAP. A large portion of the data base resides on the bulk memories and only the "working set," that is the collection of pages containing the relations required by the currently processing queries, resides in RAP memory.

In order to reduce paging overhead, overlapping of paging I/O with query processing is essential. To achieve this, each cell has been extended to contain two memory components. At a given time, one serves as the active or processor memory while the other acts as the buffer or alternate memory. The memory serving as the active memory is used in query processing while the other acts as the I/O buffer to permit paging to take place concurrently with query processing. The roles of the memories can be reversed for each cell independently as required during the operation of the system. Thus, RAP logically contains two cyclic memories—one serving as the active associative memory while the other is a buffer. The hardware logic for switching between cell memory pairs has been designed in detail for RAP.[4] The extra logic required for doing this adds little to the complexity of the overall system.

The RAP controller is still connected to the front-end computer via a dedicated channel to receive programs and transfer results of users' requests. However, the current buffer is driven by a separate I/O controller which is connected to the front-end computer by a separate channel. The paging to and from the buffer is accomplished by standard channel programs before a new query is processed.

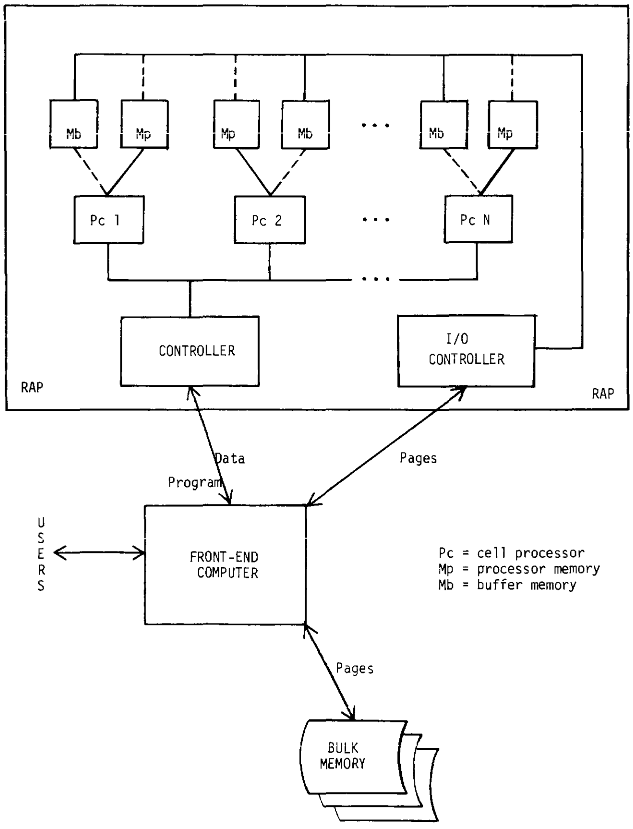

Figure 2—Hardware architecture of the virtual memory system

The paging for a waiting query is overlapped with the processing of a currently executing query. Lookahead paging is possible because RAP associatively processes all the pages of the relations referenced in a query. Since each query must specify which relations are to be processed, it specifies which pages are to be processed at the same time. Once the required pages are transferred and execution of the current query is finished, the roles of the memory pairs can be switched.

There are two other features of the RAP design which are not shown in Figure 2 that help to increase the efficiency of the virtual memory system simulated in this study. They are the fast read-out scheme and the multiprogramming facility.[4] The fact read-out scheme for retrieval queries interleaves selected tuples from different cells during a memory revolution to maximize the channel utilization. The multiprogramming facility allows queries to be divided into two priority classes and executes them with respect to a preemptive scheduling discipline to provide a foreground-background query execution facility. This allows the RAP processor to control query execution by not allowing a long query to tie-up the device. The logic for implementing hard-wired two-task multiprogramming requires the duplication of less than 10 percent of the cell hardware.[4]

A VIRTUAL MEMORY SYSTEM

Locality

The virtual memory system to be discussed is designed to exploit user characteristics that affect total system performance with respect to paging. In conventional virtual memory systems, the important property of locality of address references in a user program is used to reduce paging. In an analogous way, we define "locality of query references" or simply "locality" as a phenomenon which is manifested by a nonrandom distribution of references to the relations in a data base during the execution of a sequence of queries. High locality is reflected when a small subset of the relations in a data base are referenced more often than the other relations, i.e., the frequency of relation reference is described by a distribution with low variance. The effect of varying degrees of locality is studied in the simulation.

Unfortunately we lack experimental data and are not aware of any studies performed in connection with locality in relational data bases. However, we will present some ad hoc arguments for its existence. Locality will be loosely examined with respect to four classes or environments of processing.

There are many data processing tasks that occur in a reservation system environment such as for hotels, airlines, shipping, etc. As a deadline approaches for an entity, e.g., the scheduled time for a plane flight, the activity in the data base is expected to become concentrated within the area representing this entity. If there exists a relation for each flight which records the passenger reservations for a particular flight, then the access to those relations scheduled to depart shortly will have greater frequency of reference resulting in high locality.

A second argument for high locality is that the use of high level interactive query languages encourages "browsing". In such an environment, a user can interactively search for relevant data by step-wise refinement of queries on the same relations. The iterative refinement of queries can cause the same relations to be accessed repeatedly during a short period of time.

In a data processing environment using batch multiprogramming, we expect that queries are generated within the constructs of host language programs. These programs are usually involved in the generation of complex reports or batch updating. The logic of such programs is often repetitive which cause queries to be embedded within program loops. This could cause sequences of queries to concentrate references over a subset of the relations in the data base.

A fourth argument for high locality is that certain relations may play an important role by interrelating other relations. These relations have a high percentage of attributes whose domains are common to other relations. These relations must be referenced extensively to link data in different relations in the formulation of many queries. Because these "linking relations" may be referenced often, queries over such a data base could exhibit high locality.

The system presented was designed to exploit high locality characteristics when they exist. The results will show that a modest amount of locality can greatly extend the processing efficiency of a data base machine for processing data bases which are large relative to the capacity of the machine's memory.

The virtual memory system structure

The principal modules and data flow of the virtual memory system are shown in Figure 3. The overall control of the system is concentrated in a central MONITOR. The MONITOR is also responsible for communicating the block of individual operations of a query to drive the RAP processor.

As jobs enter the system they are classified by the CLASSIFIER module as either class-1 or class-2. Class-1 jobs are queries that have high priority and are to be processed uninterrupted such as on-line retrievals or any update. Class-2 jobs are retrieval queries with long processing times which can be run in the background, interrupted by class-1 jobs, and then resumed when no class-1 jobs are waiting to be processed. We will assume that all class-2 jobs can be resumed from their point of interruption regardless of possible effects of an intervening class-1 update job. If the semantics of the query is such that it must be completed in its entirety before any of its relations can be updated, it would be classified originally as a class-1 job. The data for each job that determines its class can be either found by examining the query's instructions or by user specified parameters. We further assume that all jobs classified as class-1 can be reordered during a small segment of time. (This policy has been made over-simplistic for purposes of the simulation. It is acknowledged that updates must often execute in a specific order.)

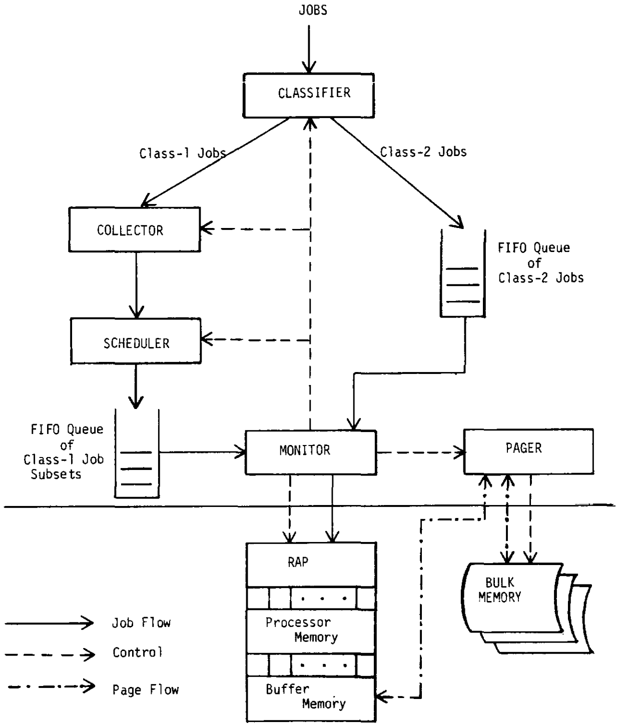

Figure 3—Structure of the virtual memory system

After classification, class-2 jobs simply enter a class-2 FIFO queue. Class-1 jobs, however, are kept in a job pool by the COLLECTOR module. Under the direction of the MONITOR, all class-1 jobs in the pool will be released to a module called the SCHEDULER. Two policies have been suggested for controlling the COLLECTOR. Only the first has been simulated. In this case, class-1 jobs are collected as long as there exist previously scheduled class-1 jobs that are waiting and/or processing. When such jobs no longer exist the COLLECTOR releases its jobs to be scheduled. If no class-1 jobs have been collected, then the current class-2 job is started or resumed if a preempted one exists. The class-2 job is allowed to process until the next class-1 job is received and preprocessed. The single class-1 job is immediately scheduled and, when its paging requirements have been satisfied, it then preempts the class-2 job and acquires the processor.

The second policy is to let the COLLECTOR collect jobs for a fixed amount of time which would be determined by the MONITOR. In retrospect, it is felt that this would have given better results because larger pools will be presented to the SCHEDULER which is designed to exploit high locality by reducing page faults through job reordering.

The SCHEDULER receives the pool of class-1 jobs and orders them by first finding the job which causes the least amount of page faults with respect to the current contents of RAP memory. This can be done because the relations referenced in the queries are known by the MONITOR. It continues to order the rest of the jobs by finding the next job whose pages most overlap RAP and so on. The ordered pool of jobs are then partitioned into an ordered set of job subsets such that all the relations for each subset can be contained within the data base machine memory. The ordered subsets are then placed in a FIFO queue to wait for the processor.

The final module to be discussed for the virtual memory system is the PAGER. It is responsible for the paging or buffering strategy and the page replacement policy. Paging is performed on a non-demand basis. This is possible because the pages required by a subset are known before processing starts. The demand paging philosophy encountered in programming systems does not apply here, because, having job subsets sitting in the queue, one can start the processing of a current subset and at the same time start paging data into the buffer for the following subset. This scheme is aimed at reducing the average amount of idle processor time that a subset causes due to paging.

The replacement policy for pages in the data base machine memory is to first replace any pages that have not been updated and are not referenced by jobs in the ordered subsets waiting in the queue. If more space is required, then those referenced farthest in the job subset are replaced. An actual page-out occurs only if the replaced page was updated, otherwise it is simply overwritten in the buffer. Page-outs occur after the role of the cells' memories, which contain the pages to be replaced or paged-out, are switched from active memory to buffer memory.

The effectiveness of the SCHEDULER and PAGER in exploiting locality is measured by an index called "system locality (SLOC)". SLOC is defined as follows. Let pg[i] be the number of unique pages that are required by subset i and pgcom[i] be the number of pages in common between subset i and the contents of RAP memory at the time when paging for subset i is to take place. Thus,

$$\text{SLOC} = \sum_{i=1}^{n} \text{pgcom}[i] / \sum_{i=1}^{n} \text{pg}[i]$$

for i = 1,2, . . . , n consecutive class-1 job subsets. The system locality will be near one for environments requiring little paging between subsets and near zero for environments requiring excessive paging. System locality depends on the degree of locality, the number of pages in the entire data base relative to the number of pages that can be contained in RAP memory, and the size of the relations in the data base.

SIMULATION OF AN ON-LINE ENVIRONMENT

Lacking experimental user data, an on-line environment has been hypothesized and simulated for the described virtual memory system.[5] The data base machine is modelled with the expected parameters for a moderately large size RAP processor. The simulation was coded in GPSS on an IBM 370/165.

The on-line environment

The application environment studied could be conceptualized either as an on-line reservation system for hotels or airlines or a parts distribution and inventory system. Most of the jobs fit the class-1 description with a few class-2 background batch jobs representing management reporting, billing, financial accounting, payroll, etc. The arrival rate of queries is fast and most require short processing times. Most queries involve only a few relations. The following is a list of parameters used in the experiments. The times are given in terms of the number of revolutions or circulations of the RAP memory.

RAP:

(a) 1 revolution (rev) = 50 milliseconds
(b) RAP processor = 200 cells
(c) RAP memory capacity = 400 pages
(d) active memory = buffer memory = 200 pages
(e) page size = $0.5*10^6$ bits
(f) paging rate = 1 page/rev

Data base:

(a) total data base size = 2000 or 5000 pages
(b) number of relations for short jobs = exponential (mean = 1.5 relations)
(c) number of relations for long jobs = exponential (mean = 3 relations)
(d) number of pages per relation = 5, 10, 20, or 25 pages

Locality:

(a) low—modelled by a uniform distribution
(b) medium—modelled by an exponential distribution
(c) high—modelled by a hyperexponential distribution

As each job (query) is generated in the simulation, one distribution is referenced, depending on the locality being simulated, to determine the relations needed by the job.

Arrival and processing time distributions:

(a) job interarrival time=Poisson (mean=40 rev/job)
(b) processing time for short jobs=exponential (mean=4, 8, 16, or 32 rev)
(c) processing time for long jobs=Erlang-2 for class-2 and exponential for class-1 (both with mean=104 rev)
(d) processing time for class-1 jobs=hyperexponential (due to (b) and (c))
(e) processing time for class-2 jobs=processing time for long jobs (due to (c))

Job proportions:

(a) proportion of class-1 vs. all jobs=0.90
(b) proportion of updates vs. all jobs=0.40
(c) proportion of long updates vs. all jobs=0.03

The above parameters were chosen in such a way as to create a system load which guarantees that a class-1 and/or class-2 job would almost always be present in the job mix. Thus, the RAP processor in this experiment would rarely be idle due to empty job queues. However, idle processor time would be caused by extensive paging requirements.

Simulation results

The goal of this study was to determine the relative effects on the average time-in-system, referred to as the response time, for a class-1 job when the following were varied:

(a) short job mean processing time
(b) number of pages per relation
(c) locality
(d) data base size

Also studied was the effect of these variables on system locality which reflects the paging performance from the system's point of view.

Figure 4 shows the effects of processing time for short jobs (proctime), locality, and data base size (dbsize) on RAP system response for class-1 jobs. For this experiment the number of pages for a relation was fixed at 10. The response time, RTIME, indicates the average time a class-1 job spent in the system. The results can be approximately summarized as a family of straight lines of the form "y=a*x+b". For the experiment we get:

RTIME:=proctime+((log dbsize)/locality)

where ":=" means "proportional to." That is to say, response time is directly proportional to processing time, as would be expected, with an upward shift depending on locality and data base size. The line "y=x" is shown because it represents the theoretical optimum for the environment simulated. The average response time can never be less than the average time it takes to process a job.

The somewhat linear upward shift in the curves away from the optimum is due to idle processor time because of paging. The paging requirements are reduced by high locality, but increased in a diminishing way (this will be explained later) when the total data base size grows larger relative to RAP memory capacity.

It should be noted that the curves slowly converge toward the optimum for longer processing times. This is to be expected since the number of pages for a relation are fixed in this experiment. Longer processing times allow more paging to overlap with processing and, when the processing times are long enough, there will be time to do all paging before the next job subset is to be processed.

Figure 5 shows the effects of relation size in terms of the number of pages (npgrel), locality, and data base size (dbsize) on RAP system response time for class-1 jobs. For this experiment the average processing time for a short job was set at 8 revolutions. The results can be summarized as follows:

RTIME:=((log dbsize)/locality)*npgrel+proctime

That is to say, response time is directly proportional to the size of relations and the slope of the relationship is affected by locality and data base size. The line "y=proctime" is shown since it represents the average experimental optimum as discussed earlier.

The fact that response time is directly related to the

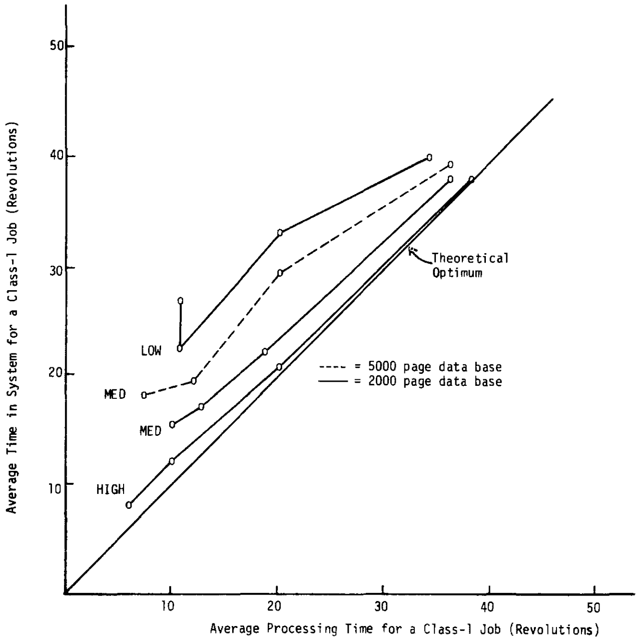

Figure 4—The effect of locality, processing time, and data base size on system response

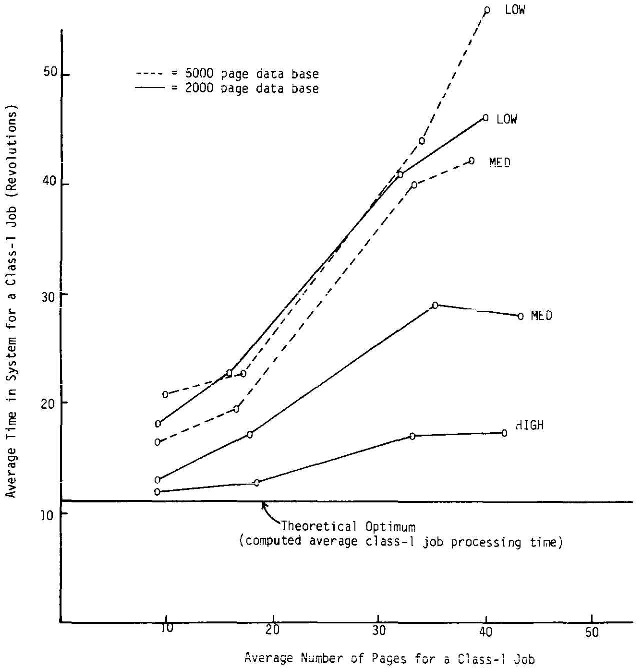

Figure 5—The effect of relation size, locality, and data base size on system response

average number of pages occurring in relations of the data base is not surprising. Since all pages of a relation are required to be in RAP memory to be processed, the more pages required, the more paging is to be expected. Given a fixed average processing time, we expected and also observed that response is degraded when large relations must be paged.

However, the effect of locality can be profound because it affects the slopes of the response time curves. When the locality is higher, there is a good chance that some of the relations currently in RAP memory will be needed by the following job subset. Therefore, the effect of paging larger relations will not be so dramatic.

Data base size also affects the slope of the response time curves. As the data base gets larger relative to RAP memory, the effect of locality is diminished. That is, the same pattern of locality will be spread over more relations causing the locality to appear more random. It should be noticed that for the low (random) locality curve, the effect of increasing the size of the data base was very small. It is observed that paging due to random locality will be independent of data base size. When extensive paging is required because of random reference, it does not matter what size of pool contains the pages.

Figure 6 shows the effects of these experiments on the average system locality (SLOC). The data from which these curves are derived also showed that system locality is independent of a job's processing time or relation size for a fixed locality distribution. The results can be summarized as follows.

SLOC := (1/(log dbsize))*locality

That is, the higher the locality the better the system will perform since less paging will be expected. However, as the data base size grows, the effect of locality will diminish and performance will approach that of a random locality environment.

SUMMARY AND CONCLUSIONS

The Relational Associative Processor (RAP) is an experimental "backend" non-numeric processor for implementing a data base management system which supports Codd's relational model of data. RAP architecture is based on the observation that relational operations of search, retrieval, statistical computation, and update are inherently associative and set-oriented. The design incorporates an array (i.e., parallel set) of interconnected associative cellular processors which are driven by a central controller and statistical processor. Each cell is composed of a microprocessor and a sequential circulating memory (e.g., a track of a drum or disk, CCD's, bubble memories, etc.). Each data base operation is executed within the cells which operate in parallel directly on their memories. RAP accomplishes a complete set of data base operations without the need for indexing and its associated software and maintenance.

The capacity of a RAP device implemented with

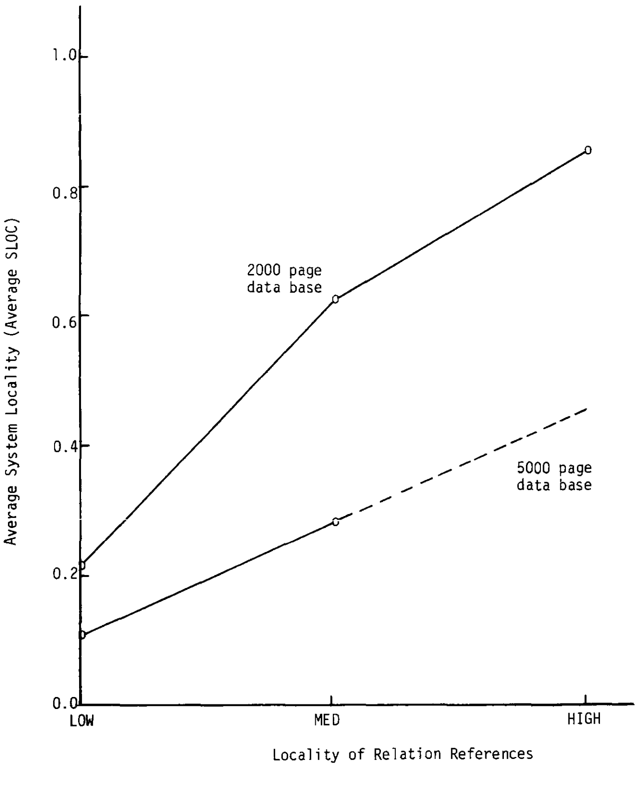

Figure 6—The effect of locality and data base size on system locality

current IC and memory technology can be estimated to contain from 10^8 to 10^9 bits of associatively processable data. Because of this limitation, a virtual memory environment for RAP has been proposed and its performance simulated. The environment incorporates conventional memories for bulk storage and a single RAP system—both controlled by a front-end computer. An entire relational data base is divided into pages of size equal to one RAP cell memory. A buffer memory is added to RAP to permit the overlap of paging with processing.

Each RAP program represents one relational query (job) on one or more relations. The system maintains an ordered queue of waiting queries. Before the next selected query is processed on RAP, a table look up is made to determine if all the pages for the query are present in RAP memory. If any pages are not currently residing in RAP, they are paged in replacing the pages for the relations referenced farthest in the job queue and/or those not needed at all such that pages that have not been modified are replaced first. The jobs waiting to be processed are scheduled by ordering them into a queue in such a way that paging is reduced. It has been found that user environments which contain small relations or process queries exhibiting either long processing times relative to paging requirements or some "locality of relation reference," can efficiently page data between large data bases and data base machines without significant losses in performance.

ACKNOWLEDGMENT

The authors are happy to acknowledge the contribution of Raymond Nakano who developed the simulation program and made many valuable comments throughout the preparation of this paper.

This work has been supported by the Federal Department of Communications, the Department of Supplies and Services, and the National Research Council of Canada.

Managing the census data base—Data description, acquisition, and manipulation

by JAY-LOUISE WELDON
New York University
New York City, New York

ABSTRACT

The U.S. Bureau of the Census collects and maintains a broad base of socio-economic and demographic data on population and housing in the United States. Summarizations and statistical information from this data base are made available to the public in printed reports. In addition, portions of the data are made available in machine-readable form, and thus are appropriate input for further research studies.

For most potential users, however, many obstacles exist in making use of the machine-readable Census data. These obstacles may be classified into three areas: the identification and selection of relevant data items from the available data to support a given research objective, the acquisition of accurate and complete data, and the physical storage and processing of such a large data base.

This paper discusses each of these problem areas and identifies the factors involved. Illustrations of possible solutions are presented, based on the author's experience with the Census data base at the University of Pennsylvania. Guidelines for dealing with such problems are provided for other prospective users. Finally, some general recommendations are made for avoiding or reducing these types of problems in future Census data products.

INTRODUCTION

The basic Census data base, as maintained by the U.S. Bureau of the Census, contains the actual (or encoded) responses for each individual who completed a Census questionnaire in the 1970 Census of Population and Housing. Portions of this data base are made available to the public in three forms:[9,10,11]

(i) *printed census reports,* which summarize various responses for certain geographic areas;

(ii) *summary data tapes,* which also contain response data summarized by geographic area but in computer-readable form; and

(iii) *sample data tapes,* called the Public Use Sample, which contain selected data records from the basic Census data base, also in computer-readable form.

The printed reports are the most frequently available and immediately usable of these three forms. These reports are available in most libraries and provide summarizations of basic housing or population characteristics for the most commonly accessed geographic regions. For example, from the reports a researcher may gather data on counts of housing units or on population by age or sex for counties or states. While convenient, the printed reports may not suffice for many researchers. For example, data may be required on more specialized data items, or by smaller geographic areas. For computer analysis, the researcher may wish to obtain a large volume of data records in computer-readable form. In these latter cases, the summary tapes and the Public Use Sample are required as data sources.

The summary data tapes, organized into six parts called "Counts," contain the summarizations from which the printed reports were developed. The six Counts differ with respect to the data tabulations they contain and the size of the geographic areas for which these data are summarized. Each tabulation represents the result of cross-tabulating one or more questions from the Census questionnaire. As such, more than one data item (or cell) may be contained within one tabulation. For example, the tabulation "Population by Race" requires four data cells, corresponding to three racial groups plus the total. The geographic area for which the tabulations are summarized are identified in each record by a set of codes. The summary data tapes contain summarizations for states, counties, and Standard Metropolitan Statistical Areas (SMSA's), as well as for smaller areas, such as census tracts, blockgroups, and Minor Civil Divisions (MCD's).

The Public Use Sample tapes contain data records of actual questionnaire responses with most identifying information removed. These records are selected according to different sample sizes and for different geographic areas, and grouped into six files according to these two characteristics. The data items in the Public Use Sample records are coded responses rather than counts or tabulations. However, coded geographic information is used to identify each record, as in the summary data.

The decision to use and/or acquire either type of computer-readable Census data forces the researcher/user to confront a number of problems. The problems encountered can be classified into three general areas: data description, acquisition, and manipulation. Problems in data description arise when the user attempts to identify and/or select the data items and geographic areas most appropriate for his/her research. Data acquisition problems center around the user's ability to obtain complete and accurate data in a form compatible with his/her computer installation. Manipulation problems are largely due to the overwhelming size of the Census data base (over two thousand reels of computer tape, as originally produced from the Bureau of the Census). The user/implementor is faced with questions of how to store and access this large data base in the least expensive fashion.

This paper addresses each of the three problem areas and presents guidelines for potential census users in each area. These guidelines are based on experience with the implementation and use of the Census data base in a university environment. In addition, recommendations are made for improving future Census data products and services.

IDENTIFICATION OF DATA TABULATIONS AND AREAS

Before evaluating alternatives for Census data acquisition and manipulation, the prospective user must be able to identify and select those data items which are required for his research. The two-dimensional logical structure of the computer-readable Census data base requires that a potential user select both the *tabulations* he wishes to use and *geographic areas* for which these tabulations are summarized.

Selection of tabulations

Problems in identifying and selecting appropriate tabulations from those available arise due to (i) duplication of variables, and (ii) questions of data reliability. The same variable (e.g., housing unit value) may appear in several summary data Counts, though in a slightly different context in each (see Table I). User aids, such as the *1970 Census Data Finder*, should be consulted to locate the tabulations that may be of interest under more general subject headings. In every case, the user should refer to the formally defined Census Concepts[9] to insure proper interpretation of the terms used, e.g., "mixed parentage" under race.

TABLE I—Representative Tabulations Relating to Value of Housing Units in the Census Summary Data

Item	Tabulation Number	Count
Aggregate $ value (of housing unit)	17	First
Units for which value is tabulated by value class, by race	35	First
Aggregate $ value for units with all plumbing facilities	27	Second
Value, type of household, age and race of head	57	Second
Aggregate $ value	1	Third
Value	22	Third
Aggregate $ value	1	Fourth—Housing
Value, occupancy status, and race of head	52	Fourth—Housing

Reliability problems include questions of sampling, allocations, and actual errors in the data. Since a minimal number of questions (e.g., five on Population) were asked of all Census respondents, all other tabulations are based on questions asked of a sample of respondents. These sample counts are weighted to approximate the total, but actual totals and weighted totals may not agree in every case. Further, users of tabulations or small geographic areas, such as block-groups or enumeration districts, may find that the totals on a sample question reflect the responses of an unacceptably small number of actual responses. For example, a 5 percent sample item on a 300-household census tract would reflect only 15 actual households. For items that are further divided, e.g., into rental or owner-occupied, the count will be even lower.

"Allocations" are substitutions made by the Bureau of the Census for data items missing from the original Census responses. This procedure is documented and data indicating the allocations that were made exist within the Census data base. However, a user who makes a hasty selection of tabulations without investigating the impact of these pseudo-data may be jeopardizing his results. A high proportion of allocations for any data item affects the reliability of all tabulations utilizing that item.

Certain tabulations may be missing entirely from the summary data tapes. In cases of small area tabulations, the Bureau of the Census often suppresses data items that may impair confidentiality. For example, income tabulations might be suppressed for block groups containing only two individuals older than 65. These situations are indicated by a series of suppression codes placed into the data record at the time of suppression. The user must simply be aware of their meanings and make sure any access software handles these zero-filled fields accordingly.

Incorrect tabulation data discovered by the Bureau of the Census are generally reported in Bureau publications, such as the *Data User News* (formerly called

Small Area Data Notes). However, it behooves the user to be alert to these announcements, since error correction is the responsibility of the owner of the data, not the Bureau. Further, such errors are reported as they are discovered and are not reflected in the primary documentation accompanying the receipt of Census data. Thus, a diligent user is forced to scan back issues of Census publications to spot errors that may affect his analyses.

Selection of geographic areas

In selecting geographic areas, the user is faced with problems involving geographic codes, record-sequencing, area matching, and missing data. All geographic areas represented in the Census summary data are identified by numerical codes. The Census Bureau provides a user aid called the Master Enumeration District List (MEDList) in which each code is associated with the corresponding state, county and area or place names. In order to access the summary data for any area, the user must know the codes of the areas desired, since no names exist on the tapes. While codes are also used in the Public Use Sample, no corresponding list exists for these codes. To further complicate the issue, the codes used in the P.U.S. are not always the same as those in the summary data.

A user who is dealing with regions or areas that do not coincide with census geographic areas must match the census designations with the region desired. Doing this may require overlaying the boundaries of these "special" areas on Census maps or using the Address Coding Guide (ACG). The latter is a list of block faces and their associated census tract designations originally used to properly sort Census responses. Using the ACG may enable a user to convert his "special" regions into tabulated areas. Or, at worst, he can describe these regions in terms of addresses and request a special tabulation from the Bureau.

Even for fairly standard geographic areas, the sequencing of the summary tapes may prove an obstacle to easy access. A "sequencing key" field, made up of various geographic codes plus category codes added for the summary, exists in each data record and the order of the records in the file is based on this field. As a result, the order of the data records may differ substantially from the order a user might expect. The physical sequence, of course, influences the length of search and access time for data records in a sequentially organized data file, thus affecting the user's processing costs.

Missing data records that are lost due to processing errors (e.g., in tape copying) or are truly non-existent (because no tabulations exist for that Census tract) present another costly dilemma for the user. Such omissions are usually discovered as the data are processed, and thus may force the user to suspend or redesign his analyses in mid-stream. Unfortunately, preliminary completeness checks are also costly unless they can be performed as a by-product of tape copying (e.g., a list of all geographic areas represented on file).

ALTERNATIVES FOR DATA ACQUISITION

To the potential Census data user, the next step is obtaining access to the data he or she needs. In addition to the Census Bureau itself, there are several other types of agencies through which Census data are available. These agencies fall roughly into three categories: Census-designated processing centers, data suppliers, and suppliers of computer services.

Organizations which are designated by the Census Bureau as processing centers provide data retrieval and tape copying services for census data users. These centers may be private or public, and operate for profit or on a nonprofit basis. They are not controlled or certified by the Bureau of the Census, but once recognized they are added to a list of such centers which is available from the Bureau on request. Since each center is operated independently, a user may find from one tape reel to the entire Census available at the centers in his location.

Various private companies serve as intermediaries between the Census Bureau and Census data users. These organizations operate in a "value-added" mode, supplying users with data that is in a more efficient format than that provided by the Bureau. A most extensive variety of services, such as special tabulations and software products, also available from such agencies. Two organizations which supply Census data and services in this vein are the National Data Use and Access Laboratories of Rosslyn, Virginia (DUALabs), and the National Planning Data Corporation of Ithaca, New York.

Some organizations that market computer batch processing or time-sharing offer Census data services to their users. Such services include access to selected portions of the Census data and/or software access and display packages. Those services available over time-sharing networks, such as CENSAC on National CSS, Inc. and CENSTAT on CDC's CYBERNET, usually include data access plus software. Smaller services bureaus, such as UNI-COLL, Inc., Philadelphia, Pa., offer customized software systems to process data obtained by the users.

The advantages to using any of these secondary sources for Census data are ease of access and the availability of special services, e.g., consulting or software. However, ease of access is limited to those data made available by the organization selected. Many of these agencies concentrate on a few oft-requested tabulations or on one geographic region. Even those from which all data is available may charge more for access to data items that are rarely used. Further, the software services provided are usually standardized, with customized processing or special tabulations available at extra cost.

A user who wishes to obtain the original tabulations and do his own processing has the choice of dealing directly with the Census Bureau or with one of the secondary sources that provide tape copying services. The advantage of the latter is the receipt of data in a much more efficient form. For example, as offered by the Bureau of the Census, most Counts are supplied on a one state per tape reel basis—quite uneconomical in terms of storage and processing costs.

MANIPULATION OF THE CENSUS DATA BASE

The Census Bureau had maximum transferability as its objective in structuring the files of Summary Data and the Public Use Sample. In response to this objective, the data are made available in the most standardized fashion: in sequential organization, on magnetic tape, recorded at low density, encoded in one of two standard character codes (EBCDIC or BCD), often one state per reel, and with equal, fixed-length records. These characteristics, however, inflate the size of the Census data base and make its manipulation most inefficient. To improve storage and processing efficiency, the user should investigate changes in form and size, storage medium, and organization.[12]

The size of the Census data base is unnecessarily inflated by the use of equal-length data records and standard character codes. The former necessitates a large proportion of blank characters in many files, to fill fields unused in those records. The latter requires larger data fields for numeric values than would be necessary if binary representation were used. After making the above changes the user may be well-advised to pursue further reductions in data base size through the application of data compression techniques.[5] Zero suppression and simple character packing (two digits per byte) achieved compression ratios from 43 percent to 73 percent in the University of Pennsylvania Census data base.[12]

An appropriate change in storage medium, e.g., from magnetic tape to disk, must be determined with respect to the user's processing installation. The factors involved include the amount of data to be stored, the relative costs of tape versus disk processing, and the extent and frequency of processing anticipated.[13] In the University of Pennsylvania environment, transfer of user-requested tabulations from tape to disk as needed resulted in a sizable reduction in processing costs for a modest (and temporary) increase in storage charges.

Efficiency in accessing Census data can be further improved by changes in the organization of the data. Access to the Census data, as originally produced, is constrained by all the limitations of sequential files: variable access times for data dependent on location within the file, linear search for desired data, and a minimum number of data relationships actually represented by the file structure (e.g., geographic proximity or association by household). However, radical variation from the original organization puts the user and his data at variance with the published documentation. While this may be acceptable for a small portion of data, users maintaining a full Census data base, e.g., for a university community, would find the extra documentation burden unwieldy.

The approach to change in Census data organization at the University of Pennsylvania was to retain the original sequence of data records while regrouping these records into separate sub-files, and building an index to the new sub-files. Sub-files were defined either by geographic region (e.g., counties) or by record count (e.g., 500 records). In both cases, access costs for data in these files was substantially (50 to 60 percent) less than for access to the original state file. The level of indexing employed, however, still required sequential search within the sub-files and use of the index to locate specific records was limited by the sequencing imposed on the original file.

CONCLUSIONS AND RECOMMENDATIONS

The problems that face potential Census data users with respect to data description, acquisition, and manipulation indicate that the Census data base is not readily available to most researchers. With the next decennial Census rapidly approaching, it behooves those who have experienced some of these problems to suggest ways in which they might be ameliorated.

One recommendation would be that the Census Bureau assume the role of data base administrator (DBA) for the Census data base. That implies that while making the data available to a wide range of users, the Bureau would retain control over the data base. A radical means of doing this, that is now technically feasible, would be to make the Census data base available over a nation-wide network which users pay to access. In this way, the Bureau would physically retain control over the data and be able to assure their physical integrity and structural validity. Access methods and utility programs could then be standardized and shared amongst all Census users.

Another approach would have the Census Bureau retain only *logical* control over the data base. This would be an extension of the Bureau's current mode of operation. Portions of the Census data base would be physically transferred to users (for a fee) but the Bureau would be responsible for promoting accurate and efficient manipulation of Census data by applying the tools of documentation and standards.

To fulfill such a role, Census documentation would have to be improved in the following ways:

(a) It must be structured and cross-referenced as an integrated hierarchy, where the user could start at a general subject area and easily locate all relevant information down to the nature of specific tabulations and areas;

(b) it must be dynamic, so that continuing notices, error advices, and new data products could be easily reflected when they are pertinent; and

(c) it should be priced in such a way that participating research organizations and libraries would be motivated to purchase the entire set, not isolated fragments.

The concept of standards with respect to Census data would also have to be broadened. In addition to formatting standards required for transferability, the Bureau could provide standard access routines, oft-requested utility routines (e.g., for elementary statistics) or interface routines for the most common statistical packages, e.g., SPSS or BIOMED. For users with incompatible processing environments, these standards could be set forth in the form of guidelines or logic flowcharts, from which users could create their own software.

As with any other data base, once administrative tasks are removed from each group of diverse users and returned to a centralized agency of control, access and integrity will be improved. To do less with a data base of the size and importance of the Census, is to implicitly restrict public access to a valuable national resource.

ACKNOWLEDGMENT

The author wishes to express her appreciation to Mr. David F. Sanford, Wharton Econometric Forecasting Associates, Philadelphia, Pa., for his consultation and advice on this paper.

Defining management's information needs

by TREVOR JOHN BENTLEY
Tilling Construction Services Ltd.
Collingham, England

ABSTRACT

Before we can discuss Management Information Systems on a coherent and beneficial level we must know the needs of those at whom the information is directed. It has been said that a good salesman can create needs for his product and there is no doubt that this is what has happened in the development of computer based systems. It is time we found out what our customers' real needs are and it is time that we admitted to ourselves that these needs may not always require the most sophisticated solution.

This paper describes a survey which sets out to establish management's information needs by focussing on the decisions taken by the managers and the information necessary to provide the input for the decision process. This identification of decision points and the subsequent analysis of information needs is an essential prerequisite for the successful design of meaningful information systems. The steps to be taken are set out in detail together with my comments based on the practical experience of carrying out such an analysis. At this time the survey has not been completed but by June '76 results should be available for discussion.

THE PROBLEM

The problem to which this research addresses itself was clearly defined by James D. Gallagher who sets the following goal for an information system.

> "The ultimate goal of an effective management information system is to keep all levels of management completely informed on all developments in the business which affect them. To do this, the data-processing personnel and those entering information into the system should know exactly what data to collect and which to tabulate, and management on its part has the obligation to be able to write down its actual requirements for internal information."[1]

The problem of knowing "exactly what data to collect and which to tabulate" is not new to management. Edward T. Elbourne recognized this in 1914 when he wrote.

> "It is quite possible for the Management to collect more information than it can use to advantage, or which is more costly, or hinders production more, than the information is worth. This is a real danger that has to be guarded against continuously, for routine that serves a valuable purpose when initiated may cease to be useful by some later change in conditions."[2]

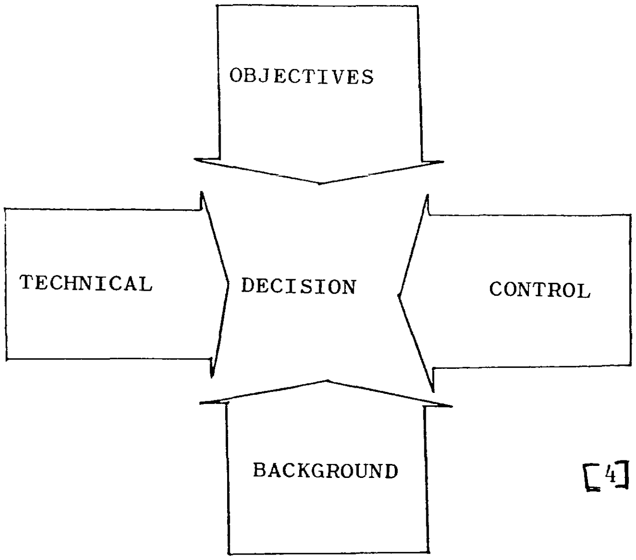
Information is the raw material which the manager needs to make a decision. Without information the manager is unable to carry out his function in the organization.

> "The manager needs information to assist him to select courses of action i.e., take decisions, to control the implementation of action and to record the success or failure of the action taken. It is necessary therefore to define the decision making areas of each manager's job in order to provide information which will be of help."[3]

The relationship of information to decisions is fundamental to the research and is clearly a vital consideration in the development of the right approach to the problem. The manager must then receive information related to his job, his responsibilities and the decisions which he takes. Such information can be broadly categorized.

"The manager needs several kinds of information:

(a) the objectives which he is to attempt to achieve;
(b) technical information about specific jobs, for which he is responsible;
(c) control information based on feedback of the results of decisions so that corrective action can be taken;
(d) background information about activities related to those for which he is responsible and of the company and the environment in which he is operating."



Some of this information will be available, some will not. It is obtained from both internal and external sources. Managers already have sources of information which they use for making decisions and the research must start from the present position and examine—

1. The information presently used,
2. The information needed but not available, and
3. The information which cannot be obtained.

> "The manager will never be able to get all the facts he should have. Most decisions have to be based on incomplete knowledge—either because the information is not available or it would cost too much in time and money to get it. To make a sound decision, it is not necessary to have all the facts; but it is necessary to know what information is lacking in order to judge how much of a risk the decision involves, as well as the degree of precision and rigidity that the proposed course of action can afford. For there is nothing more treacherous—or alas, more common—than the attempt to make precise decisions on the basis of coarse and incomplete information."[5]

The research will aim to answer the following questions.

1. How can key decisions be isolated?
2. Can a decision structure be devised?
3. How can the information requirements of the decisions be assessed?
4. Can the utility of the information be determined?
5. How can the degree of risk be related to the availability of information?
6. Can an information system be designed to satisfy management's needs?

Information is a peculiar thing which varies depending upon when it is received, how it is received and who receives it. The same piece of information may be interpreted differently by different managers depending upon their attitudes and approach to the decision concerned.

> "Like management itself, management information has vital human implications. . . . To demonstrate a point, then, let's consider the implications to various people of a train whistle penetrating the evening dusk.
>
> To the saboteur crouching in a culvert it might signify the failure of his mission because the whistle indicates that the train has already passed over his detonating charge without causing an explosion. To the playboy it might presage the imminent arrival of a transgressed husband. To the fireman in the cab of the locomotive it indicates a drop in steam pressure and the need for restoking the furnace. To the lonely wife it means the return of her travelling husband. To the man with his foot caught in the switch down the track it preshadows doom. . . . For another (preparing to retire) it signifies time for prayer. . . . In brief, the nature and significance of any information are fundamentally and primarily functions of the attitudes, situations, and relevant responsibilities with respect thereto of the people involved with it. . . .
>
> . . . Information is management information only to the extent to which the manager needs or wants it; and it is significant to him only in terms of its relation to his accumulation of relevant knowledge and plans and to his personal responsibility."[6]

The problem being faced is therefore a complex and difficult one. There is unlikely to be a specific solution, but if a way can be defined to analyze and categorize information needs then the aim will have been achieved.

> ". . . There is a frighteningly common desire today to prove that incredible amounts of information can be developed with electronic devices by preparing business reports that are incredibly long, incredibly dull, and, all in all, just plain incredible.
>
> Information alone is not enough. Try visualizing for example one of our big daily newspapers if it were presented straight off the wire in continuous columns, with no headlines, no attempt to avoid duplication, and no simple means of judging the relative importance of the various news stories or putting them in proper perspective. Would you even attempt to read such a paper? I think not. Yet management is frequently forced to hunt through a haystack of irrelevant information in its reports in order to find for itself the needle of pertinent fact. What is needed, obviously, is a planned system of business intelligence—or, as the

author of this report prefers to call it—a "management information system" which selects, rejects, edits, and headlines business information—in short, which turns it into business intelligence.[7]

THE SURVEY

Meaningful information

Meaningful information can be defined as follows:

(a) For data to be called information it must add to the manager's store of knowledge.

(b) To be meaningful the increase in knowledge must be relevant to the manager's decision-making activities.

For example there is no point whatsoever allocating overheads to cost centers when the cost center manager has no control over those costs. Neither control nor information will be improved by such arbitrary accounting conventions.

It must be realized that the majority of the data presented in monthly accounting reports does not fall into the category of 'meaningful information', as most of the data contained in the accounts is already known to the manager from whose activity it originated. It is certainly not new to him. It has simply been converted into misleading monetary terms. This is particularly so in a period of high inflation. It is quite clear that we must provide data in terms of quantities and hours and other inflation-proof measures.

Defining management's needs

It is vital that management's information needs are examined so that meaningful information systems can be designed. The System Designer, however, must not:

(a) Ask the manager what he wants; simply because he will not be able to answer, unless the question can be related to his decision areas.

(b) Tell the manager what he needs; this will and does cause resentment and leads to systems oriented managers rather than management oriented systems designers.

(c) Give the manager what is available; this is the most common practice and has, I believe, led to the paperwork explosion that is burying management in useless data. The computer has unfortunately added to the paperwork explosion by providing more information which is now more readily available, a good deal of which is irrelevant.

The systems designer and the manager working together must establish the following.

(a) The decisions taken by the manager.

(b) The information ideally required for those decisions.

(c) The information currently available.

It is probable that this analysis will result in the situation depicted in Figure 1.

Achieving the above is more difficult than it might appear, and unless a carefully structured approach is taken it will be impossible. There is no alternative to a detailed systematic analysis on the following lines.

Step 1: *Determine decisions*—This can only be done by spending some time with the manager and learning from observation and analysis the decisions he takes. It will be apparent from this that his decisions will fall into the following categories.

Routine: taken regularly; highly structured with easy access to the data required, e.g., raising a credit note for a pricing error.

Mechanical: taken less frequently, but still structured with known data requirement, e.g., producing a production schedule.

Complex: taken infrequently, unstructured, depending largely on current circumstances. Unknown information requirement, i.e., cannot be predetermined.

If the impact of these decisions on the managers' results can be assessed, then a Decision Grid can be completed for each manager. (See Figure 2)

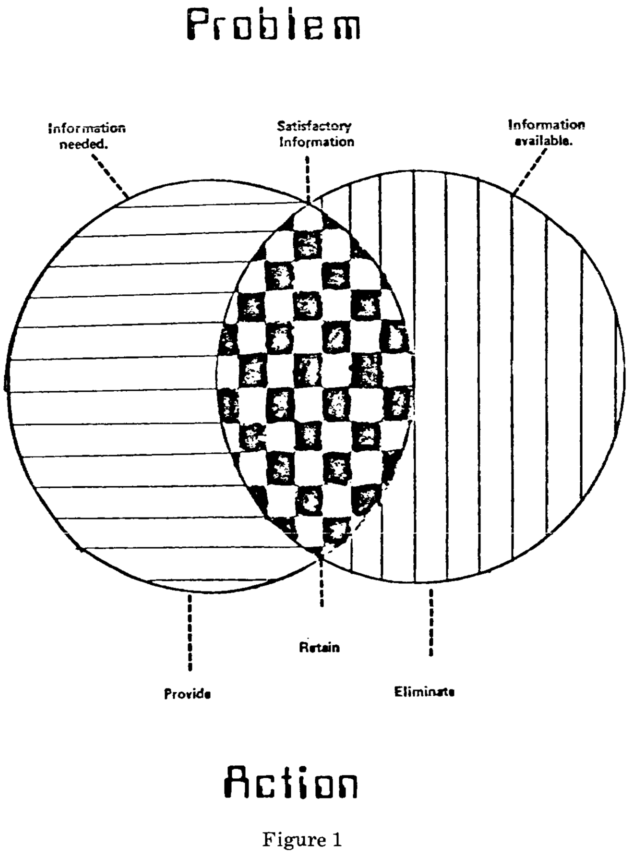


Figure 1

KEY DECISION GRID

IMPACT SPECTRUM	Minor	Important	Vital
COMPLEX			
MECHANICAL			
ROUTINE			

Figure 2

Step 2: *Information Analysis*—For each of the decisions on the Decison Grid it is necessary to produce an Information Analysis Grid (See Figure 3), which records the information ideally required in the following sections.

Class: Available and used
Available not used
Not currently available

and

Category: Vital
Desirable—economic
Desirable—uneconomic

It is then important for the manager to assess the degree of risk if the information is not available. This can be recorded as HIGH, LOW, or by the use of probability scales.

Step 3: *Decision Analysis*—With the above information it is now possible to complete the Decision Analysis

INFORMATION ANALYSIS GRID

	VITAL	DESIRABLE		Degree of RISK if information is not available
		economic	uneconomic	
Available and used				
Available not used				
Not currently available

Class: A available and used
B available not used
C not available

Cat: A vital information
B desirable and economic
C desirable but not economic

Figure 4

(See Figure 4) which is the master document for the design of the system. On the Decision Analysis the information requirement is split into the four main types of information—

Objectives (Plans)
Technical
Control
Background

This will be used to define where the information comes from, the frequency, content, accuracy level, etc. All important points for effective systems design.

Step 4: *Providing the Information Required*—Referring to Figure 1, Action should be taken to—

(a) produce the information required,
(b) eliminate the information not required.

Producing the required information may take some time to achieve as it will call for the amendment of some systems and almost inevitably the re-design of other systems. A good deal of useless information can be dropped fairly quickly and this should provide some relief for the inundated manager.

The above steps are implemented in the following way.

(a) The managers concerned are invited to a seminar which explains the relationship of information to decision making and its importance to their individual performance.
(b) Following the seminars the managers are visited and interviewed by the researcher who assists in the completion of the Decision Grid and Analysis Sheets.
(c) The researcher then analyzes the results and presents a report covering:
    (i) The decision points.
    (ii) The importance of each decision.
    (iii) The information required.
    (iv) The existing source, if any.
    (v) The basis of the new system if one is required to provide information not currently available.

Throughout the above the researcher must act only as an adviser and analyst, it is imperative that the manager assesses his own information needs related to the decisions which he takes.

BASIC INFORMATION SYSTEM CONCEPTS

When the manager's needs have been established the kind of Management Information system which is most suitable for the circumstances must be examined. It is fatuous to think that the existing system is of any use whatsoever until the comparison between what is needed and what is available has been made.

There are three principal categories of Management Information Systems.

(a) *Data Bank*
All data is recorded for every transaction and placed on file. It is then available for answering questions.
(b) *Systems Basis*
Information flow designed to accept and process data as a management tool. Leads to extensive systems with complex programming.
(c) *Combined Systems/Data Bank*
This is a Decisions Based System approach and provides systems for certain areas oriented to decision making and a data bank for others dependent entirely on management needs.

The most applicable approach for the majority of companies is that indicated in (c) above, namely a combined systems/data bank approach, the reasons for this are as follows:

(a) Complete data banks are impracticable, in that much of the information is obsolete before it reaches the file and even when it is there it can be very difficult to retrieve. Questions cannot be sufficiently pre-determined to allow for an adequate questioning sequence to be built into the file. Some of the underlying concepts of this approach are not acceptable e.g., all data is not valuable and generally it depreciates with time. In addition to which the form content and frequency of information should not be dictated by the systems, but by the needs of the decision making process.
(b) The total system approach requires extremely complex systems designed on the basis of how information can be used by functions and the understanding of the flow between functions and processes. This makes the whole information network system oriented, inflexible and too complex to be understood by the management using the information.

Decision based systems have several advantages.

(a) It is necessary to identify decision areas and then ensure that resources are available.
(b) Management's information needs must be clearly defined and it is usually established that less but more relevant information is required.
(c) Information is directly related to the task and thus ensures it is available in the right quantity, of the right quality, and at the right time.
(d) More efficient use of computer hardware is possible when it is directed towards management needs.
(e) The production of relevant information for making decisions should lead management, if they use this information correctly, towards making better decisions.

COMPUTERS AND MANAGEMENT INFORMATION SYSTEMS

The term Management Information System is linked in most people's minds inexorably with computers. This link is understandable as all current literature on Management Information Systems concerns itself exclusively with computer based systems. It is not, of course, necessary to use computers when discussing information systems, they do have their place and it is part of the System Designer's function to recognize when to use computers and when not to use computers.

The computer's main strength lies in three areas.

(a) Routine Data Processing.

(b) High capacity fast access storage and retrieval facilities.
(c) Mathematical models for simulation.

Routine data processing is mainly concerned with accounting procedures and related analysis for information purposes. This is still the major application area, particularly in the U.K. The computer's ability to handle large volumes of routine data extremely quickly in batch mode has led to the wide development of such routine batch processing applications. They are not as glamorous as the so called "Integrated Management Information System" applications few of which exist.

The use of high capacity, fast storage and retrieval facilities has led to the growth of on-line and real-time operating systems, which however effective at controlling airline bookings, do not provide much if any management information. A large UK holiday company used real-time systems for booking control, and then batch processed the data for accounting and information purposes. Unfortunately the company went bust.

Simulation models are undoubtedly a valuable management tool and can aid decision making. However, their development requires a high degree of mathematical competence, and a profound understanding of the business problems. Attributes rarely possessed by the same manager. If models are to be used effectively then they must be—

(a) Small and relatively simple,
(b) Used regularly, and
(c) Built by managers.

One of the risks of using computers in decision making is that the model builder will attempt to construct programs containing value judgments, and it is here where failure must occur. In addition the social aspects of decision making cannot be programmed.

> "Since no computer programs have yet been written which pick from an open-ended range of possible selections, it is now impossible to arrive at 'managerial' decisions by automatic process."[8]

The system designer must first assess the problems before he attempts to develop any single approach to the solution. I personally believe that the computer specialists have for too long been offering management a solution in search of a problem.

It would be of great benefit to most companies if the systems designer obtained answers to the following questions before computers were included in the plans.

(a) Is the existing non-computer system the best possible?
(b) Is there any other way?
(c) Do the system requirements fall within the strengths of the computer?
(d) Five reasons why a computer must be used over any other system.
(e) The importance of the system to the company.
(f) What will the company lose if the system fails?
(g) What are the benefits in £p from successful implementation?

STAGES IN DEVELOPING THE MANAGEMENT INFORMATION SYSTEM

As we have already seen the systems designer is faced with three major problems in designing a decision based information system.

(a) Obtaining an understanding of information and its importance to the managerial function.
(b) How to establish what information any particular manager requires in order to meet his decision making needs.
(c) The means by which this information can be collected, stored, processed and retrieved.

At the beginning of this paper I suggested a means of establishing management's information needs. The systems designer, by using the approach indicated, should have obtained answers to the following questions.

(a) What are the key decision areas at each level of activity?
(b) What information is required to make the decisions?
(c) What information is lacking?
(d) How can it be obtained and at what cost?
(e) Does it require amending existing systems or introducing new ones?

A systems framework can be established which will indicate what work has to be done to provide the needs of management. Existing systems cannot be withdrawn and replaced overnight, so a plan has to be formulated. Rationalizing existing systems based on this framework will produce the most immediate benefits. This is done in two stages:

(a) Prepare improvement program indicating the priority areas.
(b) Simplify existing procedures.

The flow of information from computer based systems must be examined to ensure that the files hold data in the most useful form for meeting the information requirements of management. The conflict arises as follows and limits the effective use of the computer.

(a) Files are designed to hold information in the sequence most appropriate to the operation of the computer systems.
(b) Information required is seldom needed in the same sequence that facilitates rapid operation on the computer.

The possible solution is to create files based on information needs and secondary files or improved systems to handle the operational data needs.

The provision of an information system for management must be tackled slowly with the development of individual subsystems linked together by the decision based reporting system.

Developing new systems should be one of evolution for the following reasons.

(a) Too many activities to be absorbed at one time.
(b) Human effects of change.
(c) Complexity of changes.
(d) Limitation of available man hours for effective systems design.

CONCLUSION

I am convinced that the provision of—

the right data, at
the right time, in
the right place, for
the right reasons,

is the principal aim of the systems designer, however, he cannot achieve this aim without a close involvement with management and a deep understanding of management decision making processes.

Managerial response to an information system

by ROY H. IGERSHEIM
American Management Systems Inc.
Troy, Michigan

ABSTRACT

One of the most common problems in implementing a successful information system is its threatening nature to users of the system—particularly middle managers. The behavioral implications inherent in the implementation of an information system were studied by testing the following two propositions:

- Acceptance of an information system is positively related to involvement in the implementation of the information system.
- Acceptance of an information system is negatively related to the perception of the system as threatening.

Three hundred thirty one middle managers from five different organizations were sampled. An overall response rate of 72 percent was achieved utilizing an anonymous three-part questionnaire. Various statistical techniques were utilized to validate the proposed scales used in testing the hypotheses.

Based upon the data analysis, the two propositions are strongly supported. There is a definite positive relationship between a middle manager's acceptance of an information system and his participation in the analysis and design of the system. In addition, there is a negative relationship between a manager's acceptance of an information system and the perceived threat of the system to such behavioral factors as job satisfaction, job skill, job opportunity, job originality, job status, and job salary.

INTRODUCTION

The entire management information system (MIS) field must still be considered to be in its embryonic stage. For approximately the last two decades computer-based information systems have been utilized by industry and government and the computer's potential recognized as a vital management tool in daily operations. This increased capability has brought about complex data processing (D.P.) applications and a growing awareness of the need to integrate these applications in the form of a MIS. In turn, this has led to numerous technical and personnel problems that must be overcome if such systems are to be successful.

One of the most common problems in implementing a successful information system has been its threatening nature to users of the system—particularly middle managers. It is a widely accepted tenet that information systems should be designed, developed, and implemented for middle managers. Generally, however, their needs and perceptions about the system have been given little, if any, consideration. If these middle managers fail to understand or accept the system, it is not likely that they will use it to perform their job more effectively.

The behavioral implications inherent in the implementation of an information system were, therefore, studied. Specifically, the study determined whether or not middle managers in five selected organizations perceive the MIS as threatening in terms of various behavioral criteria factors and whether or not they accept the MIS. The following two propositions were primarily examined:

1. Acceptance of an information system is positively related to involvement in the implementation of the information system.

2. Acceptance of an information system is negatively related to the perception of the system as threatening. The following behavioral variables were examined in this regard: job satisfaction, job skill, job opportunity, job originality, job status, and job salary. The interrelationships of these variables were also examined; therefore, as a corollary to the two primary propositions, it was proposed that a positive relationship exists between each of the behavioral variables.

It is surprising that the behavioral problems associated with information systems have not previously been investigated. Much has been written describing the characteristics of a successful management information system. However, the main emphasis has been in the direction of technical factors—hardware and software—and overall MIS considerations such as problem definition, problem analysis, and problem solving. Research in the area of user response to the MIS and how acceptance/lack of acceptance is related to their involvement in the implementation of the MIS and the perceived threats that the MIS has to them has not yet been undertaken. There has also been extensive research in the area of attitude measurement,[9,12,18,25] but little of this area pertains to information systems. Instead, research has disclosed that there are few operational computerized management information systems considered to be successful—possibly because the human factor was not given enough consideration. As Allen Rowe observes, people are the key ingredient in a MIS.[19] M. Scott Myers actually defines a MIS as a "process of people interacting in order to apply resources for the achievement of various goals."[16] Neither of these authors, however, nor any others present any empirical evidence regarding the behavioral implications of a management information system.

It is also necessary to note that during the past decade numerous terms were used to describe the different types of computer and systems applications that were being developed. The same term has been defined in different ways by various authors and in different disciplines.[4,7,21,23] For this reason and to avoid any possible misinterpretation the following meanings are to be given to the following terms.

A. Management Information System—or Information System for Managers—a system that provides the proper information to the proper person, at the proper time and at the proper cost.

B. Middle Managers—composed of those members of management above the level of foreman and below the level of vice president.

C. Perceived threat—the perceived potential forced movement away from a desired position or date.

METHODOLOGY

The sample consists of 225 middle managers from five organizations possessing an actively-utilized, computer-based management information system. Two of these five organizations are agencies of the United States Government based in the Washington, D.C. metropolitan area; the other three are large eastern industrial corporations. Middle managers were selected as subjects because they are the prime users of the MIS. In the governmental agencies, this group was comprised of GS12's, GS13's, GS14's and selected GS15's. A breakdown of subjects by organization can be found in Table I. A total of seventy-two percent (246 respondents) of the questionnaires distributed (341) were returned and found usable.

Data was collected from July through October 1973. All participants completed a three-part questionnaire developed for this study. Subjects were in no way asked to identify themselves—either by name or job function. This questionnaire required the respondents to react along a six-point continuum to 57 attitudinal statements concerning the MIS and to six statements measuring their involvement in its implementation process. The statements asked and the variables being measured were arrived at based upon a review of the MIS and behavioral science literature and the author's prior experience in the field.

Top management distributed the questionnaires with a cover letter as subjects were from several different departments and often different physical locations. Also, the subjects in this study within the industrial organizations worked on different shifts and previously started vacations of the subjects could not be rearranged. The direct support of top management and anonymous nature of the questionnaire assured a greater response rate. At least one follow-up letter was sent to all participants in this study approximately one week after the initial distribution of the questionnaire. In two organizations, questionnaires were returned anonymously to top management and then forwarded to the author; in the other three organizations, subjects were furnished stamped, self-addressed envelopes and questionnaires returned directly to a Box number. As can be observed from Table I, the response rate was not affected by the different methods of questionnaires return.

Factor analysis[13,15,24] was used to test the *a priori* scale structure. The purpose of this analysis was to reduce the number of variables to those showing a common variance and to determine if the items making up each *a priori* scale were in fact parallel. The *a priori* structures did generally, in fact, hold up.

The *a priori* scales were then modified as a result of the factor analysis and these modified scales were then used.

The mean score and standard deviation of each of

TABLE I*

	Total Subjects Returning Questionnaires	Total Questionnaires** Distributed Within Organization	Response Rate In %	Total Usable Questionnaires
Organization 1	59	86	69	54
Organization 2	55	83	66	51
Organization 3	33	44	75	30
Organization 4	57	73	78	49
Organization 5	42	55	76	41
Total	246	341	72	225

* The participating organizations wished to remain anonymous; therefore, no organization names will be given. Organizations 1 and 2 are governmental agencies; organizations 3, 4, and 5 are industrial firms.

** The distribution of questionnaires within each organization included all middle manager/users of the management information system within one or more specific departments.

the scales was computed and then the scales were correlated using the Pearson Product Moment Correlation in the SPSS statistical package.[17] The scales were correlated on an individual basis by organization and then these organizations were combined and grouped together as a composite (Table II).

RESULTS

The results of this study are presented in Table II: Columns 1 through 5, for each behavioral factor, contain the correlation coefficient of one individual organization. Column 6 for each behavioral factor contains the correlation coefficient for the entire sample. As can be observed the scale reliability using the Veldman test (α) for each of the factors is greater than .632 which appears to indicate that the resultant scales, based upon the factor analysis, are quite reliable. In fact, the reliabilities of the involvement, acceptance, job satisfaction and job originality scales are greater than .8.

In addition, many of the correlation coefficients have a significance level of greater than .001. This indicates that the proposed relationships for each individual organization and for the composite grouping of organizations strongly support the basic propositions. For example, the correlation coefficient between perceived job satisfaction and acceptance of an information system for all 225 respondents is .72. Given that the significance level of .001 is .020, this result appears to be quite significant. This implies that there is a strong positive relationship between acceptance of an information system and job satisfaction.

The data should be interpreted by using the following procedure. A high positive correlation statistic on the behavioral factors—job satisfaction, job skill, job opportunity, job originality, job status, and job salary—implies that there is low threat to those factors while a high negative statistic implies that there is a high threat to those factors.

DISCUSSION

To describe and analyze the data presented in Table II, this section examines each of the factors, determines which relationships exist, why they exist, and whether or not any pattern can be observed. In order to determine relationships between scales, each of the hypotheses will first be analyzed by individual organizations and then in composite form. Thus, the individual organizations participating in the survey can compare their data to other organizations and to the composite grouping.

Organization 1

The data for this organization shows that a strong positive relationship exists between acceptance of an information system and a manager's involvement in the implementation of that system (.36). This occurs possibly because the information system was designed by this organization's management and by a group of external consultants. This system was designed on a large scale third generation equipment, taking into account all of the users of the system. With regard to a manager's acceptance of an information system and a manager's perceived behavioral threats, a very strong positive relationship exists between acceptance and job satisfaction (.67), job skill (.64), job originality (.62), and job status (.60). In addition a strong positive relationship exists with the other behavioral

* The α coefficient equates to the reliability of the scale using the Veldman test This test is based upon the entire sample of 225 cases.

** Column 1 thru 5 for each scale contains the correlation coefficient of one individual organization.

Column 1 is data based upon 54 cases & its significance level is {.001 > .42, .005 > .35}

Column 2 is data based upon 51 cases & its significance level is {.001 > .42, .005 > .36}

Column 3 is data based upon 49 cases & its significance level is {.001 > .41, .005 > .36}

Column 4 is data based upon 30 cases & its significance level is {.001 > .52, .005 > .46}

Column 5 is data based upon 41 cases & its significance level is {.001 > .44, .005 > .38}

Column 6 for each scale contains the correlation coefficient of the entire sample grouped together & its significance level based on 225 cases is {.001 > .020, .005 > .017}

Columns 1 & 2 contain data from two large governmental agencies.

Columns 3, 4, 5 contain data from three large industrial firms.

criteria and acceptance—job opportunity (.30), job salary (.35) and involvement (.36)—but they are not as strong as the former scales. This indicates that job opportunity, job salary, and involvement are not perceived as important as the other factors as it relates to acceptance. The data, therefore, appears to indicate that those individuals accepting the information system do not in any way feel threatened by it. Individual middle managers within this organization are very satisfied with their job, perceive that they have a high skill level, possess much job originality, and have a high degree of job status.

Upon examining the interrelationships of the various behavioral factors, generally one finds a strong positive relationship. The only major exception is the interrelationship of job salary to involvement (.05) which is not significant.

Organization 2

The data for this organization, a large governmental agency based in the Washington, D.C. area, indicates that all the proposed relationships are true. This organization has large third generation IBM computing equipment on which their information system was implemented in 1970. Primarily this information system is an output reporting system designed by external consultants with the advice of this organization's top management.

There appears to be a very strong positive relationship between acceptance of an information system by managers using the system, their involvement in it (.55); and acceptance of the information system and the lack of threat of the system. Individuals within this organization do not find the information system threatening. For example, the relationship between job satisfaction and acceptance (.83) is very strong in a positive way when one considers that a significance level of .001 is .42. The corollary propositions—the relationships between the behavioral variables—is also very strong. The data for this organization in comparing it with the other organizations is far greater than those in significance level and strength. All this appears to indicate that the individuals in this organization are not threatened in any way and accept the information system. This fact could be the result of employment by the government from which one's job is quite secure.

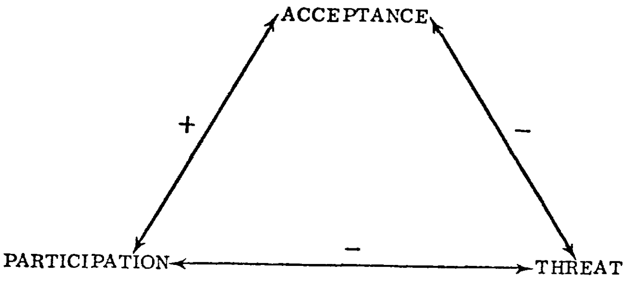

Figure 1—Visual results of hypotheses

Organization 3

The data for this large industrial firm is quite similar to the data for organization 2. This organization primarily uses its information system in the evaluation of various centers. As a consequence, therefore, it was designed by accountants for accountants to meet their needs. This small IBM computer system is used also to keep track of inventories and for warehousing purposes.

A very strong positive relationship exists between acceptance of an information system and involvement and acceptance and all the behavioral factors. It appears that the three most important factors relating to acceptance are job satisfaction (.76), job skill (.71), and job originality (.76). The other factors, though significant, are not as important. A conclusion that could be reached is the more satisfied a person is with his job, the more likely he is to accept the information system.

Among the interrelationships of the behavioral factors, job status appears to be less significant than the others. For example, the data appears to indicate that there is no relationship between job status and job salary or job status and involvement. This appears to indicate that salary and the amount of involvement in the information system by the manager has no bearing at all on his job status. This conclusion is quite plausible as the information system in this organization was primarily designed by the controller and his staff and many users of the information system were not involved in its analysis and design.

Organization 4

This organization, headquartered in a small city with rural plant sites, has an IBM computer system upon which the information system has been implemented. Managers in this organization really did not participate in the implementation process, but were forced to use the outputs of the system. Also many of these managers are located at various plants within a fifty mile radius of headquarters.

The data for this organization differs quite appreciably from the data from the other organizations. None of the propositions are strongly supported. In fact, acceptance of an information system is negatively related to perceived job salary (–.33). This implies that an individual's acceptance of an information system is threatening to his perceived salary level. Interpretation of this fact could lead to the conclusion that salary level is perceived to be lowered because of the information system. In addition, there appears to be no significant relationship between acceptance and job opportunity. Maybe the people in this organization do not feel that the information system gives them many additional opportunities possibly because of the location of this company and/or the backgrounds of the individual participants.

The remainder of the data generally supports the positive relationship purported. It does not appear to be as conclusive as the other organizations because the significance level is .005. Some of the interrelationships of the various behavioral factors are very low. For example, the following factors are quite low—job skill to job salary (.13), job status to job salary (.14), involvement to job status (−.01), job salary to involvement (−.19).

Organization 5

The data for this organization in general supports the propositions undertaken in this study. The relationship between acceptance of an information system and a manager's involvement in the implementation process is positive but less than the .005 significance level (.34). This statistic indicates that involvement is not as important a factor relating to acceptance as some of the other factors. The relationship between acceptance of an information system and an individual's perceived job satisfaction (.53), job skill (.53), and job originality (.59) is positive and very strong indicating that these factors are more important to an individual's acceptance of an information system.

The relationship between acceptance of an information system and job opportunity (.40) and job status (.28) is positive, but not as strong as the previous relationships. There is no appreciable relationship positive or negative (.06) between acceptance of an information system and perceived job salary. No possible explanation for this relationship could be found. The various interrelationships of the behavioral factors are all positive and generally they are quite strong. In fact the relationship between job satisfaction and job originality (.88) is extremely strong.

The composite

Upon examining the composite data (Column 6, Table II) one can observe that a very strong positive relationship exists between acceptance of an information system and the amount a manager was involved in its implementation and acceptance of an information system as it relates to each of the behavioral factors. It appears, however, that the data falls into two groupings:

—acceptance of the information system with job satisfaction (.72), job skill (.73), job originality (.70) and job status (.63).

—acceptance of an information system with job opportunity (.42), job salary (.35), and amount of involvement (.43).

Both of these groupings have a greater than .001 significance level but the first one ranges from .63 to .73 while the second one ranges from .35 to .43. This data implies that the key factors relating to acceptance of an information system are perceived job satisfaction, perceived job skill, perceived job originality, and perceived job status. What appears to be a significant finding is that involvement in the information system is not as important a factor as those above. Also, these composite findings, in general, support the findings of each organization.

In addition, the correlational data presenting the interrelationships of the various behavioral factors are all positive, have a significance level of greater than .001 and with the exception of involvement, are very strong. The following relationships appear to be the strongest: job satisfaction with job originality (.87) and job satisfaction with job skill (.81).

CONCLUSION

Based upon the data analysis, the two propositions appear to be strongly supported. There is a definite positive relationship between a middle manager's acceptance of an information system and his participation in the analysis and design of that system. In addition there is a negative relationship between a manager's acceptance of an information system and the perceived threat of the system to such behavioral factors as job satisfaction, job skill, job opportunity, job originality, job status, and job salary. The data presented in Table II clearly indicates that a manager who accepts the information system generally was involved in its analysis, design, or implementation and does not feel threatened by the system. Another way to demonstrate this conclusion is in Figure 1. This figure shows the positive relationship that exists between acceptance and participation and the negative relationship that exists between acceptance and threat and participation and threat.

Based upon the data presented it appears that in order to implement a successful information system the needs of the users (middle managers) must be taken into consideration. This can best be accomplished by getting them involved in the implementation process. If they participate in the design of the MIS, they will be more likely to accept it and use it as an aid in the decision making process. This fact should be considered by all systems analysts when designing information systems.

Transaction queuing and cylinder logic access in the Time, Inc. magazine/book/record system

by CARL R. GERAMI
Time, Inc.
Chicago, Illinois

and

T. RUSSELL SHIELDS and RICHARD J. WEILAND
SEI Computer Services
Chicago, Illinois

ABSTRACT

BRGE, the Time, Inc. Magazine/Book/Record online computer system manages one of the largest existing data bases directly updated online (five billion characters). System activity is managed by an extended CICS system with the ability to route and reroute transactions to appropriate terminals. A conglomerate transaction journal is maintained to serve as an audit trail and as the primary backup mechanism for restarts and recovery. When file restoration is necessary, the journal is simply used as a transaction source, and restoration is concurrent with continuing data entry. The data base is maintained on twenty-five 3330-II disks using the Cylinder Lists of Data (CLOD) file organization method, and accessed via the Cylinder Logic Access Method (CLAM). These permit both sequential and random access to a file, and handle overflow in a monolithic and extremely speedy manner.

INTRODUCTION

The Time, Inc. Magazine/Book/Record system (BRGE) is a CICS-based system running on an IBM 370/168 MP mainframe with 6,144K (6 megabytes) of main storage. The principal extension to CICS is the replacement of vendor-supplied file access methods with new file organization and access methods that give greatly improved access times and considerable additional maintenance flexibility and data base integrity. The system provides subscription fulfillment and related services for a customer community of 26 million subscribers.

About one-half of the customers are magazine subscribers to *Time, Sports Illustrated, Money, People,* and *Fortune.* The remainder are subscribers to book series (*The Old West, Life Science Library,* etc.) and record series (*The Story of Great Music, The Swing Era,* etc.) offered by Time. About two-thirds of system activity surrounds books and records, where customer activity tends to be roughly bimonthly rather than roughly annual as it is for magazines.

The system processes all transactions relevant to fulfillment, about 750,000 transactions per week. The transactions come from an optical scanner reading machine printed documents, and from 200 CRT terminals housed at the Time and Life Building in Chicago. BRGE handles incoming orders, payments, account adjustments, address changes, and provides a facility for customer services inquiries. In addition to the customer data base which will be described in some detail below, BRGE is also responsible for maintenance of ancillary files including the inventory file, the product dictionary (which translates product codes to product descriptions), the effort key file (which maintains statistics including product prices for each individual promotion generated for magazines, books, and records), and the postal guide (which maintains the correspondence between city/state and zip code*). The combined data base resides, in compacted form, on twenty-five 3330-II disks, and is backed up weekly onto tape.

This paper describes processing in BRGE, with particular emphasis on the control of information flow within the online portion of the system, a transaction journaling/backup scheme which has proved most successful in maintaining file integrity and processing continuity, and a database organization and access method (CLOD/CLAM) that permits smooth and transparent file growth and maintenance and which gives, in a 200-terminal, 150,000 transaction-per-day online system, a response time of approximately one second.

* It is an interesting historical note that zip codes were developed by the United States Post Office as an outgrowth of Time's routing codes.

Significant features, in brief, include:

- Consistent processing of all transactions regardless of source.
- Maintenance of a conglomerate transaction journal that permits rapid and transparent restart/recovery procedures.
- A multiple queue online transaction processing scheme which directs transactions to the terminal best able to handle them, and redirects transactions automatically in case of problems.
- The Cylinder Lists of Data (CLOD) file organization method and Cylinder Logic Access Method (CLAM) which permit both direct and sequential file access simultaneously, and which manage very large quantities of overflow information without noticeable loss of response speed.

TRANSACTION PROCESSING AND JOURNALING

All transactions in BRGE, regardless of source, are processed in a consistent manner. The primary mechanisms that permit this are a Front End that transforms an incoming transaction into a consistent internal format for further processing, and a Back End that performs all physical file maintenance and maintains the Transaction Journal.

Remaining processing of the transaction is performed by programs running under CICS, which make reference to the transaction via a consistently formatted 1K-byte internal transaction area (ITA). Each transaction type interacts with the Front End to place information from the transaction into predefined locations within the ITA. No program except the Front End modifies the ITA, and program problems elsewhere cannot affect transaction integrity. Once information is in the ITA, processing proceeds based exclusively on the transaction type itself, and the information it supplies. The origin of a transaction, whether from a CRT, from an optical scanner, or from the backup Transaction Journal, becomes essentially transparent at this point, except that the source is noted for error notification and later operating summaries.

As control passes among the programs that process a transaction, additional information supplementing the ITA is gathered on validation, invoicing, and statistics generated from processing. Records relevant to the processing of the transaction are obtained and put in associated buffer areas from which inquiry information is extracted, and into which requested changes are placed.

After activity on a transaction is complete, whether by satisfying the transaction through normal processing, or through error termination, control passes to the Back End.

The Back End has two primary functions. If a book/record transaction completes normally, the Back End rewrites all modified records as appropriate. In case of error termination, the Back End consults the error code posted by the program which discovered the problem and the transaction source indication, to determine where the transaction should be referred for further handling. This process is discussed in more detail later.

Regardless of errors, the Back End releases any record buffers reserved for the transaction, and writes a Transaction Journal Entry (TJE) to tape. The TJE contains an image of the entire ITA, plus information on the disposition of the transaction, and statistical and financial information for later report generation. When completion is normal, invoice data, and the text of form correspondence with appropriate blanks and options filled in may also be included in the TJE. Bills and correspondence are generated directly from the Transaction Journal, respectively daily and weekly.

Two copies of the Transaction Journal are written simultaneously on two separate tape units. Each TJE is a variable length record, up to 6250 bytes in length, and a fixed number of TJE's is written to any particular tape reel to promote interchangeability of volumes between the two copies written.

The Transaction Journal serves two purposes. The first is to maintain an audit trail for magazine, book, and record processing, and to provide a medium from which operating statistics, operator performance measures, and financial summaries can be created. The second is to provide coordinated backup of the activity of the system. In case of operating system crash, or disastrous data loss through hardware or human failure, the Transaction Journal provides a mechanism for restoring the current state of the system without needing to re-enter any transactions manually.

For soft crashes without data loss, the last reel of the Transaction Journal is scanned to determine which transaction was the last accepted from each terminal, to notify the operator where to resume. Tapes from the optical scanner are similarly and automatically repositioned. Once notification to the terminals and scanner tape has been given, data entry resumes.

In the rare case that the files are lost, the files are initially re-created from tape copies that are generated weekly. Concurrent with data entry, which resumes following initial re-creation, the Transaction Journal is mounted and read as though it were an additional transaction source. TJE's corresponding to invalid updates and to inquiries that did not require a data base change are bypassed. Valid update transactions are reprocessed, with the ITA from the Transaction Journal moved back into memory for processing. A new version of the Transaction Journal is created, reflecting both the file restoration process and the concurrent entry of new data from the CRT's and scanner.

Although plans are in progress to put magazine file updates online like book and record processing, the magazine portion of the system currently performs updates in a weekly sequential run. The system validates transactions against the data base online, and saves them in the Transaction Journal for later application. The Transaction Journal processing facility provides the ability to draw selected types of transactions from the journal (in this case, magazine updates), so that no special segregation of transactions is required.

TRANSACTION QUEUES AND ERROR PATHS

It is expected in the course of routine processing that a variety of error conditions will arise, due to misentering of information, inconsistencies between the transaction and the data base (e.g., customer sends money, file shows nothing owing), or program and system errors. In addition, conditions may arise that are not within the purview of the CRT operator who originated a transaction.

The basic philosophy of BRGE is to make these exceptions as transparent as possible to the operator if the operator cannot be expected to handle them himself. An association is made between varieties of exceptions and a series of special handling queues. When an exception arises, control passes to the Back End for further processing. If the Back End determines that the error can be handled by the originating operator (for example, a miskeyed data item, or incomplete information entered), an appropriate screen is displayed to the operator requesting the correction or clarification. Once the requested information is entered, the transaction is reprocessed.

However, if the error discovered is identified as not being handleable by the originating operator (usually a file anomaly or inconsistency requiring discretionary action at a level above that of the operator), or if any inconsistency is detected on transactions from the optical scanner, the transaction and associated information is queued for action at an exception terminal. Alternatively, an operator may force a transaction into an exception queue when, regardless of program decision, the operator does not feel capable of handling a problem transaction. Each exception terminal is staffed by personnel specially trained to manage a particular class of problem (e.g., city/zip code inconsistencies).

When a transaction is switched by program decision to an exception queue, it will appear to the originating operator to have processed normally. The design parameter here is that since the operator is not equipped to handle the condition that has arisen, there is no point in troubling him about it.

A special case is a situation in which, during transaction processing, a program interrupt occurs, as distinguished from a program-detected anomaly or decision point. The most frequent cause of such an interrupt is simply a bug in one of the transaction application programs. In this case, the transaction and associated information is placed in a special queue for programmer attention. This convention has proved enormously useful for helping to detect and eradicate bugs that are highly data and circumstance dependent. Having available the exact data that generated an interrupt makes this level of debugging far easier to deal with than having only the knowledge that an interrupt occurred. And again, the originating operator is not distracted or delayed by a condition over which he has no control.

At the terminals that draw from the exception queues, whether they are exception terminals or programming terminals, a consistent mode of operation is maintained. When a terminal assigned to a particular exception queue indicates its readiness to proceed, the interrupted transactions are called up and re-executed one at a time.

In most cases, the error condition that initiated the transaction's being placed in the queue will recur. Now, however, the terminal initiating the transaction is the terminal capable of handling the problem. An appropriate error report is given, and the exception operator can take the action he sees fit including, when necessary, re-directing the transaction to another queue. In addition, it will sometimes happen after one problem has been dealt with that another problem will arise, requiring the requeuing of the transaction to handle the subsequent problem.

In some cases, when a queued transaction is called up for re-execution, the error will not recur. Often the cause of this non-replication is that an anomaly between transaction and file has disappeared through other file maintenance that took place between the original exception and the re-execution.

A common program interrupt is one due to a deadlock situation that was detected by BRGE. In its simplest form, deadlock will occur when transaction X already has record A and also requires record B in order to proceed; and transaction Y has record B and requires record A to proceed. If a set of transactions are in this kind of contention, BRGE cancels all but one of them, and requeues the cancelled transactions for later processing. Cancelling the transactions releases the records under their control to permit the remaining transaction to complete. When called back up, a cancelled transaction will typically not encounter record contention again, and will simply run normally to completion.

Personnel at the exception and programming terminals will be unaware of transactions that upon re-execution complete normally. Their attention will be requested only when the error recurs.

DATA BASE

The BRGE data base consists of the customer/subscriber file and a series of ancillary files.

- *Customer File.* This file consists of five billion characters of customer information, one record per customer, in segmented form. Magazine data is currently kept separate from book/record data. A customer will appear in the file for each of his magazine subscriptions, and once if he is a subscriber to one or more book/record series. Each record has a root segment containing identifying information, credit status, and a summary of information in the remaining segments (if any). Magazine records have only a root segment. In the book/record portion of the file, a segment represents purchases in a book or record series. Plans are in progress to reorganize magazine information into a unified scheme like books/records.

Book/record customer records are processed using a segment logic facility. In memory, each segment appears as an individual variable length record, locatable by application programs in well-defined spots in memory. The segments are gathered together and combined into a single variable length record for peripheral storage. When read back into memory, the combined record is redistributed into individual segments for processing, but only when a segment other than the root is required.

- *Inventory File.* This file applies primarily to the book/record portion of BRGE, and contains information on the quantity and location of each product available for sale. Time currently maintains an inventory of 646 different titles in 13 warehouses in the U.S. and Canada, shipping approximately 1.25 million items a month. Up to three hundred different inventory items are included in the inventory file for each warehouse location. Online order entry makes direct adjustments to the inventory file.
- *Product Dictionary.* The product dictionary maintains, for each book and record series, a translation between the series code and descriptive names for the series. Several descriptions of varying lengths are maintained, for use in a variety of contexts. Similar code-to-description tables are kept for each item within a series.
- *Postal Guide.* The postal guide falls into two parts. The first is an alphabetical listing of U.S. cities, states, and zip codes, with variants and probable misspellings. A corresponding Canadian list is also maintained. When a city/state/zip is entered into the system it is verified through this alpha listing. If no match is found, the entering transaction is rerouted to a postal specialist for examination and correction. A special keying feature is used in alpha lookups: The access method provides for access on partial keys; that is, presentation in sequence of all records whose leading key positions match a given partial key. But in addition, records in a file may have designated short keys: Any requested key whose leading portion matches the designated short key will select the record containing the key. In particular, if a unique city name or a leading portion of such a name corresponds to exactly one zip code, it may be designated as a short record key. Regardless of misspelling or variation of the state, if the city is entered correctly with zip code, a postal guide match will be made. This feature is also useful for cities with multiple zip codes. For example, Chicago can be entered (along with variants) as *Chicago, IL 606* and an entry with the proper leading digits of the zip code present would cause a hit on the file. As added verification in this case, a range check is also made on the trailing digits, once a file hit has been accomplished, eliminating the need to enter all 80 Chicago zip codes separately into the postal guide.

  The second portion of the postal guide is a numeric zip-to-city/state translator. Once data entry is verified, the zip code is maintained in a customer record, and city/state information is excluded. City/state is reassociated with a record (for label printing purposes, for example) through this second postal guide section.
- *Effort Key File.* An effort key is a code assigned to each individual promotion made in magazine, book, and record marketing efforts. The effort key file maintains statistics on the results of each promotion to date, and includes the specification of rules for fulfilling the promotion, including prices for the items promoted, sequence for shipping of items in a series, payments terms, special conditions, etc. Terminals in Time's New York corporate offices monitor the daily activity of this file to help guide the overall marketing effort. Online order entry causes immediate update of effort key statistics, so that this file is always current to the moment.

FILE ORGANIZATION AND ACCESS

All of the files described in the previous section are maintained together as a single OS file to minimize job control, system control information, and interaction with the operating system. The logical independence and identity of the files is maintained via a file organization method called Cylinder Lists of Data (CLOD), and a corresponding Cylinder Logic Access Method (CLAM). CLAM is an EXCP-level access method that operates on IBM 360's and 370's under OS and VS, to permit sequential and random file access.

The only consistency that CLOD requires among the files it controls is that they use a common block size, and are located physically on the same variety of storage device (3330-II drives at Time). CLOD maintains, for the disk extents made available to it, a list of available cylinders for allocation to the logical files it controls. Similar lists are developed for each file as cylinders are allocated to the individual files. Records within the files are maintained in order by key. Ignoring overflow for the moment, reading records cylinder-wise according to a file's cylinder list results in the file's records being read in order. Any file may be maintained either in ascending or descending key order. The cylinder list itself is in correspondence with the allocation sequence, but has no intrinsic numeric order.

When a file requires an additional cylinder, it is allocated from the extent that has the fewest cylinders currently allocated. One of the effects of this allocation scheme is that files tend to be evenly spread over all available extents, minimizing the contention on a particular volume for access to a heavily used file. Additional volumes and extents may be added without interrupting processing, and CLAM will display operating and access statistics on request, to assist in performing load leveling. CLAM provides the ability during normal execution to transfer cylinders of data among extents to spread out heavily accessed portions of a file.

The key file consists simply of the sequence of first keys from each block. Given the cylinder list and the block size, the correspondence between the nth key in a key file and its block is readily and speedily established. Key files may be kept on a direct access medium, or in memory. In BRGE, which uses full-track blocking, only the customer/subscriber file's key file is kept on peripheral storage.

One additional level of indexing is always present, in the form of a core index to the key file. The core index is an index to the blocks of the key file, exactly in the same manner that the key file indexes the main file. With the choice of a reasonable block size, there is never any reason to keep this core index anywhere but in main memory. For the subscriber file, with five billion characters of data across twenty-five packs, the core index occupies only about 3K bytes of storage.

CLAM resembles ISAM and VSAM in that it permits both sequential and random file access. However, CLAM operation, particularly regarding the handling of overflow, is quite different. The handling of overflow records is designed to minimize the number of additional seeks needed to find the records. This is accomplished by keeping records that overflowed from the same block physically together to the greatest degree possible.

To describe overflow processing, two levels of record collections in addition to the block and the logical record are needed: the *bundle* and the *span*.

A bundle is simply a related collection of one or more logical records. Several bundles may be combined to form a block.

A span is the collection of all logical records addressed by a single entry in the key file. If a main data block has no associated overflow records, a block and a span are identical. However, if overflow records are associated with a block, the span includes the main data block plus all associated overflow records. The records which constitute a span are logically all in order by key.

At the point that a main data block overflows, a bundle is created from the logical records that will not fit into the main data block. In particular, trailing records from the end of the span are placed into an overflow bundle, leaving a full block of records from the beginning of the span in the main data area. This overflow bundle may be combined with other overflow bundles to form a block within an overflow cylinder. (All files controlled under the CLOD share the same overflow cylinders). A flag and pointer are included with the main data block to direct CLAM to the appropriate overflow block when necessary. Such an additional access will be made when the flag is set, and when (assuming ascending file order) a desired record's key lies between the key of the last record actually in the main data block and the key beginning the next sequential span.

CLAM's speed in locating overflow records comes largely from a very dynamic control of the overflow area, insuring that overflow records from the same span stay together. When adding a new record to an overflow bundle, it may happen that this newly enlarged bundle, plus the other bundles from the same overflow block no longer will fit into a single block. In this case, the just-modified overflow bundle is split away from the other bundles, and placed into a new block which will accommodate it.

As a consequence, finding an overflow record never requires more than one additional seek, unless more overflow records exist for a single span than will fit into an entire block. In addition, if space becomes available in the main data block through deletion of a main block record, the span is reapportioned to move overflow records back into the main data block. Freed space is immediately available for reuse.

Although CLAM/CLOD include provision for introducing slack space into main data blocks at the time that a file is created or reorganized, the speed of handling overflow generally makes such provision unnecessary. Situations have been observed in which the presence of more than 2,000 cylinders of overflow records had no noticeable effect on online response time.

All files organized together under CLOD share the same pool of buffers (hence the requirement for consistent block size). A program may specify whether CLAM should return the address of a record within a buffer for direct processing, or move the data to a program-defined area. When a data buffer is freed, it is linked to the end of the chain of available buffers. If a request is made for a record in a freed buffer in which no errors appear, before the buffer is reused, the request will be satisfied without any I/O operations, by reactivating the buffer and removing it from the available chain.

CLAM permits a file to be accessed simultaneously as though it were two independent files. It is possible for a program to process a file sequentially, and also periodically request a record from the same file randomly by key, based for example on a flag and pointer present within the record being sequentially processed. Sequential processing, when resumed will continue with the next logical record.

CLAM has its own facilities for providing exclusive control of blocks to programs performing update activities, and includes tests for determining deadlock situations. A program specifying read-only file use is not restricted from access to a file, even when an update is taking place. A specific block being updated is, of course, locked up for the duration of the update.

Other facilities contained directly within the access method include:

- Record compaction/expansion exits. Routines may be supplied for any CLOD logical file to perform compaction and expansion of logical records. On input, CLAM will locate a compacted record, call upon the expansion routine supplied for this file, and return control to the program requesting the record as though an uncompacted record had been read from the file directly. The converse operations are performed for output.
- Record segmentation facilities. CLAM will accept a collection of record segments, each with the appearance of an individual variable length record, and combine the segments into a single variable length record for placement in the file. The record may be composed of up to 64 segments corresponding to a bit table or to a combined key area at the front of a combined record. CLAM will resegment such a record for program use upon request. Both segmentation and compaction may apply to the same file.
- Handling queue files. CLAM commands provide for the special handling of queue files. Basic facilities include the ability to add records (messages, transactions) to the end of the file, and to draw records from the front of the file in standard first-in, first-out fashion. Multiple sources and draws may be operating on a queue simultaneously. In addition, facilities are available to examine records beginning at the front of the queue, or to search for records with special keying within the queue. Records are actually deleted from the queue only on specific command to do so.
- Access from all languages. Primary use of CLOD and CLAM to date has been via assembly language, in which a complete set of macros are available to direct file activity. In addition, a subroutine SEICAM, accessible via standard call from all high level languages provides these languages with EXCP-level CLAM access to CLOD files. Commands are included to read and write records, open and close logical files, add extents, perform segmentation and combination, and to retrieve statistics on file activity.

HISTORY AND CONVERSION

Until 1974, Time operations were carried on via emulation of IBM 7070 on an IBM 370/158. Each magazine and book/record series had its own masterfile, and each was processed separately in a classical card-tape environment. Time developed a design for conversion to a unified system, but found that operating costs and times were unacceptable using standard vendor-supplied software. Implementation of the unified design through an extended CICS system with new file organization and access techniques was accomplished through a combined effort of Time, Inc. personnel and SEI Computer Services. Principal design for CLOD/CLAM was done by T. R. Shields of SEI. Implementation began in May 1973, and conversion and production on the new system both began in April 1974. Conversion was accomplished by a straightforward translation of old masterfiles into BRGE transactions. BRGE itself was used to process the transactions and thereby enter the content of the old masterfiles into the unified customer database. Product files were so converted over a period of about five months. At the point that a product was designated for conversion, activity on the product was suspended while conversion took place, after which activity resumed under the new system. Conversion suspensions of activity were typically two to five days, but only on the one product being converted. For all other products, activity continued as usual. The system was fully operational and converted in September, 1974. At that time BRGE ran on an IBM 370/158 under SVS. The system is currently running on an IBM 370/168 MP under MVS.

One additional point on the conversion process is worthy of note, namely that conversion using the new system itself provided a thorough check-out of system features and intercommunications. Particular use was made of the programming exception terminals for locating and fixing bugs. Although considerable quantities of transactions would appear in the program bug queues, the catching and fixing of a bug would typically cause the uninterrupted flush-through of a large percentage of the queued transactions. During the conversion process, a peak transaction processing rate of 80,000 transactions per hour was observed. The system retains the capacity to process at this rate, but normal operations have not to date been able to generate transactions at a rate corresponding to the system's full capacity.

Generalized software for translating data*

by EDWARD W. BIRSS and JAMES P. FRY
University of Michigan
Ann Arbor, Michigan

ABSTRACT

Many data processing installations are confronted with the problem of data conversion. Some of the conversion problems are conversion of files foreign to the installation, conversion of files into a data base management system format, and conversion of all data to upgrade hardware or software. Simple file organizations pose few conversion problems, while logically and physically complex data bases emphasize many conversion problems. The current approach of writing specific translation programs is time consuming and frequently inaccurate; a new approach is desirable.

To address these conversion problems, The University of Michigan Data Translation Project has developed a generalized translation methodology. This methodology has been applied in the development of several prototype data translators. These translators have progressively advanced the physical transformation capabilities (reformatting) and the logical transformation capabilities (restructuring). The reformatting capabilities of the translators include the ability to access and modify the physical storage structures which support sequential, indexed sequential, and network organizations. The restructuring capabilities allow complex restructuring of lists, trees, and networks.

Future extensions to the translation methodology include the decomposition of the translation process into small, but specific steps. Languages would be developed to address each of these small translations, and could lead to a generalized accessing mechanism and a data interchange form.

INTRODUCTION

The computer field is a rapidly expanding area with advancements in computer hardware and software technology that are paced by the increasing sophistication and awareness of the users. Expanding utilization of computer facilities and the ever increasing application demands continue to usurp valuable resources. Caught in the middle of this situation is the data processing manager, who must satisfy the demands of the user community and yet maintain the economic attractiveness of the computer system.

One of the many problems facing a data processing installation is the conversion and transformation of data bases. Typically this problem ranges from the conversion of computerized files from other installations (foreign files), the restructuring and reformatting of extant data bases, to the translating of data into various forms required by different applications.

Concomitant with the increased use of data base management systems, the data base administrator is faced with the necessity of creating and/or integrating existing files into data bases or of restructuring existing data bases. The latter capacity, while necessary to make effective use of the data base, is not typically found in data base management systems.

To take advantage of the economic benefits of new hardware/software capabilities and data base management systems, the data processing manager and the data base administrator need a variety of data base conversion tools. The current manual approach of writing specific programs for each conversion is both time consuming and costly. A fresh approach to the problem is therefore needed.

In order to address the data conversion problems of the Data Processing installation, a new software technology has been developing over the past five years called data translation. One group developing a data translation methodology is The University of Michigan Data Translation Project, where several prototype data translators have been developed. These developments and related activities are aimed at providing both the data processing manager and the data base administrator with facilities for foreign file conversion, data base integration, data base restructuring, and data conversion resulting from upgrading hardware or software and changing user requirements.

The purpose of this paper is to describe the progress at The University of Michigan on data conversion based on the development of a data translation methodology. The paper identifies those areas of data base

* This work was supported by the Department of Defense, Defense Communications Agency, WWMCCS ADP Directorate, Reston, VA Contract No. DCA 100-75-C-0064.

conversion in which the translation methodology has been successfully developed and is ready to be applied to current data processing problems. It describes current areas under development and those which are in need of further research.

The paper begins by describing the current research on data base conversion and develops the data translation approach. Next, the evolution of data translators at The University of Michigan is traced in terms of their logical and physical capabilities and in terms of generality achieved. The paper concludes with some observations on a generalized data translation methodology and enumerates those areas which need to be researched.

BACKGROUND AND APPROACH

Within the last five years, a means of attacking the data base conversion problem in a general manner has been proposed.[1–4] It is interesting to observe that all of these efforts employ some degree of generality and are based on a descriptive approach, which describes the source and target data bases and the necessary transformations required to derive the target data base instances from the source. These descriptions, couched in a high-level declarative language, provide the basis for two implementation approaches for a generalized translator. The *interpretive* approach develops a generalized processing program,[1] and the *generative* approach creates a specific translation program[4] for each conversion.

The University of Michigan Data Translation Project's approach,[5] emblematic of others, consists of two steps:

1. The user specification of the necessary descriptions, and
2. The execution of data translator based on these descriptions (Figure 1).

The user supplies descriptions of the logical, physical, and relational aspects of the source and target data bases, along with the specifications of the restructuring transformations required to map source data into the target data. Two languages were developed to provide these descriptions; the Stored-Data Definition (SDDL) which is used to describe the source and target data bases, and the Translation Definition Language (TDL) used to describe the restructuring transformations.

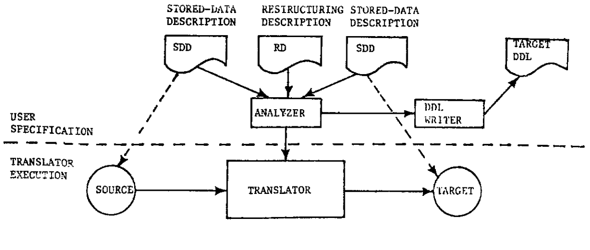

Figure 1—Data description approach

The SDDL is based on the language proposed by Taylor.[6] This high-level language uses a modified CODASYL model of data. At first glance, the SDDL is similar to the data description language of a data base management system, but a closer look reveals several important differences. The stored-data definition language, based on common data definition practices, is actually an extension of the logical DDL to the more physical implementation aspects. It describes the mapping of the user logical structure to physical storage structure, the mapping of the physical storage structure to a storage device, and the access paths to the data.

The Translation Definition Language, on the other hand, deals primarily with logical transformations of data and describes the translation of source instances to target instances. The language was developed at The University of Michigan and began as a simple association list of source item names and target item names, but it has since developed into a powerful restructuring language. Detailed discussions of these languages can be found in References 5 and 7.

The SDDL and TDL descriptions are processed by an Analyzer which produces an Encoded Stored-Data Description (ESDD) and an Encoded Restructuring Description (ERD) respectively, which in turn are used to drive the translator.

An anxiliary module which need not be generalized, the DDL Writer, uses the Encoded Stored Data Definition of the target to construct a data definition of the target data base in the language of the target DBMS. Major benefits of this module include not only the immediate use of the data base by application programs, but more importantly, the user verification of the target description. The DDL Writer allows the user to verify in a language familiar to the user that the target data description is consistent with his view of the target data base.

The second step in the translation process is the physical transformation of the source data into the target data. Driven by the data descriptions prepared in the first step, the second step employs three components; a Reader, a Restructurer, and a Writer (Figure 2). The Reader accesses the source data base, the Restructurer transforms the source data into a form suitable for the target, and the Writer creates the target data base.

The Reader module, driven in part by the source ESDD, performs many functions; sequentially accessing physical records, physically deblocking these records, logically identifying their components, and automatically creating an internal data base processable by the Restructurer. In dealing with complex data base structures, the Reader must keep track of

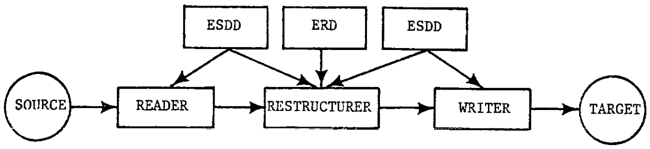

Figure 2—Components in the translation process

access paths between these unblocked records so that the Restructurer is provided with an accurate representation of the source data base.

The Restructurer accesses the internal representation of the source data base and converts it to a representation of the target data base. The conversion from source to target is a transformation of the logical structure and is directed by the ERD which contains the restructuring specifications.

The Writer, driven in part by the target ESDD, creates the target data base by constructing target data derived from the Restructurer's internal data base.

The approach by The University of Michigan, described above, is an interpretive translation approach in which stored-data descriptions provide parameters to a generalized translation algorithm. An alternative approach, a generative one, creates specific translators for each translation[4] (Figure 3). There is, of course, a hybrid approach in which some of the components in the model of the interpretive approach produce executable code, while other components remain interpretive.[2] The interpretive approach was chosen because it provides a good research tool and facilitates the building of series of data translators.

EVOLUTION OF DATA TRANSLATORS

The translator development at The University of Michigan has designed four translators: a Prototype, Version I, Version II, and Version IIA. Only three of these designs, however, have been implemented; Prototype, Version I, and Version IIA. The various designs were developed to address different problem areas, and each translator design has produced a major contribution to the generalized translation process.

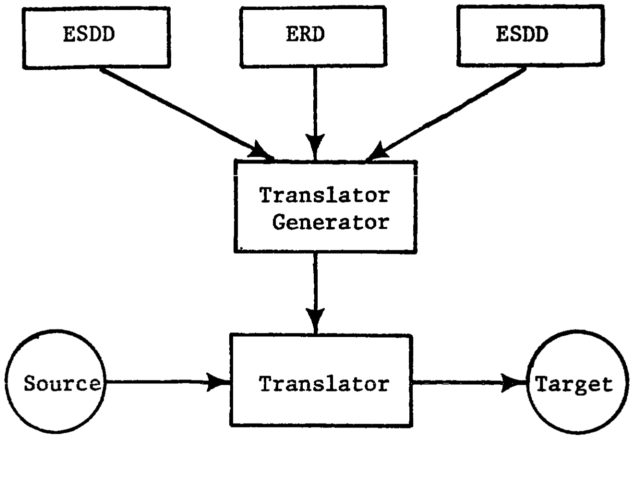

Figure 3—Alternative DDL driven data translation

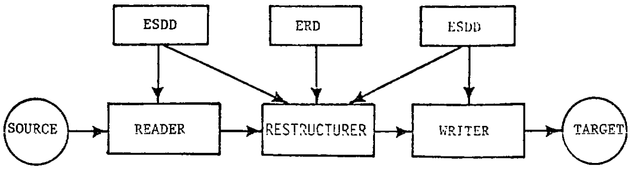

Figure 4—Prototype translator

The translator's capabilities are divided into two categories; physical and logical. The Translator's physical capabilities are characterized by the Input/Output processing ability of the Reader and Writer. The translator's logical capabilities are measured in terms of the restructuring proficiency of the translator's Restructurer component.

In the remaining portion of the paper, the purpose, architecture, major contribution, physical capabilities, logical capabilities, generality, and implications of each design are discussed.

Prototype translator

The prototype translator was developed to provide a framework for further research and to verify that the proposed technical approach was sound.[8] The architecture of the prototype translator was very similar to the translator model described in the previous section (Figure 4). The Restructurer, however, only performed an identity transformation, merely associating source item names with target item names.

Prototype's physical capabilities

There was not a great deal of generality in the prototype; the Reader module only accessed one source data base; and the Writer module only created a single output. The source data base was a NIPS data base unloaded in a variable blocked sequential format (Figure 5A). NIPS ran on the IBM 360/370 series of com-

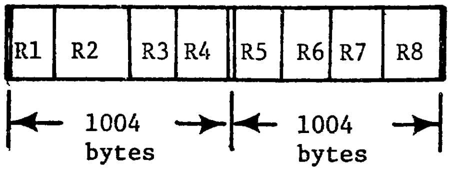

Figure 5A—NIPS format

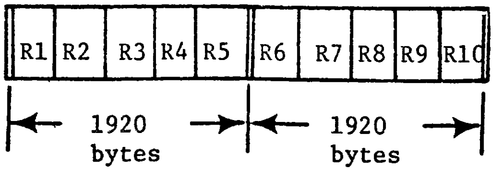

Figure 5B—H6000 system standard format

puters and allowed two-level hierarchical structures with a maximum 256 different groups.

The Writer was also straightforward. It constructed a structure similar to the NIPS data base structure, in the Honeywell 6000 System Standard Format. The H6000 System Standard format was similar to the IBM variable blocked format (Figure 5B).

The Reader and Writer operated with sequential media, and physical concatenation (i.e., a simple mapping algorithm) was used to maintain the hierarchical relationships in both systems. Both systems used similar mapping, so reordering of record types was not necessary.

Prototype's logical capabilities

The Prototype translator does not perform restructuring, and when no records were eliminated, a one-to-one correspondence existed between group instances in the source data base and those in the target data base (Figure 6). Consequently, the Restructurer only processed one group instance at a time. It performed item conversions as necessary and allowed the user to modify the order or storage representation of items within a group.

Generality

The only general module (not coded specifically for the NIPS to H6000 System Standard Format) was the Restructurer. Its generality was possible because of the level of insulation provided by the encoded forms of the SDDL and TDL languages which provided all the necessary information for the table driven architecture of the Restructurer. In contrast to the Restructurer, the Reader and Writer were very specific and used the operating system facilities to perform input/output.

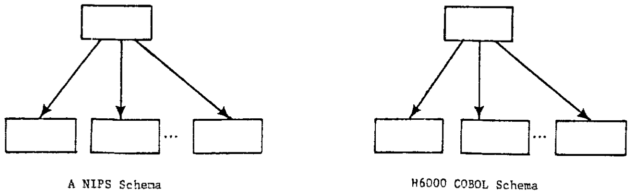

Figure 6

Design implications

Although the prototype performed a very simple translation, its major contribution was the framework for a series of generalized translator implementations. The Prototype design provided a consistent set of interfaces: between the languages and translator modules, through the encoded tables, and among the translator modules by a set of table access routines and common data formats. Throughout the development of generalized translators, this basic architecture has proven to be technically sound.

Version I translator

The Version I translator (Figure 7), although very similar to its predecessor, made some progress toward generality. Version I was developed to perform both the forward and reverse translations (NIPS→System Standard format and System Standard format→NIPS). Furthermore, the COBOL System Standard format files were constrained to a format acceptable to WWDMS, a data management system on the H-6000 computer system.

The purpose of this translator was to further verify that the translation methodology was sound and to demonstrate that the translation was reversible without loss of information. The latter proved to be an interesting technique to verify that a translation was correctly performed.

Version I's physical capabilities

The Reader and Writer were required to access and create both NIPS and H-6000 formats (Figure 5B). The Reader and Writer modules were parameterized to enable them to read and write both organizations. Additionally, the Reader was generalized by taking greater advantage of the Encoded SDD. Thus, the Reader's capabilities were generalized to handle most sequential tape formats.

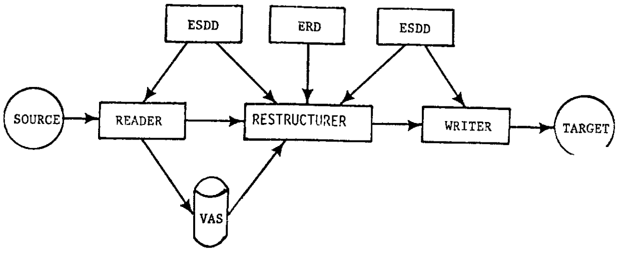

Figure 7—Version I translator

Version I's logical capabilities

The major difference between the Version I translator and the Prototype translator is the addition of a basic restructuring capability. The major objective of Version I was to demonstrate that the inverse translation (source-target-source) was feasible and indeed produced the "original" data base. Restructuring was often required, because the source, COBOL-WWDMS data bases, had eight levels of hierarchy, but the target, NIPS, could only handle a two-level hierarchy. To permit such translation, the first restructuring capability developed was *compression* of hierarchical levels. For example, a two-level target schema was constructed (Figure 8) from the multiple level source schema. In order to preserve the information of the source data base, the Restructurer created a new group PROD-PARTS and replicated the PARTS information in this new group of target data base.

Generality

The increase in generality of the Version I translator occurred primarily in the Reader and Restructuring components. A new section of the SDDL was developed to provide a better description of physically sequential media. This additional section permitted the deblocking, spanning, and identification operations to be generalized. The Restructurer increased in complexity through addition of the parsing and restructuring functions. These additions to the Restructurer were driven by additions to the SDDL and TDL. Thus, these language additions maintained the generality of the Restructurer component.

The Restructurer became complex, but the software architecture insulated it from the source and target data bases. Its complexity was isolated and could be addressed by revising single modules, as opposed to developing a new translator. The compressing restructuring capacity proved to be quite general. Not only could adjacent levels of the hierarchy be combined, but multiple levels of the hierarchy could be combined into a single level.

Design implications

The Version I translator design required the capability to compress schemas. The compression operation required access to an entry instance. An entry instance can be very large, and a mechanism was added to the translator to give the Restructurer direct access to the entry instance. This mechanism was termed a Virtual Address Space (VAS). The Reader constructed the VAS from group instances contained within one entry instance.

Version II translator design

The objective of the Version II design was to increase the input and output data base classes and to expand the restructuring capabilities of the translator. The architecture of the Version II design was different from the previous translators (Figure 9).

The main difference between the Version II translator and previous designs resulted from the realization[1] that the more complex restructuring operations became, the greater the volume of data required. Such complex restructuring also required broader accessibility to the data base. Because the Restructurer requires many access paths to data, some of which are not available in the source data bases, an internal form of the source data was designed, the Restructurer Internal Form (RIF). A data management function was also incorporated to manage the RIF which allowed the Restructurer to access the RIF directly.

Version II's physical capabilities

The capabilities of the Reader and Writer were to be increased to handle sequential, indexed sequential (ISP), and network (IDS) structures (Figure 10 A,B,C).

These capabilities were to be implemented using a general control structure in the Reader for invoking the specific accessors for the different organizations. The lowest level components were parameterized.

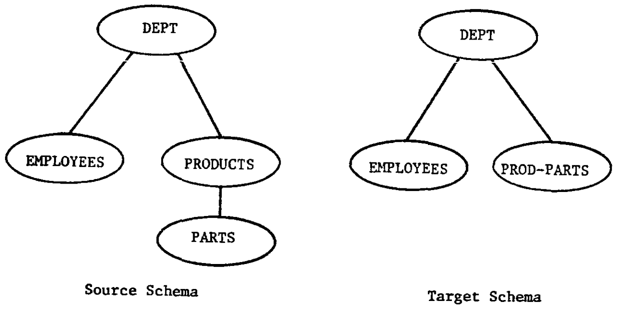

Figure 8

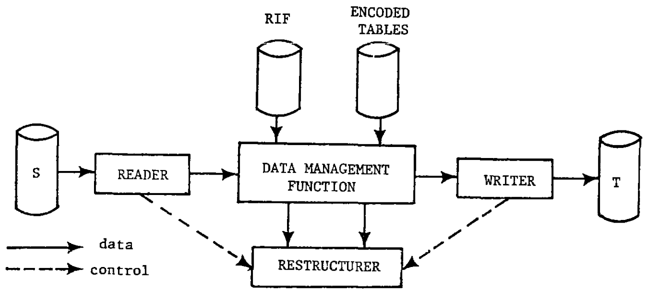

Figure 9—Version II design

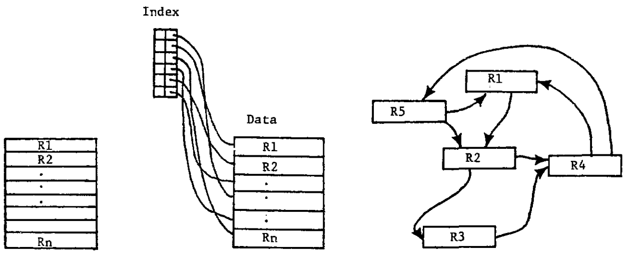

SEQUENTIAL Figure 10A

INDEXED SEQUENTIAL Figure 10B

NETWORK Figure 10C

Figure 10

Version II's logical capabilities

The general problem in restructuring data bases was a very difficult and complex one with no established solutions. The initial research[9] indicated that restructuring for hierarchical structures was feasible, but was yet to be implemented. Consequently, Version II was designed to perform restructuring within hierarchical structures, which could possibly be subsets of network structures.

The Restructurer's design facilitated the creation of any target logical structure derivable through repeated applications of Expansion, Compression, Partitioning, and Merging restructuring operations on the source logical structure. Examples of these restructuring operations are shown in Figure 11.

Generality

Extending the capabilities of the Reader and Writer from Version I's sequential representations to the sequential, indexed sequential, and network representations of Version II had an impact on generality. The sequential Reader of Version I was reasonably general, but the implementation of the SDDL's extended capabilities to handle the representation of complex logical structures on disk media proved extremely difficult. Consequently, accessors, low level routines coded specifically for each organization, were designed for the more complex input/output operations and interfaced with the general software in the Reader. The Restructurer provided an increased level of generality by providing a comprehensive set of restructuring capabilities for hierarchical structures.

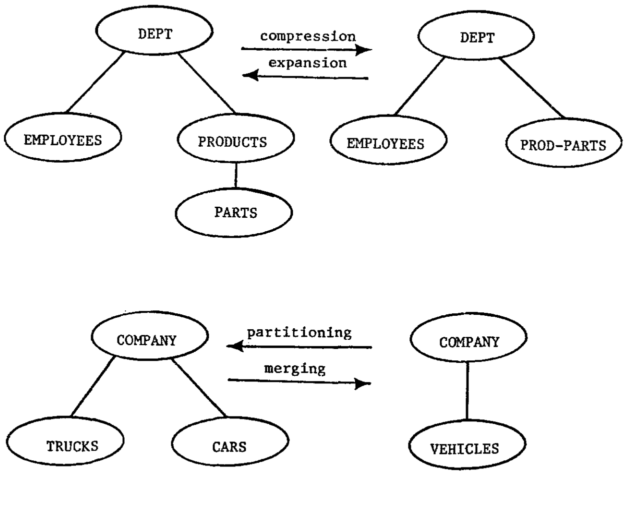

Figure 11—Restructuring capabilities

Design implications

The complex restructuring operations desired for the Version II frequently required access to the entire data base. This requirement led to the development of a Restructurer Internal Form (RIF) in the Translator and the result that the read function had to be performed completely before the Restructurer was envoked. In order to help manage the complex and voluminous RIF data base, a data base management system[10] was added as a major component of the Translator's design. This DBMS was used not only to provide direct access to information stored in the RIF, but also was used to manage the internal tables.

Version IIA translator

After evaluating our design of the Version II translator and some actual data base reorganizations, a decision was made to emphasize restructuring at the expense of the physical capabilities—reading and writing. An alternative design, the Version IIA translator, was developed which focused on the restructuring within the I-D-S data base organizations.[11] The specific nature of the translator allowed the design effort to focus on user orientation as well as restructuring. It was decided that an expanded version of the I-D-S DDL could be used for the description of the source and target data bases. The I-D-S DDL was augmented by using Level 66 descriptions. Another DDL analyzer, specific to I-D-S, had to be developed, which not only processed the extended DDL but also produced the Encoded SDD (Figure 12).

Version IIA's physical capabilities

Since the Version IIA had to restructure I-D-S data bases, the input/output class of the Reader and Writer were limited to these structures (Figure 10C). However, the Reader was generalized to populate the RIF from multiple source I-D-S data bases which allowed the integration of I-D-S data bases, the addition of new data and structure, and the addition of new relationships among existing data instances.

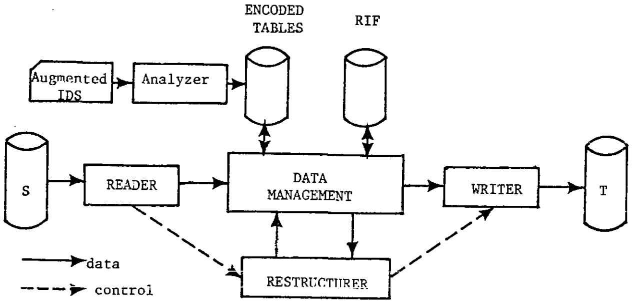

Figure 12—Version IIA translator

The Writer, since it was coded for I-D-S data bases and used the I-D-S access methods, could perform limited storage optimization through reformatting of the target data base. The various storage parameters (place near, . . .) available in the I-D-S DDL could be used to create more efficient target data bases.

Version IIA's logical capabilities

The Restructurer made a major research and development step by extending its capabilities to network structures. The Restructurer implemented was extremely powerful and could not only change the implementation structure of existing I-D-S relationships, but also had the capability to create structures more powerful than I-D-S I could process. Some of these restructuring capabilities developed in addition to the Version I capabilities are shown in Figure 13A-13C.

Generality

Overall the Version IIA translator is less general than the Version II design chiefly because the Reader and Writer were tailored to process I-D-S data base thereby simplifying the coding effort. The specific approach to the Reader and Writer stemmed from the Version IIA emphasis on the Restructurer, and the difficulty of implementing the extended SDDL to describe complex structures residing on disk media. The Restructurer, however, maintained its generality by the table driven architecture and greatly expanded its capabilities from hierarchical to network structures.

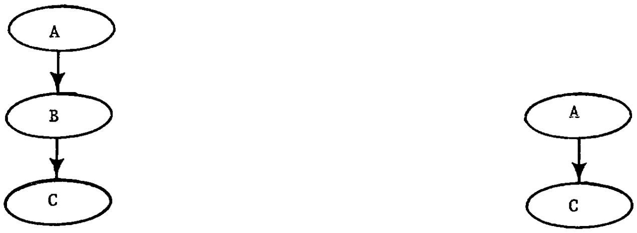

Figure 13B—Creating a relational entity AC from AB and BC

Summary of capabilities

During the evolution of the Michigan data translators, both the Physical and Logical Capabilities of the translators were increased in incremental steps. The capabilities of the Reader and Writer modules have been extended from sequential to network data base representations with some loss of generality. Restructuring capabilities have increased from simple renaming of structures, through hierarchical restructuring to network restructuring. Although it was necessary to expand the Restructurer's accessibility of the data base from a single record to the entire data base in order to achieve these sophisticated restructuring capabilities, the generality of the Restructurer was preserved through the RIF and the DBMS. In addition to the translation capabilities, it became clear that additional capabilities of adding data and new relationships to the data base were necessary and implemented in the Version IIA. The evolution of the basic capabilities of the various Michigan translators are summarized in Figure 14.

REFLECTIONS ON THE DEVELOPMENT OF DATA TRANSLATORS

Over the past four years, The University of Michigan Data Translation Project has developed a series of increasingly more general data translators based on a stored-data definition language approach. In reality, a general data translator is a series of three interpre-

Figure 14—Comparison of capabilities

tive mini-translators; a Reader, Restructurer, and Writer. In order to perform a translation from a source data base to a target data base, the Reader accesses the source data base, the Restructurer performs the required logical transformations on the source and develops the target structure, and the Writer constructs the target data base. These mini-translators may be categorized according to the type of transformation performed—either physical or logical. The Reader and Writer perform primarily physical transformations, while the Restructurer performs a logical transformation. The requirement to perform complex logical transformations in the Restructurer had a substantial impact on the architecture of the Translator particularly in the areas of data handling and representation. The complexity of the transformation required direct access to all components of the data base and an internal form of data was developed for the Restructurer. To address representation of complex logical structures for the internal form and to provide direct data access, a data management facility was implemented within the Restructurer.

The efforts at The University of Michigan and Honeywell have established that it is technically feasible to convert data bases created by one DBMS into a form required by another DBMS in a reasonably general manner. The generality is achieved through a stored-data definition language which directs the translation process. The translation can be quite complex; for example, changes in word length, blocking factors, data representations, and logical structures. Additional translator capabilities include: the addition of data, addition of relationships, and integration of data bases.

The economic feasibility of the SDDL driven approach has been demonstrated for simple data base structures and representations. However, as the generality of the translation process increases, the complexity of the language increases correspondingly. An alternative approach would use the host DBMS DDL to produce the ESDD (as in the Version IIA). This would simplify the user's task but would require a DBMS specific program to construct the ESDD. Such an approach would allow translation with only one unfamiliar language, the Translation Definition Language.

FUTURE DIRECTIONS AND DEVELOPMENTS

The interdependency of the logical and physical aspects of data, coupled with the dependence of the physical transformation on the hardware/software environment, makes generalized data base conversion a complex but challenging problem. The data translation methodology developed separates this problem into a logical and physical transformation processes which allow specific modules to address these transformations. Significant results have been achieved in generalizing the logical transformation process—the research, development and implementation of a generalized Restructurer. Although a generalized Restructurer has been shown to be technically feasible, its economic justification has not been demonstrated. The economic feasibility of the approach is in doubt because of the slow execution speed of the Restructurer (Version IIA), however, an optimization effort has been initiated which should greatly improve the efficiency of this process.

The achievement of complete generality in the physical transformation process has yet to be achieved. It appears much more difficult since the deeper one goes into the actual representation, the more complex the description process and the implementation of the physical transformation modules. For example, inverted structures that are implemented in SYSTEM 2000 and ADABAS are extremely difficult to translate because the SDDL for such organizations must not only describe the data, but also describe the format and semantics of the indices. Extending this part of the SDDL, the Reader, and the Writer modules to handle these organizations would require a substantial effort. At this point in the research, the development of a completely general physical transformation modules does not appear to be economically justifiable.

Building on this result, a vehicle for further decomposing this complex process into its physical and logical components needs to be developed. One such candidate is a common Data Interchange Form (DIF) for the transferability of structured data bases. Although the development of the Data Interchange Form is not easy and requires an additional transformation in the translation process, it would nevertheless be a simplifying ingredient. The design and specification of a common Data Interchange Form would result in:

(i) Separation of the hardware/software environmental considerations;
(ii) Development of specific accessors and constructors to address the physical transformation process;
(iii) Distribution of the effort between the source and target machines;
(iv) Development of a more efficient internal form of data for the Restructurer.

Further, the development of a Data Interchange

Form would facilitate the general transportability of structured data bases. Such transportability would not only occur using interchange media (e.g., tapes), but also occur over communication networks (e.g., ARPANET).

Another argument for a Data Interchange Form is that it allows the translation process to be more explicitly decomposed. The stored-data definition language could be divided according to individual transformation, which would allow different forms and types of the language to address the differing levels of detail in the translation process. The translation modules would be more dependent on their respective environments and, consequently, easier to build. Further, such a decomposition would allow optimization to take place at different stages in the translation process.

The design and specification of a common Data Interchange Form still requires research and development. It must be self-describing in that it would access interpretively, independent of the environment in which it was created. The Data Interchange Form must be logically capable of expressing the most sophisticated data base structure known, but be physically simplistic without being overly inefficient. Consequently herein lies a direction for future research.

Experiments with a symbolic evaluation system

by WILLIAM E. HOWDEN
University of California at San Diego
La Jolla, California

ABSTRACT

Symbolic evaluation techniques can be used to determine the cumulative effects of a program's calculations on the branching predicates and output variables in the program. If the evaluation techniques are carefully and selectively applied, they can be used to generate revealing symbolic representations of the computations carried out by the paths in a program, and of the systems of predicates that describe the input data that causes program paths to be executed. A symbolic evaluation system called DISSECT is described which can be used to analyze FORTRAN programs. The system includes a sophisticated command language that allows the user to selectively apply symbolic evaluation techniques to different program paths and subpaths. The command language allows the user to carry out different levels of symbolic testing of a program and to construct systems of predicates that can be used to automate the generation of numeric test data. Experiments with the system which illustrate its advantages and limitations are included. DISSECT can be used to carry out a systematic, documented reliability analysis of a program. The paper concludes with a discussion of the potential use of systems like DISSECT as the basic software certification tool in the software development process.

INTRODUCTION

When a program path is executed by running the program on a given input, the correctness of the path for that input can be determined by examining the effects of the calculations carried out by the path. If the path is executed "symbolically" rather than with actual data, it may be possible to use a single execution to illustrate its correctness on a large subset of the input domain rather than on just a single value. Symbolic execution of a program is carried out by giving dummy symbolic values rather than actual numeric (string, logical etc.) values to all or some of the input variables of the program. An expression in the program involving variables with symbolic values is evaluated by substituting the current symbolic values of the variables into the expression. The resulting expression is then simplified algebraically. All operators having only actual as opposed to symbolic operands are evaluated in the normal way. The resulting expression is the symbolic value of the original expression.

Figure 1 contains a program for carrying out polynomial interpolation.[1] The documentation for the program describes it as consisting of four segments, each of which computes part of the interpolation process. Lines 34 through 48 are supposed to compute a set of coefficients a_i which are given in terms of y_i and Δ_i by the formula:

$$a_k = \frac{y_k}{\prod_{i=1}^{k-1} (\Delta_k - \Delta_i)} - \sum_{j=1}^{k-1} \frac{a_j}{\prod_{i=j}^{k-1} (\Delta_k - \Delta_i)}$$

The program is written so that a_k corresponds to A(k), Δ_i to DELTA(i) and y_i to Y(I1+i−1). Symbolic values are designated by alphanumeric strings surrounded by quotes. Suppose "I1," "DELTA (I)" I=1, 10 and 2 are assigned to I1, DELTA(I) I=1,10 and NTERMS at statement 36 and "A(1)" to A(1) at statement 37. Then the effect of the calculations carried out in a single iteration of the loop in lines 34 through 47 can be determined by symbolically executing the code and printing out the values of A(1) at statement 36 and A(k) at statement 46. Figure 2 contains these symbolic values. The quotes designating symbolic values are deleted from the output to increase readability whenever this is unambiguous. Inspection of the values reveals that they agree with the formula and that this part of the program is correct for all input data having NTERMS=2.

Symbolic evaluation can be used to generate symbolic representation of the effects of the calculations carried out by paths in a program. It can also be used to generate sets of predicates in input variables which describe the input data that causes different program paths to be executed. A "complete" symbolic evaluation analysis of a program can be used as the validation documentation for the program.

Certain features must be present in an automated symbolic evaluation system in order for the system to be useful in analyzing realistic programs. The user

Figure 2—Symbolic values for A(1) and A(2)

must be able to easily set up and carry out a number of different analyses. He must be able to select subsegments of a program and individual paths or classes of paths. The system must contain facilities for assigning actual or symbolic values to variables and for printing out values of variables at different points in a program. The user may also wish to print out systems of predicates formed by symbolically evaluating the branch conditions in a path and to check the consistency of these systems.

The remaining sections of the paper describe a sophisticated symbolic evaluation system called DISSECT and a number of experiments using the system. DISSECT can be used to analyze programs written in ANSI Standard FORTRAN. In the experiments the system is used to analyze two complex statistical routines taken from Reference 1.

THE DISSECT SYSTEM

(a) Structure of DISSECT—The DISSECT system operates on two input files and produces an output file. One of the input files contains a FORTRAN program to be analyzed and the other contains the DISSECT commands which tell the system what kind of symbolic evaluation analysis to carry out. The output file contains the results of the analysis.

The command file for a DISSECT analysis is divided into a number of *cases*. The program in the input file is processed completely for each case. Each case has a section for a text description of the part of the program to be analyzed by the case. This text is not processed by the system and is considered to be the specification for the case, The rest of a case contains commands which identify the part of the program which corresponds to the case, commands which assign (symbolic) values to variables and commands which specify what output is to be generated.

The output file which is generated by a DISSECT analysis is also divided into cases. Each output case contains the case specifications and commands as well as the output generated by the system for that case. The user can check the validity of his program by comparing case specifications with system output for cases.

A program *path* is a possible flow of control through the program. A path is *feasible* if at least one element of the program's input domain causes that path to be executed. In general, a complete set of DISSECT cases for a program should "cover" the program in some sense. One approach is to analyze each feasible path (up to some number of iterations of loops). Complex programs having many paths can be divided into segments and analyzed using separate cases.

(b) DISSECT commands—The DISSECT commands can be divided into three groups: path selection, output and value commands. The commands can either be given in the *global commands section* of a DISSECT command file or can be given as part of a case. If they appear in the global commands section they apply to all cases. The commands can be used with or without a statement sequence number. In general, when used with a sequence number they are executed only when the system is evaluating that statement. Otherwise they are used for every statement or, in some cases, are only applied at the end of the DISSECT analysis of a program path.

(c) Path Selection Commands—DISSECT processes a case by symbolically evaluating one or more paths in a program. The path selection commands cause DISSECT to select part of a program for analysis by directing it to follow certain paths through a program. The "SELECT" command is used for directing DISSECT to follow a specified branch or branches from a conditional branching statement. The "LOOP" command directs DISSECT to carry out a given number of iterations of a loop. Loops are specified by naming the statement number of the first statement in the loop.

Examples

(i) n SELECT .GT. will cause DISSECT to select the .GT. branch from an arithmetic conditional statement n.

(ii) n SELECT ALL will cause DISSECT to set up a subpath for each branch from conditional statement n.

(iii) n LOOP k will cause DISSECT to iterate loop n k times.

(iv) n SKIP m will cause DISSECT to skip from statement n to m during processing of a program. SKIP can be used to set up cases which only deal with paths through segments of a program rather than the whole program.

(d) Output commands—The user of DISSECT can generate several different kinds of output. The PATH command causes the system to print out the sequence numbers of the statements in the paths in a case. PATH DESCRIPTION will cause the output of all of the statements in the paths. PREDICATES will result in the construction of symbolically evaluated systems of predicates which describe the input that causes paths to be followed. The OUTPUT command can be used to print out the symbolic values of variables, symbolically evaluated subroutine calls and symbolically evaluated program output statements. If an output command is preceded by a statement sequence number then the command is invoked when the system encounters that statement during its symbolic evaluation of the program. If the command is not preceded by a statement number then, in general, it is invoked after the completion of any path belonging to the case containing the output command.

(e) Value commands—The most important value assigning command in DISSECT is the ASSIGN command. ASSIGN can be used to assign either actual or symbolic values to any variable at any point in the processing of a program. The DISSECT system is designed so that symbolic values are automatically assigned to variables whenever the variables appear in SUBROUTINE headers or COMMON or input statements. The automatically assigned symbolic values are text strings formed from the variable names. ASSIGN can be used to override these default symbolic value assignments or to assign actual values.

ASSIGN is used in basically two different ways. In many situations, the user will want to carry out a symbolic evaluation of a path in which some of the variables are given actual values. He can use ASSIGN to give these values to the variables at the beginning of the path. In other situations a complicated segment of calculations on several variables divides naturally into several segments and a user will want to print out the symbolic values of one or more variables at the end of one segment and then reset the values of the variables to simple symbolic values before continuing with the processing of the next segment. The ability to do this avoids the necessity of having to analyze complicated symbolic expressions resulting from the symbolic execution of several conceptually distinct sequences of operations.

(f) Conditional Execution of commands—There are two ways in which a user can specify that a DISSECT command is to only be applied under certain conditions. The first involves the use of a *conditional form.* If a command appears in the form "IF condition THEN command 1 [ELSE command 2]" then command 1 is only carried out if the condition holds (and command 2 if the condition does not hold). Conditional forms are not commands and cannot be nested.

Conditions are constructed using three types of expressions. The first consists of ordinary program expressions in program variables. The second consists of the special variable ATTRIBUTE and the third the special function LOOPCOUNT(n). DISSECT contains a number of commands for attaching *attributes* to paths during their symbolic evaluation. It is possible to specify that the execution of a DISSECT command is conditional upon association of a given attribute with a path. LOOPCOUNT(n) returns an integer giving the number of times that loop n has been iterated by the path currently being traversed. When the function is called it is assumed that the statement currently being processed by DISSECT is in the loop and that LOOPCOUNT(n) is the number of iterations that have been completed during the current traversal of the loop.

The second way of conditionally carrying out a DISSECT command involves the use of the CONSISTENCY option. Many of the DISSECT commands can be used with several flags. When the CONSISTENCY flag is attached to a command the system constructs the predicate that would be added to the system of predicates for the current path if the command were to be executed. If the addition of this predicate to the system would cause the system to be inconsistent then the command is not executed. The CONSISTENCY option can be used to stop DISSECT from traversing program paths that would result in the generation and analysis of infeasible program paths. The consistency routines which are currently implemented are very simple. Although they will catch only certain kinds of inconsistencies they have proved to be very powerful.

A related feature in DISSECT is the DEFAULT option. DISSECT expects that certain kinds of program statements will always have a command associated with them. It expects the command file to contain, for example, path selection commands for each conditional branching statement which it encounters when it is processing a program path. In general, a user may only want to construct commands for a fraction of the branching statements in a program. He can "cover" the remaining branching statements by constructing selection commands which have no statement number and which include the DEFAULT option. When DISSECT reaches a conditional statement it first looks to see if there are any selection commands for the statement which do not have the DEFAULT option set. If there are none it then tries to find a selection command that it can apply which has the DEFAULT option set. Recall that DISSECT commands which do not have statement numbers are applied by DISSECT to all appropriate statements during the processing of the program.

EXAMPLES

(a) Interpolation Example—The first example describes the use of DISSECT in analyzing the interpolation program in Figure 1. In both this and the next example DISSECT was used to confirm that the program agreed with its specifications. The INTERP routine is written so that the number of points NTERMS used in the interpolation process may be less than the number of points available (NPTS). The first segment of the routine, lines 1-25, decides which points to use. It involves choosing a value for I1. The points X(I1), X(I1+1), . . ., X(I1+n−1) in the program correspond to the points x_1, x_2, . . ., x_n in the documented formulae (n=min{NPTS, NTERMS}). The documentation states that x_1 (i.e. X(I1)) "is chosen so that x_1 and x_n straddle x". "If the value of x is too close to the lower or upper limit of the values of x_i, the corresponding value of x_1 or x_n is set equal to the limiting value."

The documentation for this segment of the program is quite vague. A casual reading of the program reveals that the segment is of some complexity and has a number of paths. The process that is to be carried out by the part of the program appears to be typical of the types of processes that may not work for limiting values in the input. It was decided to examine the paths through this section of code for NPTS=1 and 2 (the limiting cases) and also for NPTS=3. The DISSECT command file for those three cases is given in Figure 3.

These three cases cause DISSECT to analyze all paths in the program up to statement 28 for NPTS=1, 2 and 3. Case 1 has 10 paths, case 2 17 paths and case 3 24 paths. This is a large number of paths but it was found that the output for each was easy to read and that it was easy to determine if the program was correct for the case. The output for each case is divided into subcases, several of which are reproduced in Figure 4. Each subcase corresponds to a path.

The structure of the code in the first segment of the program is such that the complete set of paths for cases one, two and three indicates that the segment is correct. Note that we have not formally proved that the segment is correct. The symbolic predicates and values which are produced assist the user in reading the code and in carrying out a proof which is partly formal and partly informal.

The second segment of DISSECT, lines 26-33 is supposed to compute the following values of Δ and Δ_i.

$$\Delta=\frac{x-x_1}{x_2-x_1} \qquad \Delta_i=\frac{x_i-x_1}{x_2-x_1}$$

The correctness of this segment is easily confirmed with two or three simple cases. The commands for the case where NPTS=2 are given in Figure 5.

The output for this case is given in Figure 6. In the program Δ is represented by DELTAX. In reading the output recall that x_i is represented by $X(I1+i-1)$.

The Case 6 command ASSIGN I1="I1" ensures that the output for Case 6 will use the symbol I1 to stand for I1 rather than the value it may have as the result of earlier calculations.

Symbolic output for the code in the third segment, lines 34 through 48, appears in Figure 2. The segment was thoroughly examined by looking at the output for the cases where NPTS=3 and 4.

The final segment of the program, lines 49 through 60, is supposed to compute the formula:

$$y(x)=a_1+\sum_{j=2}^{n}\left[a_j\prod_{i=1}^{j-1}(\Delta-\Delta_i)\right].$$

This segment can be checked by constructing cases corresponding to n=1, 2 and 3. The case containing the commands for n=2 appears in Figure 7. The program uses the variable YOUT to represent the value y(x). The output for the case appears in Figure 8.

(b) Correlation Example—The complexity of the INTERP routine is due both to its control logic and its array manipulation operations. DISSECT was useful in analyzing INTERP by allowing the user to look at how the program operated for arrays of given dimensions.

In the correlation example, DISSECT was used to

Figure 7—Case commands for analyzing last segment of program

analyze a program whose complexity is entirely due to its control logic and to the computations it carries out. The program has no arrays and is not complicated by looping mechanisms for carrying out array operations.

The PCORRE routine is used to determine the probability $P_c(r,N)$ that N random data points would yield a linear-correlation coefficient as large or larger than an observed correlation value $|r|$. The documentation for PCORRE lists two formulae which are supposed to be computed by the routine. For $v=N-2$, one of the formula is for v even and the other for v odd. The formula for v even is

$$P_c(r,N)=1-\frac{2}{\sqrt{\pi}}\,\frac{\Gamma[(v+1)/2]}{\Gamma(v/2)}\left\{\sum_{i=0}^{I}\left[(-1)^i\,\frac{I!}{(I-i)!i!}\,\frac{|r|^{2i+1}}{2i+1}\right]\right\}$$

where $I=\frac{v-2}{2}$ and Γ is the gamma function. The formula for v odd is equally complex.

The PCORRE routine divides naturally into three segments. The first determines the quantity v and whether it is even or odd. The second and third compute $P_c(r,N)$ for even and odd v. The part of the code that computes $P_c(r,N)$ for v even is reproduced in Figure 10.

A command file containing the case in Figure 11 was constructed for analyzing PCORRE. The output for one of the subcases which analyzes the first two segments of the routine is reproduced in Figure 12.

The text strings in quotes after some of the commands in Figure 11 are attributes. Each time a path follows a branch associated with a particular SELECT command, the path is assigned any attributes listed for that branch. The complete collection of attributes for a path is printed along with the output for the path. The use of attributes makes it easy to identify paths in terms of particular properties associated with the branches in the paths.

```
CASE 9
PATH: 0-3 51-56 55 57 52 58-59

 : 8  51  **ASSIGN DELTA=DELTA
 :21  59  YOUT=A(1)+A(2) * (DELTAX-DELTA(1))
```

Figure 8—Output for Case 9

It is evident from this output that the formula is correct for the case where v is even and $(v-2)/2=1$ DISSECT was also used to generate symbolic out for the cases where $(v-2)/2=2$ and $(v-2)/2=3$. This output taken together with the pattern of the code in the program, indicates that the program computes the correct formula for v even. DISSECT was also used to generate symbolic output for the code which calculates $P_c(v,N)$ for v odd.

RELATED WORK

The DISSECT system is built on an earlier path analysis system[2] which can be used to generate descriptions of the sets of input data that cause classes of program paths to be executed. The major improvement is the addition of a command language which allows the user to selectively control the application of the analysis routines. In addition, DISSECT has many features not present in the previous system.

Several systems have been constructed which can be used to carry out program analysis similar to those which can be carried out with DISSECT. The EFFIGY,[3] SELECT,[4] RXVP[5] and the system described by Clarke in Reference 6 all allow the selection and evaluation of paths in computer programs. The DISSECT system is closest to the EFFIGY and SELECT systems. Symbolic evaluation can also be used in constructing program proofs.[7,8]

DISSECT is unique in its use of cases to structure the validation analysis of a program. It is also the only system that includes a language that allows a user to write simple analysis procedures (the command language). The EFFIGY and SELECT systems are path-following procedures which the user directs by selecting conditional statement branches interactively.

CONCLUSIONS

In the experiments with DISSECT which are described above, the user was faced with analyzing and determining the validity of a program he had not seen before. He was provided with the program and documentation and no outside help. The pattern of usage of DISSECT was one in which the user alternated between reading a program and running DISSECT. First the program and the documentation were studied and a preliminary command file constructed. The

Figure 12—Symbolic output for case 1.1 of analysis of PCORRE

command file was based on an initial understanding of the structure of the program. The output which was generated by DISSECT from the preliminary command file was often inadequate. In some cases, too many paths were generated for a piece of code. In other cases, more analysis of a piece of code, or analysis with different actual or symbolic assignments of variables, was needed. A second DISSECT analysis resulted in a better understanding of the program which sometimes prompted the user to carry out a third analysis.

The readability and usefulness of DISSECT output can be judged from the above examples. The output was generated from either the first or second command files which were constructed in the process of analyzing the programs. One or two additional versions of the command file would produce what would probably be the final version.

It is our experience that systems like DISSECT can be useful in two ways: The first is the help that the system can give the user in carrying out a validation analysis of a program. The output from a symbolic evaluation of a piece of code is often much more revealing than output from an execution with actual data. Similarly, the symbolic evaluation of a system of predicates associated with a path provides documentation describing the input associated with the path.

DISSECT can be useful in helping to "unravel" the computations carried out by different types of programs. Some programs are complicated to read because they are cluttered with the control structure needed to carry out an operation iteratively over the elements of a data structure. The validity of these programs can often be checked by looking at the manipulations that are carried out for structures of fixed sizes. DISSECT can be used to generate descriptions of these manipulations. Other programs are complicated to read because they contain control structure for constructing, and at the same time computing a value for an iterative formula. The number of iterations used in constructing the formula is often dependent on an input variable. DISSECT can be used to generate the instances of this formula that are computed by the program for different numbers of iterations. These instances, together with a knowledge of the structure of the iteration used by the program are often enough to convince the user that the program is correct. Examples 1 and 2 illustrate this use of DISSECT for programs of this type.

The second way in which DISSECT can be useful is in forcing a systematic, intuitively meaningful validation discipline on the programmer. DISSECT can be used as the basis of a validation methodology for a verification group. In verifying a program, the user must first break the specifications for the program down into cases. Each case is then described in terms of a case specification. The parts of the program which are supposed to take care of these cases are identified using the command language. The system carries out the specified analysis and the user compares the output with the case specifications. After several rounds of improving the cases and possibly correcting program errors, a full validation document is produced. Experience may indicate that other types of validation analysis facilities should be added to the DISSECT without changing the basic structure of the system.

There are several situations in which systems like DISSECT may fail or not be useful. If a program is in error because some case was not coded into it, and no DISSECT case is constructed to correspond to this forgotten case, then the error may not be discovered. It is suspected that DISSECT may not be as useful for assembly language programs as it is for high-level language numeric programs. Since, in theory, a well-structured program is self-documenting and it is possible to understand the code by reading it, it might be argued that DISSECT will only be useful for programs written in languages like FORTRAN. This is only partly true. The observations made above about program complexity due to the mixing together of control structure for manipulating data structures and the computations to be carried out on the structures are true for most programming languages. The same thing is true of complexity due to mixing together the code which constructs an iteratively defined formula together with the computations for evaluating the formula.

Further experiments will be carried out with DISSECT and improvements to the system are planned. The system will be used to analyze programs known to contain errors in order to determine its usefulness in detecting bugs. Use of the system in a full-scale software development project is also being planned.

ACKNOWLEDGMENTS

The DISSECT system was programmed by the author and R. Hoffman. Mr. Hoffman is primarily responsible for the symbolic evaluation and output routines.

Part of the algebraic simplifier in the output routine was derived from a program which is part of the SELECT system.[4] The use of the program is gratefully acknowledged.

The research described in the paper was carried out as part of a McDonnell Douglas Astronautics project in program testing which is funded by the National Bureau of Standards. The project is supervised by Z. Jelinski and Leon Stucki of McDonnell Douglas. Mr. Stucki cooperated in the design of the DISSECT command language.

Some experience with DAVE — A Fortran program analyzer*

by LEON J. OSTERWEIL and LLOYD D. FOSDICK
University of Colorado
Boulder, Colorado

ABSTRACT

This paper describes DAVE, an automatic program testing aid which performs a static analysis of Fortran programs. DAVE analyzes the data flows both within and across subprogram boundaries of Fortran programs, and is able to detect occurrences of uninitialized and dead variables in such programs. The paper shows how this capability facilitates the detection of a wide variety of errors, many of which are often quite subtle. The central analytic mechanism in DAVE is a depth-first search procedure which enables DAVE to execute efficiently. Some experiences with DAVE are described and evaluated and some future work is projected.

INTRODUCTION

There is currently a great deal of interest in creating systems capable of assisting in the development of error-free programs. This interest results both from an awareness that erroneous programs are expensive and potentially lethal and from the fact that the problems involved in producing error-free programs are challenging and stimulating. As might be expected in the case of such a problem, which has enormous economic significance and high intellectual appeal, the approaches to its solution are numerous and diverse. This diversity is shown by the following list of approaches, which is intended to be indicative and not exhaustive:

- Devise error resistant design and coding practices: The terms Structured Programming,[1] Stepwise Refinement,[2] and Top-Down Design[3] are often associated with work in this area.
- Create error resistant languages: Such investigators as Wirth[4] and Gannon and Horning[5] have identified error-prone language features and proposed languages which avoid them.
- Devise better organizational strategies for programming: The Chief Programmer Team strategy of Mills and Baker[6,7] is notable in this area.
- Prove the correctness of programs: This is a relatively difficult and time consuming process, which has been successful largely for relatively small programs. Current work,[8] however, offers hope that machine aids may eventually facilitate program proving for large programs as well.
- Build automated program testing aids: These aids can do such things as monitor program execution,[9,10,11] perform static diagnostic scans,[12,13] and help generate test data.[13,14]

It seems clear that in the future the results of work in several of these areas will be coordinated in any effort to produce high quality, error resistant programs. We feel certain, however, that because humans will always have faulty memories, be prone to commit keyboard errors, and will inject various other errors into their programs, that any such coordinated attack will surely include a testing activity. This activity should rely heavily upon automated program test aids. In addition, we feel that automated test aids are of particular importance at present, because they, unlike most of the other current approaches, offer some hope of helping determine the validity and worth of some of the enormous body of programs already in existence.

For these reasons, we created DAVE, an automated program testing aid which, we believe, embodies important new diagnostic capabilities.

DAVE AS AN AUTOMATED TESTING AID

DAVE performs a diagnostic scan of an ANSI Standard[15] Fortran program for the purpose of detecting erroneous or suspicious situations. Systems such as this are often referred to as static analysis systems, in that they do not require that the program be executed. As a consequence, their analytic results are not restricted in their applicability to a single execution. On the contrary, in DAVE's case it is possible to simulate in a limited way the effect of executing all sequences of statements in a program. Hence DAVE is able not only to detect errors, but, more important, it is also able to determine the absence of certain types of errors or suspicious situations for all possible executions of the

* This work supported by NSF Grants GJ-36461 and DCR75-90072.

program. Because of this latter capability DAVE is a valuable tool in examining existing programs for the purpose of validating them.

Should DAVE detect an error or suspicious situation along some execution sequence through the program an error or warning message describing the situation is produced. A human analyst must then determine the true importance of the message. At this point a dynamic analysis system might be used to instrument the program and gather detailed information about the progress of an actual execution of the sequence of statements which DAVE had pinpointed. Hence in this way DAVE is also useful as a debugging aid during program development.

ERRORS DETECTED BY DAVE

All program testing aids are incapable of determining whether or not a program is completely correct. A program testing aid can at best determine whether or not a program adheres to some specified standards. A violation of such a standard may be taken to be an a priori error or a suspicious condition, symptomatic of some other error. Hence in all program testing aids there must be an initial understanding of the standards against which programs are to be measured. In DAVE these standards all relate to the correct flow of data through a program. It is our contention that in a correctly executing program two rules should always be obeyed:

1. No variable will be used in a computation (referenced) until it has previously been assigned a value (been defined).
2. A variable, once defined, will subsequently be referenced before the variable is redefined or the program terminates.

DAVE's diagnostic scan determines whether either of these two rules can be violated for any sequence of statement executions. A violation of the first, called a type 1 anomaly, is a violation of the ANSI Fortran Standard[15] and is considered to be an a priori error. A violation of the second, called a type 2 anomaly, is considered to be a symptom of some other error. DAVE is able to detect a type 1 anomaly for any possible execution sequence. Thus if DAVE does not detect such an anomaly then none exists within the program. Hence DAVE is able to both detect the presence, and assure the absence of data flow anomalies. The former capability we refer to as error detection and the latter we refer to as validation. Clearly the foregoing implies that DAVE is able to validate programs for the absence of uninitialized variables.

In practice we have found, however, that anomalies of both types are usually symptoms of other errors. We have been gratified to find that the range of errors symptomatized by type 1 and type 2 anomalies is quite large, extending from misspellings to subprogram invocation errors. Because of this phenomenon of anomalies occurring as symptoms of other errors, it has turned out that DAVE has been most useful in indirectly detecting errors other than uninitialized and dead variables (in the sense of Reference 16).

More specifically, a large measure of DAVE's indirect error detection capability arises from the fact that DAVE performs its data flow analysis across subprogram boundaries. This data flow from one program unit to another must be completely determined if all possible anomalies are to be detected. Having made this complete determination, however, DAVE is in a position to also detect a variety of program unit communication errors such as illegal side effects and inconsistent COMMON declarations. Because this interprocedural data flow is often quite subtle, errors involving it are likewise often subtle and difficult for a human to identify. Hence it is not surprising that DAVE's error detection capabilities in this area have proven to be among its most useful features.

AN EXAMPLE

Figure 1 shows a somewhat contrived Fortran program which is designed to illustrate some of the error detection capabilities referred to in the previous section. The purpose of the program is to compute and

```
      COMMON /B/ AREA, COST
      READ (5,1) PSF, LCRT, D1, D2
      PI=3.1416
      IF (LCRT .NE. 1) GO TO 10
      AREA=AREAR (D1, D2)
      GO TO 100
10    IF (LCRT .NE. 2) GO TO 20
      AREA=AREAC (P, D1)
      GO TO 100
20    CALL AREAT (D1, D2, AREA)
100   CALL DOLS (PSF)
      WRITE (6, 2) COST
      STOP
1     FORMAT (F6.2, I2, 2F10.4)
2     FORMAT (1H, F8.2)
      END
      FUNCTION AREAR (A, B)
      AREAR=A * B
      RETURN
      END
      FUNCTION AREAC (PI, RAD)
      AREAC=PI * RAD ** 2
      RETURN
      END
      SUBROUTINE AREAT (B, H, AREA)
      AREAT=0.5 * B * H
      RETURN
      END
      SUBROUTINE DOLS (PSF)
      COMMON /B/ COST, AREA
      COST=PSF * AREA
      RETURN
      END
```

Figure 1—A program illustrating some of the error detection capabilities of DAVE

print out the cost of covering an area with some covering material. The program reads in PSF, the cost per square foot of the material; LCRT, an integer used to denote whether the area is a rectangle (if LCRT is 1), a circle (if LCRT is 2), or a triangle (if LCRT is 3); and D1 and D2, the two dimensions of the area (D2 is unused if LCRT is 2). The program then branches on LCRT to three different subprograms, AREAR, AREAC, and AREAT, which are supposed to compute the area of the rectangle, circle or triangle (respectively), and place the value of this area in the variable AREA. Subroutine DOLS is then called to compute COST, the product of AREA and PSF. Finally COST, the desired result, is printed out.

Close inspection of the program reveals that it contains errors, some of which are not very obvious. Perhaps the most obvious error is that the value of pi is set into the variable PI, but the variable P is used to pass this value into AREAC, the subprogram which requires it. A second error is that there is a misspelling in the subroutine AREAT. The third parameter is named AREA, but the body of the subroutine defines a value for the variable AREAT instead. Hence upon return there is no value given to the main program variable AREA, which is referenced in a subsequent computation. A third error involves the COMMON block B, which is used for communication between the main program and DOLS. B contains the variables AREA and COST. DOLS, which expects AREA to contain the computed area, uses it to compute the value of COST, which is then passed through B back to the main program. Unfortunately, the order of declaration of AREA and COST in the main program is the reverse of the order of declaration in DOLS.

Detection of these three errors would most likely be at least tedious using conventional debugging methods. The third error would cause any execution to be erroneous, but each of the first two would cause an erroneous execution only for a single specific value of LCRT. Hence it is reasonable to expect that the three errors would be ferreted out one at a time, perhaps with some difficulty, if the usual procedure of running test cases was followed.

DAVE would facilitate the detection of all three errors in only one diagnostic scan because each one causes data flow anomalies. In the case of the first error, DAVE would identify the definition of PI without subsequent reference as a type 2 anomaly. DAVE would also determine that the first argument in any invocation of AREAC must carry in a value. Hence in analyzing the main program DAVE would conclude that the invocation of AREAC would cause a type 1 anomaly, and would print an appropriate message. DAVE is unable to state directly the true error—namely a misspelling. The two anomaly messages, however, point strongly to the true error.

The second error, also a misspelling, is likewise strongly indicated by anomaly messages. In analyzing AREAT, DAVE would discover that the local variable AREAT is never referenced after definition, and print a message describing this type 2 anomaly. DAVE would also determine that the parameter AREA is neither referenced nor defined in the subroutine. This is regarded as a suspicious situation, and DAVE would produce a message describing it. Finally, in analyzing the main program, DAVE would discover that there is a sequence of statements leading up to the invocation of DOLS which does not cause the variable AREA to be defined (namely the one which includes the invocation of AREAT). No anomaly message will be printed because, as shall be seen, the third error causes DOLS to make no use of AREA. Had the third error not been present, however, a type 1 anomaly message would have been printed. In this case the interaction of two errors causes the suppression of one anomaly message. DAVE, nevertheless, produces two other messages in reponse to the second error.

The third error is a transposition of variables in a COMMON statement. DAVE would analyze DOLS and determine that it requires a value to be passed in through the second variable in COMMON block B, and that it passes out a value through the first variable in B. Upon analyzing the main program DAVE would find that COST, the second variable in COMMON block B, is never initialized before the invocation of DOLS—hence a type 1 anomaly message would be printed. DAVE would also discover that AREA, the first variable in block B, generally has a freshly computed value when DOLS is invoked. DAVE would observe the DOLS resets this value before it is ever referenced and print a type 2 anomaly message. Finally, DAVE would observe that AREA, the first variable in block B, is never referenced after its definition in DOLS and print another type 2 anomaly message. Here too, it is clear that these three messages strongly illuminate the transposition error, although it is never explicitly identified.

This brief example is intended to give an impression of how DAVE's analysis can assist in isolating subtle errors. We expect that the reader can see how DAVE is also useful in detecting other errors such as transposed statements, illegal side effects, and mismatched argument and parameter lists. Likewise the reader should be able to see that the use of an automatic aid such as DAVE is far more necessary in analyzing a large, complex, real-world program than in detecting the errors in this small, simple, contrived example.

THE DESIGN OF THE DAVE SYSTEM

DAVE performs its analysis by passing over the program units of a program, from the lowest level subprograms upward to the main program, analyzing each program unit exactly once, employing a depth-first search of a labelled flow graph of the program unit. Details of the system's design and implementation can be found in References 17 and 18, and hence are omitted here. For completeness, however, a brief simplified overview shall now be given.

DAVE's analysis is performed on labelled flow graphs, where a different graph represents each of the program units of the program. The nodes of a flow graph represent the program unit's statements and the edges represent intra-program-unit control transfers. Each node's label describes which variables are defined and referenced during the execution of the code corresponding to the node. These graphs are constructed at the start of DAVE's analysis. The graphs are easily constructed, but they cannot immediately be completely labelled, due to the undeterminable status of variables which are used as arguments to subprograms. Hence the graphs are left only partially labelled until a later phase of the analysis. All invocations of subprograms which are made by a program unit are carefully noted, however. After the last program unit flow graph has been created and partially labelled, the totality of these invocations is used to construct the program call graph, a graph whose nodes represent the program units and whose edges represent the subprogram invocations. Due to the impossibility of recursive calling chains in ANSI Standard Fortran, it is expected (although not always true) that the call graph will be acyclic. Hence there will be leaf nodes (nodes without any outedges) in the graph. These represent program units which do not invoke any subprograms. Hence the flow graphs for these program units are known to be completely labelled. DAVE now continues by carefully analyzing these program units' flow graphs.

Once a program unit's flow graph is completely labelled it is possible to determine the pattern of references to and definitions of each of the program unit's variables for each of the program unit's execution sequences. Uninitialized and dead variables are found by examining these patterns. In DAVE a variable's pattern of references and definitions is determined and examined by a depth-first search procedure (described in detail in Reference 18) which executes in time proportional to the number of edges in the flow graph. The search procedure is repeated for each variable in the program unit. It classifies each variable as either non-input, input or strict input and either non-output, output or strict output. A variable is classified input if along some, but not all, execution sequences through the program unit the variable is referenced before it is defined. If there is no such execution sequence, the variable is classified non-input. If the variable is referenced before definition along all execution sequences, the variable is classified strict input. Similarly, the variable is classified output if along some, but not all, execution sequences in the program unit the variable is defined. If there is no such execution sequence the variable is classified non-output. If it is defined along all execution sequences, it is classified strict output.

These classifications having been made, DAVE begins its search for anomalies. If a local variable is classified strict input, it is clear that a type 1 anomaly will occur, and an error message is produced. If a local variable is classified input, then a type 1 anomaly exists for some, but not all, sequences of statements. In recognition of the fact that these sequences may not actually be executable in response to any input data, DAVE produces a warning message describing the possibility of executing an anomaly bearing sequence of statements. DAVE performs similar scans for type 2 anomalies by executing searches from a definition of a local variable to determine whether the subprogram terminates or redefines the variable before referencing it.

The determination of the input/output status of non-local variables (i.e., parameters and COMMON variables) of leaf subprograms is not used immediately in the detection of anomalies, but rather is used to enable DAVE's analysis to continue for higher level program units. The program call graph is used to locate all invocations of the leaf subprograms, and now the nodes corresponding to these invocations are labelled. At the end of this process, some non-leaf subprograms have become completely labelled and the depth-first search procedure can be applied to them. This process continues until eventually the main program itself is searched.

The process of using the input/output classification of a non-local variable of an invoked subprogram to label an invoking node is worthy of some elaboration here as it incorporates a number of useful error checks. DAVE first compares argument and parameter lists for agreement in length and type. Lack of agreement is considered an error. Next, parameter output classifications are compared to arguments. If a parameter is classified as output or strict output and the corresponding argument is a constant, expression or subprogram name, DAVE produces a message. COMMON variables which carry data into or out of the invoked subprogram are identified at this time and messages describing them are made available for use as documentation. Finally, the variables in the invoking statement are examined to see whether any of them is used both as an input and an output in separate subprogram invocations. If so, DAVE has detected an illegal side effect, and produces a message identifying it.

After DAVE has searched the main program, it examines the input classifications of its COMMON variables. Error or warning messages are generated for each COMMON variable which is typed strict input or input but is not initialized in a BLOCK DATA subprogram.

IMPLEMENTATION DATA

DAVE is implemented as a Fortran program consisting of approximately 25,000 source statements. It operates in four overlaid phases, the largest of which occupies 50,000 decimal words of central memory on the CDC 6400. DAVE is written almost entirely in machine independent ANSI Standard Fortran. Some non-Standard and machine dependent coding practices seemed expedient, however, and they are quarantined to a small number of small subprograms. DAVE was developed on the CDC 6400 at the University of Colorado, but has been successfully moved to a CDC 7600 and two machines in the IBM 360/370 series. Installations on a Univac 1100 series machine and a Honeywell 6000 series machine are planned for the near future.

Under its current configuration DAVE is able to process a program consisting of a few dozen subprograms, each of which may contain no more than 200-250 source statements. These limits depend entirely upon internal table and scratch array sizes, and have been quickly altered to produce different experimental configurations. At this writing, the largest body of code which DAVE has processed has been a 2700 source statement subprogram library. DAVE is currently operational, however, on a machine with sufficient central memory to enable it to process its own source code, and this should be accomplished in the near future. The analysis of a source program by DAVE has been observed to require an average of 0.3 seconds of central processor time per source statement on the CDC 6400 and to cost approximately six to eight cents per source statement under the University of Colorado Computing Center charge algorithm.

SUMMARY OF EXPERIENCE TO DATE

DAVE has been operational on an experimental basis for a few months to date. During this time we have seen evidence that it can be a valuable tool in the production of high quality, error-free programs. Most of our experience has come from using DAVE in validating completed programs. These included a highly respected matrix manipulation system, several recent algorithms taken from the *ACM Transactions on Mathematical Software,* and a program submitted as a part of a Master's Thesis in Computer Science. Errors were detected in some of the algorithms, and the Master's Thesis was found to have numerous errors. In most cases the errors were of the type that would hamper program portability, such as reference to uninitialized variables which should have been initialized to zero, reference to exhausted DO loop indices and subprogram invocations with mismatched argument and parameter lists. In each case, the errors did not seem to prevent successful execution on the author's computer, but seemed likely to cause trouble if executed elsewhere. (There was some suspicion, however, that some of the erroneous subprogram invocations were imbedded in program segments which had never been tested or were unexecutable.)

Perhaps the most surprising observation was that DAVE's messages often gave unexpected insight into the author's coding style. For example, a program for which DAVE produced numerous type 2 anomaly warning messages did not prove to be incorrect, but rather it contained numerous loops in which indices and counters were updated immediately before DO loop endings. It was discovered that the author tended to favor WHILE loop constructions which are often awkward in Fortran. This was observed by DAVE. As another example, some programs contained subroutine definitions which did not use some parameters either as input or output. This was observed to be a symptom of the fact that the code had evolved, but not been carefully polished. We acknowledge that in the first case the author should probably have coded in a more comfortable language, and in the second the program was probably not thoroughly designed before coding began. DAVE can do nothing to prevent these serious breaches of good programming practice. It was surprising and gratifying, however, to discover that DAVE could often strongly indicate their presence—a capability which we believe is quite useful.

We have had less experience in using DAVE as an error detection aid during program development. This seems paradoxical because we feel that DAVE is very well suited to aiding the detection of subtle errors, thereby speeding program development. The high cost of using and the awkwardness in accessing the current version of DAVE, however, forestalled its use in many cases. DAVE's accessing procedures have recently been streamlined, but the high cost of using the system is attributable to a decision made during development of the prototype system to favor flexibility over efficiency. Hence high costs are likely to remain for the foreseeable future. As a consequence of this, the few programs which DAVE helped to debug all had subtle errors which had defied earlier concerted efforts at detection. DAVE was usually able to point rather directly at these. Such errors as camouflaged misspellings (e.g., CARD instead of CARDS) and mismatched argument/parameter lists were discovered in this way.

Our experience has not been entirely positive. An obvious and troublesome difficulty is DAVE's copious output. As already illustrated, a single error often generates numerous messages. Moreover, we have observed that some messages are rarely symptoms of errors. The net effect is that human analysts are often reluctant to pursue all of DAVE's messages, thereby raising the possibility that errors whose symptoms have been detected will go unnoticed. DAVE users have also complained about the unclear wording of many messages. All of these human interface problems must be solved lest DAVE's useful capabilities be buried under an avalanche of opaque verbiage.

PROBLEM AREAS AND FUTURE WORK

We consider the current DAVE system to be a working prototype. Consequently, as might be expected, it has neither the speed nor complete processing capabilities which might be expected of a polished system.

The purpose of this section is to describe the areas in which we feel DAVE is deficient and to indicate where and how improvements might be made.

One of the most immediate problems is that DAVE was designed to analyze only programs written in ANSI Standard Fortran. DAVE has since been liberalized to accept most of the Fortran dialects available on CDC equipment. Little effort, however, has been devoted to the problems of accepting other dialects. Many of the changes required in order to accept such dialects appear to be straightforward, but it is worthwhile to note that some features of some dialects (e.g., the ENTRY feature found in FORTRAN V[19]) cannot be properly analyzed by DAVE without substantial alterations.

More serious is the fact that there are a number of features of ANSI Standard Fortran which are currently incorrectly or inadequately handled by DAVE. A notable and discouraging example of this is the treatment of arrays. Currently DAVE treats all arrays as simple variables, thereby blurring all distinctions between array elements and eliminating the possibility of detecting certain anomalous uses of the individual elements. Unfortunately, there are fundamental theoretical reasons why patterns of array references in an arbitrary program can never be completely analyzed by a static analysis system such as DAVE.

As already noted, the call graph of a Fortran program may not be acyclic even though the program is incapable of ever executing a recursive calling chain. Such a program cannot be analyzed by DAVE. The most promising solution to this problem seems to be to adapt DAVE so that it is able to analyze recursive programs. This is an interesting and worthwhile problem which seems solvable, and would move DAVE in the direction of being able to analyze programs written in other languages such as ALGOL and PL/I.

DAVE is also currently unable to build the complete call graph for programs in which subprogram names are passed as parameters. Hence DAVE cannot analyze such programs. As algorithm due to Kallal and Osterweil[20] is capable of building the call graph of such a program. This algorithm will probably be incorporated into future versions of DAVE.

Other problems are encountered by DAVE in trying to analyze programs containing extensive or tricky uses of aliasing constructs such as EQUIVALENCE statements and restructured COMMON lists. Most of these will be overcome in future versions of DAVE by using well-known compiling techniques. Others, such as using two EQUIVALENCE'd variables as arguments to the same subprogram, challenge some of DAVE's basic assumptions, and may never be satisfactorally solved.

Programs in which variables become undefined (e.g., the exhaustion of a DO loop causes the undefinition of the DO index) may, under certain unusual circumstances, be incorrectly analyzed. This results from our tardy recognition that variables must be typed with respect to undefinition just as they are typed with respect to input and output (i.e., they must be typed as non-undefined, undefined, or strict undefined). We have developed algorithms for performing and correctly employing this typing of undefinition, but have not yet incorporated them into DAVE.

Finally, we are actively exploring the relationship between static testing aids and global program optimization. Our investigation[21] has shown that existing algorithms in global optimization can readily be harnessed to do much of the analysis done by DAVE. Hence we foresee the incorporation of systems such as DAVE into a future generation of compilers.

A Dynamic (FORTRAN) programming system

by JULIUS A. ARCHIBALD, JR.
State University College
Plattsburgh, New York

ABSTRACT

In recent years, new insights into the nature of programming languages have been obtained from the comparative study of natural and programming languages. These studies reveal that programming languages are deficient in their ability to adapt both to new requirements and new means for communicating thoughts. A means of alleviating these difficulties, through a dynamic, structured expansion of an established programming language (FORTRAN) is provided.

INTRODUCTION

During recent years, there have been some rather significant advancements in man's understanding of programming languages. Some ten or so years ago, and continuing into the present, we find a continuing growth of interest in the concepts of structured programming.[1,2] More recently, there has been the suggestion that the nature of programming languages can be better understood by the study of natural languages and the drawing of analogies between these two different types of languages.[3] One particularly useful analogy has been suggested, that between English, a poor, but useful natural language, and FORTRAN, a poor, but useful, programming language.[4] In doing this, we note that one of the major differences between these media of thought is their adaptability to changing requirements. Specifically, we note, both through a study of literature, and a review of our own usage of the language, that English has readily adapted both to the needs of expressing new thoughts, and to the needs of better ways of expressing and communicating old thoughts. English has thus evolved in a timely manner. Indeed, the development of English has been concurrent with, rather than lagging behind, the development of human knowledge. We also note, regretfully, that programming languages in general, and FORTRAN in particular do not share this characteristic. Programming languages as we now know them, are incapable of dynamic development or evolvement. Programming methods have changed, and languages have failed to keep pace.

The static nature of programming languages is a problem of particular concern today. The earliest programming languages, such as FORTRAN, were, of necessity, created before our present day understandings of the nature and structure of algorithmic processes and programming languages were attained. (Versions of FORTRAN were in use some ten years before the notion of structure was developed.) The time has come for us to benefit from the new understandings of the structure of algorithmic processes and programming languages developed in the last ten years within the framework of FORTRAN. The ideal solution would be to extend FORTRAN so as to include the new structures.

There are two problems. First of all, FORTRAN has been standardized.[5,6] On the positive side, this was good for purposes of definition. We now have a precise understanding as to exactly what is FORTRAN and what is not FORTRAN. Even more important, this understanding is the same in Boston, Atlanta, Los Angeles, and Seattle. The definition is not subject to local dialects. On the negative side, however, along with standardization came stagnation. The existence of a standard has successfully stifled the initiative needed to make the language flexible, and adaptive. To further complicate matters, those who were not content with the status quo mandated by the standard have ventured off into their own private extensions in such a manner as to produce a set of mutually incompatible super-languages of the original common language. The overall effect has not been beneficial to the development of programming languages.

The second problem is, in reality, not a problem of the programming languages themselves, but rather a problem resulting from differences in the use of natural and programming languages. The constructs of English become meaningful as a result of interpretation by thought processes resident in the human brain. The constructs of FORTRAN become meaningful as a result of interpretation by compilers (or interpreters) resident in a computer's memory. Thus, the increased flexibility (or adaptability) of natural languages over programming languages is not a question of the relative merits of the languages themselves, but rather a matter of the superior ability of the human brain, as compared to a compiler, to program itself (or be programmed) to interpret new constructs. Thus, in order to attain for a programming language the flexibility and adaptability of a natural language, we must consider not only the language itself, but also the compiler (at least in general terms), as they are known to exist for the language. We thus must act upon Wirth's conclusion that "Language design is compiler construction."[7]

We refer here to a programming system on a given machine as being made up of a specific language and the compiler or interpreter used to interpret that language on the machine of concern. We will also refer to FORTRAN programming systems on a machine independent basis in the same manner that FORTRAN as a language is regarded on a machine independent basis. In the remainder of this paper, we will be working on obtaining flexibility and adaptability not merely for the language itself, but rather for the overall programming system. The objective is a dynamic, flexible extension of FORTRAN, as previously defined.[5] It will be accomplished through modification of the FORTRAN programming system.

It is noted in passing that the present use of static structured extensions of FORTRAN, which must be converted to standard FORTRAN, through the use of preprocessors, falls short of the above stated objective. They provide structure without flexibility. The need for a dynamic language has already been noted in the literature.[8] Conventional pre-processors simply are not dynamic. A second problem is that the preprocessors are not always machine independent. The various extensions themselves are not all consistent.

The approach of limiting oneself to a subset of the existing, standard FORTRAN from which things resembling structures can be formed is also inappropriate. This approach involves the further limitation of an already inadequate medium, rather than an extension of the medium to meet new challenges. Said in other words, this approach also fails to provide flexibility.

There is one more remaining question: "Why FORTRAN?" Again, the analogy with English. Users of English (both native and adopted) love to sit around and complain about how poor a language it is, how bad the grammar is, and how impossible spelling is. No one, however, has taken any serious steps to eliminate English. The best effort, to date, was the invention of a contrived artificial language, Esperanto,[3] a language with lots of merit and no potential. The problem is that too many people have already done, and are continuing to be doing, too many things with English to make a change feasible. Consider, for a moment, the problems that some of us are already experiencing from the change of just one small part of the language, namely the system of measures, to metric units. The same is true of FORTRAN, too many people have already done, and are continuing to do, too many things in FORTRAN to make a change feasible. FORTRAN is where the action is. The language, PL/I, intended to be a partial remedy, has no more potential than Esperanto. We are, as a matter of fact, suffering from addiction to FORTRAN. In the present situation, the pain of continued use is less than the pain of withdrawal. We thus support previous conclusions of others[3] as well as ourselves.[9]

IMPLEMENTATION

It has been shown that all programs, regardless of the language in which they are written, can be composed of three fundamental structures.[1] These structures consist of a sequential or composite structure, some variant of a predicate structure, and some variant of a repetitive structure. Regardless of the choice of variant, the result, that these structures are sufficient, remains valid.[10] (We do include, in our implementation, a fourth structure, the case structure, fully realizing that its use is not essential.) Thus, as will be seen, we will limit ourselves to D, D′, and BJn structures.[11] The point is that each structure is made up of certain, fixed parts, which, because they are independent of the language concerned, are referred to by psycholinguists as being "linguistic universals." [12]

The method of implementation that we use is to divide each program into two divisions. The first division consists of a definition of the form to be used for each part of each of the fundamental structures (or variants of the structures) to be used within the program. (We note that there may be several different definitions for each of the fundamental structures within the programs.) These structure definitions are followed by the second division, consisting of the source program itself, written in standard FORTRAN augmented by the just defined structures. Each programmer is free to define the fundamental structure in any manner that suits his (or her) convenience, thereby providing flexibility. Division one of the compilation will be the conversion of the user defined structures within the source program into standard FORTRAN statements, and the insertion of the resulting statements into appropriate places of the original source. In most situations, we "very strongly convert" in the sense of Ledgard and Marcotty, the various D, D′, and BJn structures to standard FORTRAN structures.[11] This conversion is followed by a routine FORTRAN compilation of the entire converted program. Any construct not part of standard FORTRAN must have been defined and converted. A program without structure definitions is assumed to be in standard FORTRAN, and, as such, does not require a division one of the compilation.

This differs from pre-processing, as it already exists today, in that each programmer, on a dynamic basis, creates his own form or forms for the fundamental structures. We reiterate that several different forms of each structure may be used in each program. There are no pre-established forms for the structures themselves, only the parts of the structures remain invariant. This is the feature that provides the flexibility absent in the more conventional pre-processing.

All terminology used in describing structures will be compatible with FORTRAN usage. Thus, if in defining a predicate structure, the condition itself is referred to as being a logical expression, then the condition will require no further definition. Rather, it shall be assumed that all of the attributes and characteristics of FORTRAN logical expressions will apply.

This compatibility with FORTRAN will also apply to the structure definition statements, e.g., such statements will begin in Column 7, etc.

As a specific of the implementation, the actual conversion of the user defined structures into FORTRAN must itself be done in FORTRAN, and the resulting conversion must result in standard FORTRAN statements.[5] (This in itself is difficult because of the incomplete manner in which strings are defined in FORTRAN.) The conversion of user defined structures will require the insertion of new statements labels, and may, as well, require new variable names. In those cases where the existing FORTRAN can readily be adapted to accept variable names and statement labels beginning with previously illegal characters, such as $, or #, the conversion will be simplified. In some other cases, the implementation may permit the programmer to designate and reserve specific sets of labels and names for the conversion process. Neither of these, however, can be a limitation, and, in the general case, the source program must be completely pre-scanned so that blocks of legal, unused statement labels and variable names may be identified for use in the structure conversion.

As a part of the structure conversion phase, the original structure statements will be converted into comments, so that they can be retained for documentary purposes.

STRUCTURE DEFINITION

It is emphasized that, on a program by program basis, the programmer is free to define any number of structures (including none at all) that suits his (or her) convenience in the writing of the program. The programmer will be free to define his own structures, so long as he (or she) retains all of the essential parts for each structure. Thus, in what follows, the method of definition will be presented. Examples will be included for illustrative purposes only.

While no attempt is made to either prescribe or limit the forms of specific structures, certainly, all of the control structures occurring in the more common languages (e.g., ALGOL), expressed in any natural language using the Latin alphabet, should be definable for use in the dynamic FORTRAN programming system. In our dynamic system, words like "si", "alors", and "autre" could easily be used in place of "if", "then", and "else".

As indicated previously, the actual form of the structure definition depends upon the structure itself. The structures to be used are defined in a "structure division", placed in front of the main program. The first statement of each definition (beginning in Column 7) will be one of the following depending upon the structure:

```
STRUCTURE SEQUENTIAL
STRUCTURE PREDICATE
STRUCTURE REPETITIVE
STRUCTURE CASE
```

Each of these structures has its own, unique parts, which must be defined. Starting in Column 7, the component of the structure is indicated. That is followed by the statement to be used in the program to define the structure.

As an overall program organization, each program consists of a large sequential structure (which need not be explicitly defined). Within this structure, predicate, repetitive, and case structures, if needed, must be programmed in a form defined either in the structure section, or in standard FORTRAN. Structures may be nested within other structures. Indication of sequential structures is optional, except that they must be indicated explicitly when they are made up of more than one statement and are contained within predicate, case, or repetitive structures. At the other extreme, each statement is, by default, a sequential structure of one statement. There is no need to ever explicitly define a sequential structure of only one statement, even when it is inside of a predicate, repetitive, or case structure.

DEFINITION OF SEQUENTIAL STRUCTURES

The sequential structure is extremely trivial. To define a sequential structure or a sequential block, it is merely necessary to indicate its opening and its closing form. For example, a programmer might define the structure as follows:

```
STRUCTURE SEQUENTIAL
OPENING BEGIN
CLOSING END
```

This will cause the programming system to recognize groups of statements and/or structures between the defined OPENING and CLOSING statement brackets as a sequential structure. Each individual statement will be treated as a sequential structure without being so defined, and without having statement brackets. In the general case the defined OPENING statement will be converted into a comment, and otherwise ignored. The defined CLOSING statement will be converted into a comment, and a CONTINUE with a legal label will be inserted just ahead of the converted END. The following special cases are recognized:

1. If the entire program is included as a sequential block, the defined CLOSING statement is converted into a conventional FORTRAN END statement. (It is anticipated, however, that nonexecutable statements, such as DIMENSION and FORMAT, will be placed outside of such blocks.)
2. If the structure is the THEN or ELSE part of a predicate structure, a PROCEDURE part of a replicative structure, or an ALTERNATIVE part of a case structure, a CONTINUE with a legal label is inserted just after the converted OPENING statement.
3. If the defined OPENING statement is labeled, a CONTINUE statement with this label is inserted just after the defined OPENING statement.
4. If the defined CLOSING statement is labeled, this label will be used on the CONTINUE inserted just before it.

DEFINITION OF PREDICATE STRUCTURES

The predicate structure consists of from two to four parts: a condition, an affirmative or condition—true alternative, an optional negative or condition—false alternative, and an optional closing. The condition itself functions as the opening of the structure. The two alternatives will be identified as sequential structures (possibly containing other structures). A closing may optionally be defined for the structure. If, however, no such closing is defined, the structure will be assumed to terminate at the end of the negative alternative, if any, or at the end of the positive alternative if there is no negative alternative.

As an example, consider:

```
STRUCTURE PREDICATE
OPENING IF (logical expression)
AFFIRMATIVE THEN (structure)
NEGATIVE ELSE (structure)
CLOSING END IF
```

(The use of parentheses is for generic purposes, i.e., any logical expression legal within FORTRAN, or any structure defined for the current program, may be used.)

The opening statement will be converted to a comment. A standard logical IF for the negative of the logical expression in the opening statement will be created to transfer to the negative alternative (or the closing if there is no negative alternative). This statement will carry the same label as the original opening in the structured form, if any. The positive alternative (a structure) will follow, in line, terminating with a converter generated GO TO the closing of the predicate structure. The negative alternative will then follow in line. A labeled CONTINUE will be inserted as the final statement (or closing) of the predicate structure. The user supplied indicators of the alternatives and the closing will be converted into comments.

It is noted that the requirement for a condition and an affirmative alternative structure precludes the interpretation of a standard FORTRAN logical IF as a defined structure. Use of the standard logical IF, followed by a single statement "then procedure" (other than the GO TO) is encouraged in the dynamic FORTRAN programming system. Such logical IF's possess all of the virtues of structure. Moreover, as part of standard FORTRAN, they require no further definition.

DEFINITION OF REPETITIVE STRUCTURES

The repetitive structure is, perhaps, the most difficult to define. This is a natural result of the fact that the repetitive structure permits a large number of variations. A controlled loop, whether or not it is arranged as a definite structure, has certain recognizable parts. These always include a body or procedure that is repeated many times, and a test that is performed many times, to determine whether or not to leave the loop. In some cases, the loop is controlled by a counter or index that must be initialized once and incremented many times. In some cases, there are data values to be initialized once. The testing may be done before each performance of the procedure, after each performance of the procedure or at a specific point within the procedure. In the latter case, there are, in effect, two procedures separated by a test, and organized in such a manner that there will be many performances of the two procedures, in order. (In what follows, we will not be limited as to the number of possible procedures to be repeated. We have implemented the full Omega-K structure of Bohm and Jacopini.[1]) We note, further, that there are two possible tests for leaving a loop: the loop may be continued UNTIL a certain condition becomes true, or it may be continued WHILE a certain condition remains true. (These are reverses of each other. In the former case, repeat on condition false, in the second repeat on condition true. Negating the condition permits switching of the test.)

Thus, in describing a repetitive structure, there is a mandatory opening section, an optional initialization, one or more procedures to be repeated, one or more tests for continuation or completion of the loop either before the first procedure, after the last procedure, or between any two procedures and finally a structure closing.

As an example consider:

```
STRUCTURE REPETITIVE
OPENING PERFORM
INITIAL ESTABLISH (structure) *
```

* The INITIAL part is optional.

```
CONTINUE or
COMPLETE      TEST (logical expression) ‡
PROCEDURE (structure)**
CONTINUE or
COMPLETE      TEST (logical expression) ‡
PROCEDURE (structure)**
CONTINUE or
COMPLETE      TEST (logical expression) ‡
   .      .
   .      .
   .      .
CLOSING END PERFORM
```

During the structure conversion phase of the program, the opening statement will be converted to a comment, and the initialization part expanded as previously described. A labeled CONTINUE statement will be inserted either immediately after the initialization, if any, or after the opening. Each continue part or complete part will be preceded and followed by labeled CONTINUE statements, to be inserted if not provided by the programmer. (Two of these parts coming together, however, will not have a CONTINUE inserted between them.) The continue and complete parts, as logical expressions, will be incorporated into logical IF statements, as follows:

```
CONTINUE part
    IF (.NOT. expression) GO TO closing
COMPLETE part
    IF (expression) GO TO closing
```

The various procedure parts will be converted as previously described. Immediately before the closing component, a GO TO the beginning of the first procedure will be inserted by the converter. The closing itself will be converted into a labeled CONTINUE. As in the case of all structures, all statements requiring conversion will be converted into comments.

DEFINITION OF CASE STRUCTURES

The case structure involves the identification of an (integer-valued) arithmetic expression which functions as an index and a set of alternatives or choices to be executed depending upon the value of the index, i.e., if the index is 1, choice 1 only will be executed, etc. For purposes of implementation, the arithmetic expression functions as the opening of the structure. A closing part is mandatory.

As an example, consider:

```
STRUCTURE CASE
OPENING EXAMINE (arithmetic expression)
ALTERNATIVE n CASEn (structure)*
.
.
.
CLOSING END CASE
```

The opening statement itself is converted to a comment. If the arithmetic expression is not an integer variable name, an arithmetic assignment statement will be generated, setting the expression to an integer variable. The IFIX function will be inserted if needed. A computed GO TO statement will then be created, to send control to an appropriate alternative. The arithmetic assignment statement, if any, or the computed GO TO if no assignment statement is needed, will carry the same label as the original opening in the structured form, if any. Each of the alternatives will end with a GO TO the closing statement, which, itself, will be converted to a CONTINUE with a system generated label.

GENERAL PROVISIONS

During the process of interpreting the user supplied structure definition, the definition statements will be converted into comments. A blank comment statement will be inserted following every closing component.

All comments included in the original program will be retained during structure conversion.

It is generally recommended that structures be indented to facilitate their recognition. In using this dynamic programming system, no indentation rules are imposed upon the user. Indentation supplied by the user (if any) will be retained by the converter.

SAMPLES

In what follows, learning exercises will be shown written in a form for the FORTRAN programming system, and then converted into standard FORTRAN. They are intended purely as a demonstration of the concepts previously described.

Sample 1.—Table of roots of integer valued real numbers.

A. Source in Dynamic FORTRAN

```
STRUCTURE SEQUENTIAL
OPENING START
CLOSING FINISH
STRUCTURE REPETITIVE
OPENING REPEAT
INITIAL SET
PROCEDURE
```

** One PROCEDURE part required, the remainder are optional.
‡ One CONTINUE or COMPLETE part is required, the remainder are optional. A repetitive structure may be defined with both a continue and a complete part.

* Normally, there will be three or more of these components. The lower case n is used to indicate an integer number: 1,2, . . . maximum value.

Sample 1 continued

A. Source in Dynamic FORTRAN continued

```

CONCLUSIONS

The foregoing discussion and samples demonstrate a method for moving the practice of programming into the nineteen seventies without abandoning FORTRAN. The following observations are made:

1. The user defined structures so dominate the program that, in its unconverted form, it is difficult to recognize it as FORTRAN at all.
2. The original source is free of GO TO statements, thus re-enforcing Dijkstra on the subject of that statement.[11]

GPMX—A portable general purpose macro processor adapted for preprocessing FORTRAN

by ROBERT C. GAMMILL
The Rand Corporation
Santa Monica, California

ABSTRACT

GPMX is an extension of GPM, a simple, elegant yet powerful language independent macro processor described by Strachey.[1] Unextended, GPM is not suited for preprocessing languages which use column position and end of record to delimit statements. Examples are FORTRAN and many assembly languages. Many programmers are constrained to work in such limited languages and GPMX is a simple yet powerful tool for extending and modifying these languages. Others[6] have developed preprocessors dedicated to a particular language. This has advantages for the implementor, but requires the user to learn a different preprocessor for each language he uses. GPMX is designed to work on any language so that the (non-trivial) effort of learning to use it need not be repeated later. Extensions in GPMX include macro control over: files, record input and output, spacing, conditional macro processing and compilation, access to input and output buffers, and dynamic changing of the macro flag characters. Most of the extensions are accomplished simply by putting the control information on the macro stack where the processor has access to it (ala von Neumann). GPMX has been implemented in ANS FORTRAN for portability. Several applications are shown, including GO-TO free control structures for FORTRAN. Source is available.

GOALS AND PHILOSOPHY

An important goal of this work was the development of a flexible software tool. To be called a tool (using a restrictive definition) software must be suitable for a variety of tasks, on the scale of a single human being (the user) and not dependent upon any unusual aspect of the environment (i.e., adaptable). To make an analogy, a Boeing 747 would not qualify as a tool, (under this definition) for although it is suitable to some tasks, it is not at a human scale (e.g., in terms of maintenance or costs) nor is it adaptable to different environments (e.g., small airports, short hauls, low load levels). However, a crescent wrench would qualify as a tool, since it is suitable to many tasks, at a human scale (e.g., purchasable, maintainable and portable) and can be used in almost any environment (e.g., under water). Many language processors do not qualify as tools. They have been designed for a specific task and environment, so when the situation changes they prove to be clumsy or useless. Then, the large size of most language processors makes them difficult to modify or adapt to the new situation. The lack of adaptable tools has made software development needlessly complex.

GPM qualifies as a tool. It is suitable to a number of tasks and on a human scale. The original implementation of GPM in CPL was extremely compact, and was listed in the last three pages of Reference 1. Gries[5] suggests its implementation as a student exercise (page 433). GPMX appears, to the untrained eye, to be unchanged from GPM. This is because the extensions have been carefully designed to minimize the structural change in GPM. Most of the changes have been accomplished by adding a few primitive macros and by putting the processor input-output and control information on the stack as the values of defined macros, available for use and modification. This is a simple application of the von Neumann stored program concept, and it provides the same startling increase of power to GPM that it provided to the early computers. Finally GPMX has been implemented in ANS FORTRAN for portability.

Although GPMX is a tool, we do not want to imply that it is simple for an inexperienced programmer to learn to use all its power. Simple applications of GPMX can be easy to understand, but an application that uses its full power can be extremely difficult to follow. Perhaps it is best to characterize GPMX as a tool for the advanced scientific or systems programmer, who finds it necessary to write programs in limited languages (such as FORTRAN and assembly) because of special properties they possess, yet desires to have a flexible and powerful macro processor for manipulating his source text.

GPMX provides the following capabilities:

(a) Conditional compilation—so alternative versions of a subroutine need not require multiple source files.
(b) Macro processing—allowing insertion of the same declarations in many subroutines or selective use of open or closed code.

(c) Text compacting—allowing reduction of blanks and other unused redundancy.
(d) Syntax extension—such as adding GO-TO free control constructs to FORTRAN.
(e) Language independence—since information about the language processed is carried in macros not in the processor.
(f) Power and flexibility—the elegance and simplicity of GPM has been kept while its considerable power has been increased.

DESCRIPTION OF GPM

In recent years a number of language independent macro processors have been introduced.[2,3,4] GPM[1] is one of these. In this section we will briefly survey the characteristics of GPM. GPM uses marker characters to indicate where a macro call begins "[", ends "]" and the separations between arguments ":". GPM has only six primitive (built-in) macros. An example showing the use of three of these is:

```
[DEC:[BAR:+:[BIN:3]:[BIN:2]]]     (1)
```

GPM has two data types, "binary" integer and character string. BIN converts from character string to integer and DEC does the reverse. BAR allows integer arithmetic (+−*/). Example (1) produces the character string "5" as its result. The most important primitive macro DEF allows definition of new macros.

```
[DEF:+:<[DEC:[BAR:+:[BIN:%1]:>
                  <[BIN:%2]]]>]     (2)
```

A call on the defined name "+" causes evaluation of its body (second argument of DEF).

```
[+:3:2]     (3)
```

Example (3) will also produce "5" as its result. Example (2) introduced string quotes (< and >) and formal parameters (i.e., %1). Evaluation of nested quotes removes the outermost pair. Macro bodies are normally protected from evaluation at definition time by quoting them. Access to the body of a macro without evaluation is provided by VAL.

```
[VAL:+]     (4)
```

Example (4) will return the body of the + macro, the quoted string from example (2). UPDATE stores new values in the bodies of macros.

```
[UPDATE:+:<This is a new body for +.>] (5)
```

The marker character set being used here is different from that used in GPM.[1] GPMX allows these to be changed at will, so their selection is dictated only by esthetics and local constraints.

An important feature of GPM is that macro calls are allowed anywhere. For example, [[A]:[B]] is a call on a macro whose name is the result of [A] and whose argument is the result of [B]. Also, since macro definition is done by a macro call, macro definitions may be created in unusual ways. One use of this in GPM is the temporary macro definition. If a macro definition is created in the argument sequence of a macro call, that definition will exist only so long as the called macro is being evaluated.

```
[A:[DEF:N:[BIN:3]]]     (6)
```

In example (6) the macro N will be defined (with value 3) only so long as macro A is being evaluated. If there was a previous definition for N, it will be temporarily superseded by this one. One of the important uses of temporary definitions is for self-defining macros, where the definition of the macro occurs in its own argument sequence.

```
[DEF:EVAL:<[X:[DEF:X:%1]]>]     (7)
```

Every time the macro EVAL is called, the macro X is temporarily defined and then called. Since a macro body is evaluated when its name is called, this means that the result of a call on EVAL will be the result of evaluation of its first argument. Using EVAL to cause evaluation and string quotes to defer it gives the ability to specify when evaluation is to be carried out. Thus, although Brown[4] characterizes GPM as passing parameters "by value", as shown in (10), it is possible to pass them "by name", as shown in example (9).

```
[DEF:N:3]
[DEF:A:<[UPDATE:N:[+:[VAL:N]:1]]>
            <[EVAL:%1]>]          (8)
[A:<[VAL:N]>]  <BY NAME>          (9)
[A:  [VAL:N]  ]  <BY VALUE>      (10)
```

Another important result from the ability to create temporary definitions, is that a conditional macro can be defined.

```
[DEF:COND:<[%1:[DEF:%1:%4]>
              <[DEF:%2:%3]]>]     (11)
```

The COND macro depends upon the fact that the most recent definition is used if two macros have the same name. COND executes its third argument if its first and second arguments match, and its fourth argument otherwise. Thus, [COND:A:B:C:D] will produce result D, while [COND:A:A:C:D] will product result C. Conditional execution gives access to the recursive calling capability of GPM by allowing termination of recursive loops. The standard example is the recursive computation of the factorial function (fact(i) := if i=0 then 1 else i*fact (i−1)).

```
[DEF:FACT:<[COND:%1:0:1:<[*:>%1<:>>
      <<[FACT:[−:>%1<:1]]]>]>]     (12)
```

A more practical example would show how data tables may be generated using recursion, but such examples become extremely involved.

EXTENSIONS IN GPMX

In order to make GPM useable as a FORTRAN preprocessor, new capabilities have been added. The elegance and simplicity of GPM makes this easy. In adding new capabilities to GPM care was taken to minimize the set of additional primitive macros, as the elegance of the original set is one of GPM's best features.

The most obvious area of need when using GPM as a FORTRAN preprocessor results from the fact that FORTRAN is column and line (record) oriented while GPM deals with a character string. The solution implemented in GPMX is the introduction of eleven new primitive macros which cope with the problems of record input, output and blank fill. Table I gives the macros and the output or side effect yielded by execution of each.

These new primitive macros use a special marker character for bevity and so as not to conflict with user defined macros which have one character names. In other words, [5] will not give the same result as $5, but will seek a user defined macro named 5. An early version of GPMX used [R] for $1 and [W] for $2, but access to these was often destroyed by subsequent user macro definitions. Thus, $0 through $9 are primitive macros whose meanings cannot be superseded. The user of GPMX who does not need line and column control and fears that a $ macro may occur in the input text, can disable this feature by changing the definition of the $ character to an illegal value. The utility of very short macros in simple text substitution is apparent, so any GPMX macro with a single character name (not a digit) and no arguments can be called in this manner. For example, the macro [DEF:S:<$2$6>], which can be called either as [S] or $S, is useful for moving to column 7 of the next line.

Another mechanism which has been provided in GPMX is the line distributor, which controls the distribution of GPMX input records. We are going to want to make occasional use of GPMX macros in large existing FORTRAN programs. However, scanning every character of a large program which contains only sparse occurrences of macros will be very expensive. The line distributor allows specially marked GPMX lines to be inserted in ordinary FORTRAN, so that only the marked lines need be scanned. Column 1 of each line is reserved for this purpose. The character punched in column 1 controls the handling of the line, much the way a C in column 1 of a FORTRAN line specifies it to be a comment. However, in this extension to GPM, the mode of a character may be set to any desired value (from 1 to 6), allowing succeeding lines starting with that character to be treated in a specified manner. Table II gives the mode values and actions. Default mode value of all characters is 2 except for "–" which has an initial mode value of 6. The line distributor mechanism has several uses. One of these is to provide GPMX comment lines (mode 2). Another is conditional compilation. Putting a character in mode 4 will cause all lines with that character in column 1 to be compiled. If that character is set to mode 3 on a subsequent pass, all those lines will become FORTRAN comments. GPMX lines can produce widely varying numbers of output characters, and if blanks are taken as significant, much of the output becomes unwanted blanks. Thus, it was decided in GPMX to ignore unquoted blanks in the input. This is only done on mode 6 lines, which are passed to the GPMX scanner. For those who use GPMX with another language, the column position of the line distributor control character can be changed to any desired value, through use of the UPDATE macro. Also, should the user desire to disable the line distributor mechanism, and operate in GPM mode (scanning every line), that too can be accomplished through macro calls.

Besides the primitive line format control macros, several other primitive macros have been added. These are listed below. Each has been chosen to be of general use. The second through fourth macros are the character string primitives of PL/1.

(a) [SETMODE:[BIN:5]:< C0123456789>] sets mode values of line distributor control characters. In this case the characters normally found in column 1 of a FORTRAN line are being set to mode 5.

(b) [LENGTH:[VAL:S]] returns a value (binary integer) which is the length of its argument. In this case the result will be 4 (see preceding DEF of S).

(c) [SUBSTR:<ABCDEFG>:[BIN:3]:[BIN:2]]

TABLE I—Semantics of Special $ Macros

MACRO	OUTPUT	SIDE EFFECT
$0	none	dumps the run-time stack
$1	none	reads next GPMX input record
$2	none	writes next GPMX output record
$3	3 blanks	none
$4	4 blanks	none
$5	5 blanks	none
$6	6 blanks	none
$7	7 blanks	none
$8	8 blanks	none
$9	9 blanks	none
$$	$	none

TABLE II—Line Distributor Actions Specified by Character Modes

Mode	Action	Explanation
1	Reject	No input or output listing.
2	Reject	Input list but no output listing.
3	Output	Set column 1 to C.
4	Output	Set column 1 to blank.
5	Output	Leave line unchanged.
6	Scan	GPMX scan begins at column 2.

returns a substring of its first argument. The second argument tells where the substring begins and the third tells how long it is. The result is CD.

(d) [INDEX:<ABCDEFG>:<CDE>] returns a binary integer which gives the position where its second argument first occurs as a substring of its first. In this case the result will be a binary 3. If there are no occurrences the result is zero.

(e) [WEF:[BIN:7]] writes an end-of-file on logical unit 7.

(f) [REW:[BIN:8]] rewinds logical unit 8.

Besides the addition of new primitive macros and the line distributor mechanism, a very important change has been made in GPMX. This involved moving most of the important control variables, switches and buffers to the stack, as ordinary GPMX macros whose values may be changed by UPDATE. This is a very important improvement. For example, it allows the macro flag characters to be changed during macro processing, and with no new support mechanism required.

```
 * CHANGE CONTROL CHARACTERS
 – [UPDATE:CONCHR:<@,;?()&>&1
 * SET THEM BACK
 – @UPDATE,CONCHR,([:]%<>$);$1
```

Another important use of this facility is changing logical unit numbers for the various input and output streams by means of UPDATE. Logical unit number zero has been taken to mean that no I/O should occur on the particular stream. For example, the following statements will turn on the output listing and turn off the output, for testing without compilation of the output.

```
– [UPDATE: OUTPUT: [BIN:0]]
– [UPDATE: OUTLST: [BIN:6]]
```

The ability to change the logical unit numbers for the input and output, in conjunction with the primitive macros WEF and REW, allows the GPMX programmer complete control over input and output files. Partitioning of output into two files, one for declarations and another for executable code (a frequently needed capability in a preprocessor) is easy to program at the macro level. Also, multiple passes through the input text can be carried out using these facilities.

Other important GPMX control elements can also be changed using UPDATE or accessed using VAL. One particularly important macro, COLUMN, contains the integer which tells in what column the next output character will go. This is especially useful when writing macros to format the output correctly (e.g., tabbing). The contents of the input buffer, INBUF, can be manipulated as a character string (using INDEX, SUBSTR, VAL and UPDATE) before any macro scanning takes place, so GPMX can be used as a general text processor with controlled input. This is a capability that Brown[7, page 51] specifically notes as missing from GPM, when comparing it with the TRAC language.

GPMX APPLICATIONS

In this section we will examine some GPMX applications. In all cases the examples deal with FORTRAN. This was done because FORTRAN is widely known and because it involves most of the unpleasant problems that will be encountered by a language independent preprocessor. The first example shows the generation of local variables and statement numbers as they can be applied in a DO macro. This example uses the fact that a macro definition (DEF) which is created as part of the argument sequence of another macro will exist only as long as that macro is being evaluated. This allows temporary variables to be created. Here K is used to store the local variable name and M is used to store the local statement number. (Note: %%1 means the first argument of the caller's caller).

```
 * GENERATE STATEMENT NUMBER
 * OR INTEGER VARIABLE
 – [DEF:GENSN:<[DEF:%1:<77>>
                <[DEC:[GEN]]]>]
 – [DEF:GENIV:<[DEF:%1:<IV>>
                <[DEC:[GEN]]]>]
 – [DEF:B:[BIN:1]]  [DEF:N:[BIN:10]]
 * GEN RETURNS THE VALUE
 * OF N AND INCREMENTS N.
 – [DEF:GEN:<[VAL:N][UPDATE:N:>
              <[BAR:+:$N:$B]]>]
 * EVAL MACRO EVALUATES ITS
 * ARGUMENT.
 – [DEF:EVAL:<[8:[DEF:8:%1]]>]
 * CONT MACRO PRODUCES A CONTINUE
 * CARD
 – [DEF:CONT:<$2[%1]< CONTINUE>>]
 * DO MACRO
 – [DEF:DO:<[DOBODY:[GENIV:K]>
 –             <[GENSN:M]]>]
 – [DEF:DOBODY:<DO $M $K=1,%%1>
 –                 <[EVAL:%%2][CONT:M]>]
 * CALL THE DO MACRO
 – $S [DO:<32>:<$SB($K)=A($K)>]
```

The preceding code yields:

```
  DO 7711 IV10=1,32
  B(IV10)=A(IV10)
7711 CONTINUE
```

In this example the body of the DO is not evaluated until it is passed into the interior of the DO macro. This is an example of a useful application of passing arguments "by name." Here it allows the temporary macro K to carry the local name for the integer DO variable. A disadvantage of this example is that the complete body of the DO must be passed as the second argument of the DO macro, enclosed in string quotes. This would be extremely awkward for long DO loops.

One of the goals set for GPMX was syntax extension of FORTRAN, to allow GO-TO-free constructs such as if-then-else and while-do to be introduced into the language. Initially we tried to do this in a manner similar to that shown in the preceding example for DO loops. This proved awkward, since the body of code in each part of an if-then-else had to be passed as an argument to a macro, tending to overload the stack. Furthermore, it is very desirable to be able to insert these control statements within ordinary FORTRAN code in the following manner:

```
– [IF] I. NE. 3 .AND. F(I,J).GT. 3. 4 [THEN]
        a sequence of FORTRAN statements
–[ELSE]
        another sequence of FORTRAN statements
–[FI]
```

To implement the preceding idea, we create a special macro whose body will serve as a short push-down stack for statement labels. Then we define macros to allow us to PUSH and POP this special stack, as well as one to allow us to pick up a copy of the TOP element (without changing the stack).

```
– [DEF:PUSH:<[UPDATE:%2:%1[SUBSTR:>
–                   <[VAL:%2]:[BIN:1]:>
–              <[BAR:–:[LENGTH:[VAL:%2]]:>
–                   <[BIN:1]]]]>]

–  [DEF:POP:   <[UPDATE:%1:[SUBSTR:>
–                   <[VAL:%1]:[BIN:2]:>
–              <[BAR:–:[LENGTH:[VAL:%1]]:>
–                   <[BIN:1]]]< >]>]

–  [DEF:TOP:   <[SUBSTR:[VAL:%1]:>
–                   <[BIN:1]:[BIN:1]]>]
```

Using the preceding macros, we implement the if-then-else-fi construct as four separate macros, in the following manner. The definition for GEN was given earlier in this section.

```
–[DEF:IF:<$S<IF(.NOT.(>>]
– [DEF:G:<<GO TO >>]

–[DEF:THEN:<<)) >$G[PUSH:[GEN]:>
–          <STACK]<77>[DEC:[TOP:STACK]]>]

–[DEF:ELSE:<$S$G<77>[DEC:[VAL:N]]>
–                <$2<77>[DEC:[TOP:STACK]] >
–          <[UPDATE:STACK:[GEN]:[BIN:1]]>]
–[DEF:FI:<$B<77>[DEC:>
–            <[TOP:STACK]] [POP:STACK]>]
–[DEF:STACK:$9]
–[DEF:S:<[COND:[BIN:7]:>
–          <[VAL:COLUMN]::<$2$6>]>]
– [DEF:B:<[COND:[BIN:7]:>[VAL:COLUMN]
–            <<CONTINUE>$2>:<$2>]>]
```

In this example we have introduced new macros S and B for controlling our position in the output card image. $S moves us to column 7 of the next line, if we are not already there. $B moves us to column 1 of the next line, adding a CONTINUE statement if we are presently in column 7 of a line. These two macros demonstrate how we can use COLUMN (the position in OUTBUF where the next output character goes) to control positioning of output information.

As we used GPMX on actual programs, written in structured FORTRAN, it became clear that our macro definitions for GO-TO-free FORTRAN had still not adequately solved all the problems. As a result, we changed from a single stack to double stacks, one containing the label desired for exit from a control structure and the other containing the label desired when the next cycle (pass) through a control structure is to be started. The EXIT and NEXT macros, which generate FORTRAN GO-TO's, require a first argument which specifies how far out in a nested control structure the jump is to go. We also implemented automatic indentation of the output text (as dictated by the nested control structure) and added most of the commonly mentioned control structures (e.g. CASE, REPEAT, WHILE, FOR). All of this was carried out completely at the macro level. Figure 1 shows the use of some of these capabilities in a simple program. The library of macros is given in the Appendix.

We now feel that we have achieved a useable set of macros for GO-TO-free FORTRAN. However, many further improvements can still be introduced. We note with satisfaction, however, that although we write and rewrite macros quite often, changes in the processor have become an infrequent event. An example of such an event occurred when moving GPMX to PDP-11 UNIX. It became desirable to allow the GPMX programmer to associate a filename with a logical unit number, providing complete macro time control over input and output files. This required the addition of a new primitive macro which is system dependent (not definable inside FORTRAN). The macro is [SETFILE:[BIN:<digit>]:<filename>]. Code written using this macro acts much like a job control language. It seems likely that with the addition of yet another system dependent primitive macro (EXEC perhaps) allowing execution of assemblers, compilers, loaders and other system utilities, GPMX could be used as an extensible job control monitor for minicomputers.

Recalling our earlier description of a tool, we feel

Figure 1—Use of GO-TO free control structures with FORTRAN

that GPM and its offspring GPMX are definitely tools. As we have indicated, with minor modifications these macro processors seem capable of use as general text processors, as language translators or as job control monitors. Of course, the limitations must be recognized (as when racing bicycles against cars) but the flexibility and simplicity seems astonishing.

ASSESSMENT

GPMX is an adaptable tool, easily modified or controlled by a sophisticated user. It has been moved to a wide variety of computers (including minis) in a few man-hours. A disadvantage of implementation in ANS FORTRAN is that handling card images via formatted I/O is inefficient, although essential for portability. However, the I/O in GPMX is localized in a few routines, so substitution of non-portable but efficient I/O is easy.

GPMX is dramatically different from other FORTRAN preprocessors, since it is a general purpose macro processor extended for that use. GPM was not designed for ease of use by unsophisticated FORTRAN applications programmers. Thus, preprocessors (such as MORTRAN2[6]) which were designed for that goal, tend to be more suitable for use by FORTRAN programmers unfamiliar with general purpose macro processors. However, GPMX has substantially more computational power than most other FORTRAN preprocessors, and it is language independent besides. Although MORTRAN2 and some other FORTRAN preprocessors also have macro capabilities, in most cases this is of the pattern match and simple text substitution variety. None of these have sufficient computational power to implement stacks or source symbol generation at the macro level, as demonstrated here. These advantages make GPMX especially suitable for use by advanced applications and systems programmers, for whom FORTRAN preprocessing is only one of the desired applications. A special advantage enjoyed by GPMX is that most extensions can be produced by defining new macros, while extensions in other preprocessors often involve rewriting the processor. The most obvious disadvantage of GPMX (like GPM) is its ugly syntax. The many good features should overcome this irritation in the appropriate applications.

An experiment comparing Fortran programming times with the software physics hypothesis

by R. D. GORDON and M. H. HALSTEAD
Purdue University
Lafayette, Indiana

ABSTRACT

Recent discoveries in the area of Algorithm Structure or Software Physics[1-25] have produced a number of hypotheses. One of these relates the number of elementary mental discriminations required to implement an algorithm to measurable properties of that algorithm, and the results of one set of experiments confirming this relationship have been published.[16] That publication, while significant, made no claim to finality, suggesting instead that further experiments were warranted. This paper will present the results of a second set of experiments, having the advantages of being conducted in a single implementation language, Fortran, from problem specifications readily available in computer textbooks.

The first section of this paper presents the timing hypothesis, and the elementary equations upon which it rests. The second section presents the details of the experiment and the results which were obtained, and the third section contains an analysis of the data.

TIMING HYPOTHESIS

Measurable properties of any implementation of any algorithm include:

η_1 = The count of distinct operators
η_2 = The count of distinct operands (variables or constants)
N_1 = Total uses of operators
N_2 = Total uses of operands

The vocabulary, η, is given by:

$$\eta = \eta_1 + \eta_2 \tag{1}$$

and the length, N, is:

$$N = N_1 + N_2 \tag{2}$$

From these properties, it is possible to obtain the volume, V, in bits, as:

$$V = N \log_2 \eta \tag{3}$$

and the implementation level, L, where $L \leq 1$, as:

$$L = \frac{\eta_1^*}{\eta_1} \frac{\eta_2}{N_2} \tag{4}$$

where η_1^*, the minimum possible number of operators, will equal 2 for most algorithms. (One for the name of a function, plus one for a grouping symbol operator). It has been shown[4] that the product $L \times V$ is invariant under translation from one language to another, and that for programs without impurities:[3,6,8]

$$N = \eta_1 \log_2 \eta_1 + \eta_2 \log_2 \eta_2 \tag{5}$$

From this point, the following nine steps yield the timing equation:

1. A program consists of N selections from η elements.
2. A binary search of η elements requires $\log_2 \eta$ comparisons.
3. A program is generated by making $N \log_2 \eta$ comparisons.
4. Therefore, the volume, V, is a count of the number of comparisons required.
5. The number of elementary mental discriminations required to complete one comparison measures the difficulty of the task.
6. The level, L, is the reciprocal of the difficulty.
7. Therefore, E, the count of elementary mental discriminations required to generate a program, is given by:

$$E = \frac{V}{L} \tag{6}$$

8. S, the speed with which the brain makes elementary mental discriminations can be obtained from psychology[26] as:

$5 \leq S \leq 20$ discriminations per second.

9. Therefore, the time to generate a *preconceived* program, by a *concentrating* programmer, *fluent* in a language, is:

$$\hat{T} = \frac{V}{SL} \tag{7}$$

Equation 7 may be expressed in more basic terms by substituting for V from equation 3, and for L from equation 4, with $\eta_1^* = 2$, giving:

$$\hat{T} = \frac{\eta_1 N_2 N \log_2 \eta}{2\,S\,\eta_2} \tag{8}$$

The effect of possible impurities[5] may be eliminated from equation 8 by substituting for N from equation 5. Letting $S=60\times 18=1080$ will then give, for time in minutes:

$$\hat{T}=\frac{\eta_1 N_2(\eta_1 \log_2\eta_1+\eta_2 \log_2\eta_2)\log_2\eta}{2160\,\eta_2} \tag{9}$$

Each of the variables on the right hand side of equation 9 can be readily measured (or counted) in any computer program, and the experiment described in the next section was designed to compare results from that equation with observed programming times.

EXPERIMENTAL PROCEDURE

Eleven problems were arbitrarily selected from two published sources. In selecting candidates for the experiment, problems were sought which were stated in a non-procedural form. Further, the problem statement had to be complete. That is, in the course of solving a particular problem, specific laws of physics, mathematics, etc. would not have to be derived. The problems finally selected were taken from Knuth,[27] and from Maurer and Williams,[28] and cover a wide range of topics including character manipulation, list processing, simulation experiments and mathematical analysis. The source of each problem statement is cited in Table I.

On each of eleven days, one of these problems was implemented by the senior author. In order to maintain a consistent level of performance all work was conducted in a quiet room, free from distractions, during the same period of the day. The time required to fully implement the problem was obtained. This total time included the number of minutes spent reading the statement of the problem, preparing flowcharts and writing preliminary versions of the code, writing the final version of the code, desk checking, and the time spent working to correct errors in the program. Time to keypunch was not included.

For a number of reasons, including availability and fluency, all of the algorithms were implemented in Fortran. In the course of solving a problem the correctness of the implementation was checked by executing a sufficiently complex test case for which a correct answer was known. In some cases the solution to a problem was written as a subroutine and testing required that a main routine be written. In such a case only the preparation of the subroutine was considered for the experiment. In addition, several implementations made use of subroutines previously written. Such routines were also not included.*

After each program was completed, a careful count was made to determine values of η_1, η_2, N_1 and N_2. In obtaining these values all read, write, declarative statements and comments were ignored. The results are shown in Table I.

TABLE I—Experimental Data

	Program Specifications			Software Parameters				Implementation
No.	Ref.*	Page	Problem	η_1	η_2	N_1	N_2	Time-Minutes
G1	K	158	21	15	11	59	51	19

G10	M	89	8.3.4	25	34	261	222	91
G11	M	27	3.2.4	14	10	29	21	5

* K=Knuth [27], M=Maurer and Williams.[28]

ANALYSIS OF THE DATA

The programming time predicted by theory was obtained for each program by applying equation 9 to the data in Table I. This result, T, can be compared with the observed value, T, in Table II. In addition, a count of the number of statements in each program was obtained, and the programs were ordered according to these values.

The average of the calculated values, 34 minutes, is fortuitously close to the observed value, 35 minutes. The coefficient of correlation is 0.934, only slightly smaller than the value of 0.952 reported in an earlier experiment.[16] In further agreement with that experiment, the correlation between length and observed times, 0.887, is lower than between observed and calculated times.

In conclusion, it may again be observed that one more set of experimental data does not contradict the simple hypothesis. As a result, further carefully controlled experiments by others would appear to be warranted.

* Additional details available from the author.

TABLE II—Experimental Results

Program Number	Statement Count	Programming Time-Minutes	
		T observed	T Equ. 9
G7	7	5	4.6
G11	8	5	5.4

Representations of networks

by HARVEY J. GREENBERG and JAMES E. KALAN
Virginia Polytechnic Institute and State University
Blacksburg, Virginia

ABSTRACT

Bit map and list structures are analyzed for representation of a network, using its adjacency matrix. Storage analysis, with reduction for m-partite networks, reveals a fundamental function of problem dimensions, called the "index threshold." Several examples, from industry and government, are cited to illustrate the analysis. Relative processing merits are studied, and an equation is derived to relate "processing ratio" to the ratio of the index threshold to the index size. Finally, conversion algorithms are presented, designed to minimize extra work space.

PRELIMINARIES

Let V denote a (finite) set of *vertices,* whose elements are consecutive positive integers. (If names are used, a separate internal structure is employed to identify a vertex by its index number.) Let A denote a set of *arcs,* whose elements are ordered pairs of vertices. If (i,j) is an arc in A, then vertex j is a *successor* of vertex i, and i is a *predecessor* of j.

For any finite set, S, let '/S/' denote its cardinality. For example, /V/ is the number of vertices, and /A/ is the number of arcs. The *adjacency matrix* of a network is a /V/ by /V/, 0-1 matrix with element (i,j) equal to 1 if, and only if, vertex j is a successor of vertex i. Since the adjacency matrix has /A/ nonzero entries, all of which are 1, Kalan's[11] supersparse representation yields a familiar list structure to represent a network.[2] Specifically, define a list (or file) with one record per vertex. The data items in a record are the successors (if stored by rows) or predecessors (if stored by columns). The record size is the (positive) *degree* of the associated vertex (i.e., its number of successors or predecessors, respectively). Note that while the adjacency matrix, per se, cannot represent parallel arcs, its list structure can, if this should be desired.

Another representation of the adjacency matrix is the *bit map,* using one bit per element. For every vertex, its successor list is identified by a contiguous bit string, having fixed length, /V/. Bit j is on if vertex j is a successor of the associated vertex; otherwise, it is off. Garfinkel and Nemhauser[7, p. 304] alluded to the use of bit maps to represent an adjacency matrix, although they did not consider its effect on processing.

Lefkovitz[13] identified the trade-off between bit map and list structures for set representation as ". . . the dilemma for large-scale data bases, . . ." He concluded that bit maps take more space when the lists are short, and less space when they are long.

Orchard-Hays[16, p. 81 and 212] considered, briefly, the use of a bit map in a network-related context, and the next section of this study may be considered a generalization of his threshold analysis.

Pooch and Nieder[17] provided a general survey of these two methods. They also observed the natural correspondence between set operations (e.g., UNION, INTERSECTION) and logical operations (e.g., OR, AND) which render the bit map structure attractive for such processing. However, we shall show how the apparent superiority of bit maps, in the cases cited here, really depends upon the density.

A comprehensive study of the interface between data structures and algorithms was accomplished by MacVeigh.[14] He considered fundamental numerical algorithms with matrices. We have a different, but analogous, situation in dealing with operations on the topology of a network.

It should be noted that analysis of mixed forms of bit map and list structures follows from this study of the two pure forms.

STORAGE ANALYSIS

The bit map structure uses $/V/^2$ bits, with one bit map of length /V/ for each vertex. The list structure uses h/A/ bits, where the *index size,* h, is the number of bits to store an index.

Define the *index threshold* as:

$$H = /V/^2 \div /A/.$$

(This is the reciprocal of the density of the adjacency matrix.) Then, the list structure uses more (less) space if h is greater (less) than H.

If we let h be data-driven, then we may use $h=\lfloor \log_2/V/\rfloor$. Alternatively, we may fix h to represent any network up to 2^h-1 vertices. (The latter choice is akin to current design of LP software in representing row indices.) For fixed h, we consider the range, $15\leqq h\leqq 18$. This permits representation of networks having more than 32,000 vertices, and the values in this range are convenient for most computers (i.e., h=15 for CDC 6,000's, h=16 for IBM 370's and h=18 for UNIVAC 1100's).

Before we examine the relative storage requirements for a variety of applications, note that the index threshold may be expressed in terms of the *average degree*:

$$D=/A/\div/V/.$$

That is, D is the average number of successors per vertex. Then, we note:

$$H=/V/\div D.$$

(This expression shall be useful when we analyze relative processing efficiency.)

Table I below lists problem dimensions reported by Glover and Klingman,[8] together with their index thresholds and their average degrees. The Flight Training problem is sufficiently dense that the bit map structure requires less space, even when $h=\lfloor \log_2/V/\rfloor=10$. The same is true for the first form of the Cotton Gin problem. However, this is reversed for the reduced and compacted forms; like the Treasury and Shipyard problems, the list structure requires less space, even when the index size is fixed at 18.

Actually, the figures in Table I may be misleading because, for most applications, the storage requirements of both structures may be reduced by letting semantics describe part of the topology. Before we explain further, let us consider the transportation problem[5] with the present method.

Suppose we have n suppliers and m demand points, so /V/=n+m. Potentially, there can be nm arcs, one from each supplier to every demand point. However, in practice only a fraction, say f, of these arcs are actually present. This is because a supplier is linked to this fraction of demand points, on the average (or equivalently, the average number of suppliers for a demand point is fn). Then, /A/=fnm, so the index threshold is:

$$H=(n+m)^2/fnm.$$

TABLE I—Sample Problems[8]

Problem	Number of Vertices (/V/)	Number of Arcs (/A/)	Index Threshold (H)	Average Degree (D)
Treasury	5,000	625,000	40.0	125.0
Cotton Gin				
first form	4,200	2,460,000	7.2	585.7
reduced	5,141	95,610	276.4	18.6
compacted	3,441	61,640	192.2	17.9
Flight Training	780	141,200	4.3	181.0
Shipyard	1,020	20,000	52.0	19.6

Let r denote the ratio of number of suppliers to number of demand points (i.e., r=n/m). Then,

$$H=(2+r+1/r)/f.$$

Since $r+1/r\geqq 2$, it follows that $H\geqq 4/f$. Therefore, a sufficient condition for the list structure to use less space is that f<2/9. It is not uncommon, in practice,[2] for the number of links to be less than 20 percent of the potential number (i.e., f<2), in which case the list structure would require less space, even when we fix h=18.

Now let us consider storage reduction for special networks which arise naturally in practice. The transportation problem exemplifies a bipartite network since the vertex set can be partitioned into two sets (suppliers and demand points), such that every successor of a vertex in V_1 is in V_2, and the vertices in V_2 have no successors. The target-battery network described by Furman and Greenberg[6] is another such case. Both the bit map and list structures may be reduced, as we now describe.

The bit map structure requires only $/V_1/\ /V_2/$ bits, one bit map for each vertex in V_1, each having length $/V_2/$. The list structure still represents /A/ indices, one per arc, but the value of the index size (h) need only be $\lfloor \log_2/V_2/\rfloor$. When the index size is fixed, its value can be less than 15, and we can still represent a large network. For example, if we let h=10 (convenient for CDC 6000's), then V_2 can contain up to 2,047 vertices; the cardinality of V_1 does not constrain h. For the target-battery network, h=8 (convenient for IBM 370's) would permit up to 511 batteries, which is much more than the applications cited in Reference 6.

Define the index threshold for the bipartite network as:

$$H_2=/V_1//V_2/\div/A/.$$

If we continue to assume that only a fraction of the potential arcs will be present, then we note $/A/=f\ /V_1/\ /V_2/$, so

$$H_2=1/f.$$

A sufficient condition for the list structure to take less space (with $h\leqq 10$) is: f<.10; a sufficient condition for the bit map structure to take less space (with $h\geqq 8$) is: f>.125.

We now generalize this reduction. Suppose the vertex set can be partitioned into m sets, $V_1 \cup \ldots \cup V_m$, such that every successor of a vertex in V_k is in V_{k+1}. For k=m we distinguish two cases: $V_{m+1}\equiv$empty set, and $V_{m+1}\equiv V_p$ $(1\leqq p\leqq m)$. The first case is exemplified by the transportation problem. The second case allows "feedback" from V_m to V_p, which we shall illustrate shortly.

The storage requirement for the bit map is reduced to:

$$\sum_{k=1}^{m} /V_k/\ /V_{k+1}/$$

bits, since the bit map for each vertex in V_k has length $/V_{k+1}/$.

The list structure still stores /A/ indices, but we may reduce h as in the case of the bipartite network. Define the associated index threshold:

$$H_m = \sum_{k=1}^{m} /V_k/\ /V_{k+1}/ \div /A/.$$

(Note that H_1 is the original H with feedback.)

Let us consider another problem class which is bipartite with feedback. (This is topologically equivalent to an undirected, bipartite graph.) Suppose we have a collection of elements and a collection of sets. Define a network with one vertex per set, say V_1, and one vertex per element, say V_2. If set i contains element j, then two arcs are defined: one from the i-th vertex in V_1 to the j-th vertex in V_2, and its reverse arc.

The packing/covering/partitioning problem class[7,15] may be represented by this type of network. The feedback is useful for processing since it describes those to which sets an element belongs.

PROCESSING

There are many algorithms to solve various network optimization problems. In this section, we shall consider two fundamental processes and the relative merits of the two structures.

One common process is the interrogation of the successors of a given vertex. This can be expressed as the transaction, "Fetch the list of successors of vertex i." For example, most (node/arc) labeling methods[1,2,3,10,18] use this process.

Clearly, the bit map structure requires unpacking. However, for certain implementations (e.g. CDC 6000's and UNIVAC 1100's), the list structure also requires unpacking, although it is of a different form. The actual timings depend upon problem and machine characteristics, but we can, and shall, develop a representative relative measure for this process. To help fix ideas, COMPASS macros were written to fetch the next index or declare no more successors exist. The loading of base addresses is the same for both structures, but the instructions to complete the fetch depends upon the structure. It is this latter difference which we now consider.

Using four indices per word (i.e., h=15), the list structure will execute an average of 3.75D instructions for a complete interrogation (discounting load overhead common to both structures). More generally, if the length of an addressable unit (e.g., word) is w, then the number of instructions is 3(1+h/w)D.

For the bit map, we used the normalization instruction to avoid sequential testing of each bit. If the length of the bit map is /V/, then the average number of instructions is /V/(3/20)+180D÷/V/. In general, the average number of instructions is 3wD÷/V/+9/V/÷w. For sufficiently large /V/ and D, the *processing ratio* of bit map to list structure, for the successor interrogation, is approximately:

$$T = (9/4)/V/ \div hD.$$

Therefore, we have

$$T = 2.25\ H/h.$$

For fixed h, the relative processing time depends on the index threshold: index size ratio. The bit map structure uses more (less) instructions if this ratio is greater (less) than 4/9. A consequence of this relationship is that the list structure will process with fewer instructions if it takes less space (i.e., h<H).

Table II below lists, for each of the Glover-Klingman[8] problems, the associated thresholds times the computed constant, 2.25. Those problems which favor the list structure spatially must also process with fewer instructions, on the average, for this transaction. Specifically, those problems are: Treasury, Cotton Gin (reduced and compacted), and Shipyard. In fact, the reduced form of the Cotton Gin problem is expected to process at least 34 times faster with the list structure! Its first form requires more space to use the list structure, but it would process faster for h≦16. The Flight Training problem processes with fewer instructions, on the average, using the bit map structure; hence, for that problem, bit maps are more frugal with both space and "time."

Now let us consider another type of transaction which appears to favor the bit map structure due to the natural correspondence between set and logical operations.

For covering problems, it is useful to test whether one set is a subset of another.[7, p. 302-3] The associated constraints may include partitioning (or "strict covering"); then the set difference is desired in case the subset test passes.

Since we can, and shall, assume the degree of each

TABLE II

Problems	Processing Threshold (2.25H)
Treasury	90.0
Cotton Gin	
first form	16.2
reduced	621.9
compacted	432.45
Flight Training	9.7
Shipyard	117.0

vertex is available, the test on a pair of vertices can be branched into a test for equality and a test for proper inclusion, with the potential subset identified. Further, we shall assume that the list structure has each successor list sorted.

It can easily be verified that the coding of the set equality test is essentially independent of the representation and can be tested as array-equality comparison. (It is immaterial whether the elements of the array are pieces of a bit map or several indices; only the number of loadable entries in the array counts.) Thus, the processing ratio for the equality test is:

$$T=/V/\div hD=H/h.$$

This says that the list structure takes less time to process an equality test if, and only if, it takes less space than the bit map structure.

Now let us consider the subset test. The bit map can be processed with 8 COMPASS instructions, which are executed for every word in the bit map. Thus, the number of instructions executed is $8/V/\div w$.

Define $b=h/w$ (=length of a bit map in h units). The list structure, on the average, executes $6D(1+b)$ instructions for fetch indices, and the average number of other instructions needed is 3d, where d is the larger degree. Thus, the list structure uses $9D+6Db+3(d-D)$, on the average.

If we suppose d-D is relatively small (compared to D), then the processing ratio is approximately:

$$T\div\frac{8/V/}{9Dw+6Dh}=BH/h,$$

where

$$B=8b/(6b+9).$$

Again, the processing ratio is proportional to the ratio of index threshold to index size, except now the constant of proportionality (which depends on h) is less than 1. In this case the bit map structure processes with fewer instructions, on the average, if it requires less space. For example, suppose we have $b=1/6$ (i.e. $h=10$ and $w=60$) for a covering problem having m elements and an average of e elements per set. Then,

$$H_2=m/e$$

so

$$T=.0013m/e.$$

Therefore, despite first appearances, there is a threshold whereby the list structure processes faster (and uses less space); that is, the processing ratio is greater than 1 if $m/e>750$. If we have 750 elements, then the average number of elements per set would have to be 1, not very likely. However, if we have 75,000 elements, then we need the average number of elements per set to be only 100. For some (large) models this is within reality.

We may infer from these two fundamental processes that, in general, the influence of density on processing ratio is the index threshold proportionality relation:

$$T=kH/h.$$

When $k<1$, the process favors the bit map structure; when $k>1$, the process favors the list structure. Computation of the constant (k) may be done at the macro level to predict relative performance.

CONVERSION

In this section we shall present algorithms to convert from one representation to another, designed to minimize the extra work space required.

To conserve space we wish to overwrite as much of the bit map as possible, while forming the list structure, but we cannot destroy information until it is no longer needed. Let B be the base address of the bit map (stored contiguously), and let L be the base address of the list structure. Let us suppose, for definiteness, that $L<B$. Then, $B-L$ is the work space to be minimized.

The conversion procedure begins with vertex 1 and unpacks its bit map, starting at B, into the list structure, starting at L. At a general iteration, the bit map for vertex i is unpacked into the list. Its bit map is located between $B+(i-1)b$ and $B+ib$; its list structure is located between $L+d_{i-1}$ and $L+d_i-1$, where $d_i=$ sum of the degrees of the first i vertices. Therefore, to avoid premature overwrite, it is sufficient to require:

$$L+d_i-1\leqq B+(i-1)b \quad \text{for } i=1,\ldots,/V/.$$

Define

$$M=\max[d_i-ib: 1\leqq i\leqq /V/].$$

Then, we can set

$$B=L+b-1+M.$$

To convert from a list structure to a bit map representation, we transform in reverse order. If the bit map structure uses a sufficient amount of more space than the list structure, no other extra space is needed. Specifically, if $b/V/+M+b-1\geqq/A/$, then this conversion can be accomplished within the total region (L to $L+b/V/+M+b-1$).

University of Texas
Austin, Texas

ABSTRACT

The primary purpose of this paper is to identify recent major accomplishments and prophesy future trends in the solution, modeling, and human engineering aspects of network and network-related problems.

Network and network-related problems include such mathematical problems as assignment, transportation, transshipment, multi-commodity networks, generalized networks, plant location problems, fixed charge networks, and constrained networks. In fact, it has recently been shown that the 0-1 integer programming problems are equivalent to 0-1 generalized network problems.

Network-related problems that arise "naturally" (i.e., those whose formulations make conspicuous reference to a network structure) cover a diverse spectrum of practical applications. These applications include problems in telecommunication, microdata set merging, cash flow, multi-national currency exchange, manpower planning, waste disposal, water resource management, aircraft refueling, student-professor-classroom scheduling, modular design, cutting stock, machine loading, aircraft scheduling, off-shore oil well location and drilling, and production and distribution scheduling, to mention only a few.

SETTING THE STAGE

The primary purpose of this paper is to identify recent accomplishments in formulating and solving network and network-related problems, and to propose an integrated sequence of future developments to take advantage of the rich possibilities for new advances and applications in the field. To achieve these purposes with reasonable conciseness, the next section presents a *very brief* overview of the recent major developments in network and network-related problems. These developments are then partitioned and discussed in the following sections.

RECENT HAPPENINGS

The published research on network and network-related problems prior to 1969 primarily focused on characterizing solution algorithms from a mathematical viewpoint. Very little was done in the way of investigating how broad algorithmic principles should be organized and interrelated to provide efficient computer implementation. Additionally no intensive computer code developments or rigorous empirical studies were presented. Basically the determination of the most effective algorithmic principles, and the development of special techniques for exploiting these principles in a highly efficient manner, were neglected areas.

Things have really changed since 1969! The following developments have all occurred subsequent to this date:

(1) The first reported transportation and transshipment computer codes based on the dual simplex method.[10,12,20]
(2) the first reported techniques for streamlining the out-of-kilter algorithm to enhance its computer implementation.[1,4]
(3) a number of special updating and labeling techniques and their underlying list structures for improved computer implementation of network algorithms.[5,11,13,17,19,22,28,32]
(4) the first reported transshipment code based on the primal simplex method.[10]
(5) the first transportation and transshipment codes[2,23] designed for solving large-scale problems within reasonable solution times.
(6) major advances in primal simplex network computer codes for generalized network problems[14,26,27] (in our terminology, the "generalized" network problem is the "flow with gains and losses" problem).
(7) the first constrained network computer code.[28]

These code development efforts have been accompanied by rigorous empirical studies to determine the best solution and implementation procedures. Additionally, the past six years have witnessed the formulation and solution of substantially increased numbers of real world problems as network or network-related problems.[6,9,21,25] It appears that many researchers are adopting real world implementation as one of the major goals of their efforts, and this is beginning to serve as a driving force in the development of efficient solution and modeling approaches. Indeed, a number of new modeling techniques have appeared which have substantially broadened the class of network-related problems,[9,24,25] including the discovery[18] that an 0-1 linear program can be modeled as a 0-1 generalized network problem or as a "O-U" transshipment problem. Given these advances it is appropriate and necessary to ponder and reflect on a number of questions. For example: What are the implications of these advances for identifying worthwhile directions for future research? What realms of applications have implicitly been opened up that have not yet been fully recognized? What thresholds are about to be crossed, and of these, which are the most important to examine next? What types of interactions are likely to occur between researchers and practitioners due to the unprecedented practical value of many of these advances? What supplementary developments for enhancing the use (and usefulness) of these advances are likely to emerge? The remaining sections of this paper contain some of our more concrete reflections on these questions.

TRANSPORTATION AND TRANSSHIPMENT PROBLEMS

This section attempts to summarize recent advances in the solution of transportation and transshipment problems. The total work that has been done in this area since 1969 consists of at least 10 man years of work by mathematical programmers and systems analysts. For a more complete discussion of events prior to 1975 the reader should see Reference 6.

The recent developments of simplex computer codes for networks were initiated in two major studies: those of Srinivasan and Thompson[31] and of Glover, Karney, Klingman, and Napier.[12] Both studies introduced a variety of refinements and explored techniques for taking advantage of computational trade-offs that had been left unexamined in the literature to that time. One of the significant findings to emerge from these studies was that the special updating and labeling techniques of the API method[11] (which made use of Ellis Johnson's triple label list representation[22]) contributed markedly to the efficiency of the procedures of Reference 12, and when subsequently incorporated into the methods of Reference 31, improved their performance by a factor of 2.5. This validated the expectation that a critical factor in the development of any network computer code is the manner in which an effective list structure is integrated with the operations of storing and updating the required information.

Having decided that the API method was the best updating technique then available, substantial empirical testing was conducted to determine the best starting and pivoting rules to use with simplex based codes.[10,12,31] Following this testing the first primal and dual simplex based transshipment codes were developed by Glover, Karney, and Klingman[10] and similar testing was conducted. These investigations constituted what could be called the "First Generation" of Modern Transportation and Transshipment Codes (1969-72). This period significantly advanced the speed of solving such problems and saw the first intensive application of the combined skills of mathematical programmers and systems analysts in the network area. These investigations uncovered a number of fallacies in the accepted folklore of that time. For instance, it was shown[10,12] that the new simplex based transportation and transshipment codes were at least an order of magnitude (i.e., ten times) faster than the best available out-of-kilter and dual simplex codes, and at least two orders of magnitude (i.e., a hundred times) faster than state-of-the-art commercial LP systems. Thus, considerable doubt was cast on the vintage preconception that the out-of-kilter method is inherently superior to a specialized primal simplex method, and on the more recent notion advanced by commercial LP firms that special purpose network codes are not significantly faster than state-of-the-art LP systems.

The First Generation of network advances also included the first major streamlining of the out-of-kilter algorithm for computer implementation by Barr, Glover, and Klingman.[4] This produced a sixfold improvement in solution times over previous out-of-kilter codes. Using these improvements the out-of-kilter approach was still unable to overtake the efficiency of the best simplex-based approach either in solution speed or in memory requirements.

Following in the aftermath of all these developments, and taking advantage of them, the Second Generation may be conceived as originating in 1973 with the development of a new type of list structure and updating scheme for storing and manipulating the spanning tree basis. This new approach by Glover, Klingman and Stutz,[17] called the Augmented Threaded Index (ATI) method, provided both increased efficiency and reduced memory requirement over the previously best API method. Mulvey[29] elaborated on this development by integrating the ATI approach with the distance function concept of Srinivasan and Thompson.[32] Mulvey's integration of the distance function and the ATI approach improved solution times another 10 percent at the expense of an additional node-length array of computer storage. One significant contribution of the ATI method stems from the fact that it became possible to design an in-core out-of-core simplex transportation code which only uses four node length arrays to maintain and update all basis information. This advance is of paramount importance for solving the extremely large problems that sometimes arise in practical applications. One of these is a micro-data set merger problem recently formulated by the U.S. Treasury. This problem is a transportation problem which contains 50,000 nodes and 62 million arcs. The U.S. Treasury requires problems from this class to be solved several times a year on a UNIVAC 1108, and contracted Analysis, Research, and Computation (ARC), Inc. to design and implement a code capable of meeting these requirements. By using the ATI labeling and updating method, such a code[2] has been developed in FORTRAN and to date has run problems with 5000 nodes and 625,000 arcs in less than four minutes of CP time (and nine minutes total processing time) on a UNIVAC 1108.

The most significant finding of this "Second Generation" in the area of pivot selection strategies was made by Mulvey,[29] who showed that solution times can be substantially reduced for problems with more than a thousand nodes by using a special form of a "candidate list" pivot strategy.

During the early part of this Second Generation, McBride and Graves[28] developed a general technique called the factorization method. The first implementation of this method in the network setting demonstrated the possibility of specialized application in this area. The implementation, however, proved to be substantially slower than the API and ATI procedures and required even more computer memory than the initial implementation of the API approach. These limitations were of course due in large part to the experimental nature and lack of refinement of the first implementation of any approach. Indeed, a later improved implementation by Graves (not reported in the literature) showed that the method was susceptible to substantial improvement, although it remained twice as slow as the implementation of the ATI procedure reported in Reference 10 and continued to require more computer memory, when both procedures were tested on the same computer and same problems at General Motors, Inc. Nevertheless, the factorization ideas contain a good deal of ingenuity, and future implementations may be found that are superior to those developed so far.

This concentrated burst of activity that we have called the Second Generation was quite short, and in referring to it we have indeed included mention of developments that properly carry over to the present "Third Generation." We choose to demark the beginning of the Third Generation as coinciding with the development of a third updating and labeling scheme for improving the implementation of network algorithms. On the basis of sound analytical arguments, it is quite likely that all updating and labeling schemes for simplex network codes will henceforth only augment the information kept by this approach. This new approach by Glover and Klingman[19] which appeared in mid-1974, augments the ATI method with two new functions, called the "cardinality" and "last node" functions. The use of these functions in conjunction with the ATI method makes it possible to update flows and node potentials at each iteration with a marked increase in efficiency. Further, both of these functions together require less work to update than the distance function. As a final bonus, the "cardinality function" can accommodate all of the relevant functions filled by the distance function, and hence can replace it. The net result of all these advantages produces a substantially improved procedure for implementing basis exchange operations. These latest developments are currently being tested and are expected to provide another twofold improvement in solution speed.

The current work of Aashtiani and Magnanti[1] on improved out-of-kilter procedures bears watching. In addition, Shapiro[30] has noted a previously overlooked distinction between the out-of-kilter method and the primal-dual method that may hold promise for exploiting the latter method by subgradient optimization and by the techniques of Reference 19. Thus the Third Generation promises to produce several enhancements in the implementation of the primal simplex and out-of-kilter approaches and may initiate a new generation of hybrid solution approaches.

FUTURE DEVELOPMENTS FOR TRANSPORTATION AND TRANSSHIPMENT PROBLEMS

In spite of the notable gains in network solution techniques since 1969, there is still a major area that remains to be explored. This is the area of designing appropriate techniques for accommodating and taking advantage of degeneracy. Computational testing has shown that approximately 90 percent of the pivots for transshipment problems with more than 1000 nodes are degenerate. Presently, schemes are being computationally tested by Elam, Klingman and Stutz to respond to this situation. The techniques being tested are designed to circumvent pivots and to make them judiciously. It is estimated that an effective scheme for handling degeneracy could easily reduce solution times by another 50 percent.

Another development which should prove to be a significant future advance in mathematical programming is the implementation of network algorithms on mini-computers. Given the dramatic recent improvements in the speed and memory requirements of network methods, and the major advances in mini-computer design, it now appears possible to implement relatively efficient in-core out-of-core transportation and transshipment codes in an assembly level language on most mini-computers. This belief is partly based on the work reported in References 2 and 23, which indicates that simplex based codes do not suffer undue increases in solution times by keeping the problem data in external computer memory. Further the FORTRAN code[10] has been tested on the General Dynamic's Nova computer. Preliminary testing showed that problems with 200 nodes and 600 arcs could be solved in less than a minute on the Nova. The emergence of network codes on mini-computers would afford the potential to substantially increase the use of mathematical programming in the real world. For example, such a development would make it possible to demonstrate OR techniques easily and conveniently to managers in their own offices, at management seminars, and in other countries. Further, since the computer could be dedicated to network applications, it would be feasible and highly desirable to design the operating system to minimize the human engineering aspects of problem solving—that is, to minimize the difficulties of entering, modifying, and verifying problem data, passing the problem data to the solution code, interpreting the output, and so forth. With a dedicated system such problems could be almost nonexistent to the user.

TRANSFER OF TRANSPORTATION AND TRANSSHIPMENT TECHNOLOGY TO RELATED PROBLEMS

Assignment problems

With the exception of the work by Rao and Fong, very little research has been directed toward specializing the recent network innovations to the solution of assignment problems. Consequently the most efficient way to solve assignment problems is currently unknown. Within the next two years this question will be resolved.

Current research by Barr, Glover and Klingman (to appear) has resulted in development of a new extreme point algorithm that computationally overcomes the "massive degeneracy" that is characteristic of assignment problems and drastically reduces computer memory requirements for this class of problems.

Generalized networks

Currently the updating and labeling techniques for transportation and transshipment problems are being extended to generalized network problems also called "weighted networks" or "networks with gains." The fundamental relationships by which such extensions can be carried out effectively are developed in Glover, Klingman and Stutz,[13] which shows how the diverse basis updating configurations (of which there are more than a dozen separate cases) can be consolidated into a single "general case." This result builds upon the early work of Balas and Hammker[3] who characterized the basis structure for this class of problems as a forest of "1-trees" (i.e., trees augmented by additional arcs). Additional computational simplifications of the algorithmic steps for generalized networks have appeared. For example, Maurras[27] and Glover and Klingman[15] indicate how to simplify basis updating calculations by characterizing an appropriate sequence for tracing out paths in the one-trees and for proceeding through all nodes in a subtree of a one-tree. These events led to the development of efficient simplex-based codes for generalized networks by Glover, Klingman, and Stutz,[14] Langley,[26] and Maurras.[27] Present computational results indicate that generalized network problems require about four times longer to solve than transportation and transshipment problems of similar dimension. However, a series of algorithmic and implementation advances in the next several years should substantially reduce the already impressive solution times of such problems.

Constrained network

By a constrained network we mean an assignment, transportation or transshipment problem which also includes extra linear constraints. Klingman and Russell[24] have developed a special basis compactification procedure for this class of problems that maintains all of the network as the "implicit" portion of the basis. The operations involving the implicit portion of the basis are simply carried out as they would ordinarily be for the underlying network. Thus it is possible to take advantage of the efficient procedures previously described for solving network problems. Preliminary computational implementations by Glover, Karney, Klingman, and Russell[16] indicate that this procedure is highly efficient for solving problems with one or two extra constraints. Such problems typically required only twice as long to solve as the underlying network problem. A prototype code using related ideas to handle more than two extra constraints has recently been developed by Chen and Saigal[7] although without attempting to incorporate the essential refinements required to take full advantage of the network structure or to optimize the computer memory requirements. We strongly anticipate that refined codes to handle larger numbers of extra constraints will be developed in the near future. The results of Reference 16 suggest that these codes will be much more efficient than general linear programming codes for solving this class of problems.

The importance of the basis compactification area for solving constrained network problems is difficult to overrate. It will probably be the focus of numerous active investigations and will produce the next breakthrough, similar to the GUB breakthrough, in the developments of linear programming codes. This belief rests on the observations that

(a) GUB is a specialization of the network basis compactification procedures of Reference 24,
(b) the network basis compactification extends GUB in the sense that it eliminates the nonoverlapping variable requirement of GUB.
(c) the number of real world LP problems which have network substructures is quite large.

Modeling

As a result of the projected algorithmic and implementation activities for generalized and constrained network problems, we foresee a flurry of modeling advances for these problems. In our opinion, such problems have a vastly richer domain of application than ordinary networks; e.g., examples include cash flow problems, multi-commodity problems, waste disposal problems, water resource management problems, plastic problems of civil engineering, production scheduling problems, machine loading problems, goal programming networks, stochastic and constrained regression problems, and multi-national currency exchange problems, to mention only a few.

An important educational function that should soon be adopted by members of the Operations Research and Management Science fields is to train and guide modelers and decision makers in visualizing their problems within network-related frameworks—particularly those of generalized network or constrained network problems when this is possible. A trend is already underway[18,21] toward identifying problems that can be framed cost-effectively as network-related problems. Network-related problems provide natural formulations for a vastly larger number of real world problems than previously suspected. At the same time, researchers are discovering that a variety of other real world problems can be easily transformed into this format.[18,21] Such models and formulation possibilities have been virtually unknown in the literature before now because of the lack of efficient ways to solve such problems as a class distinct from general LP models.

It is further believed that the effort to help people think of their problems in a network-related format will have far reaching and beneficial consequences in two ways. First, this type of visualization will enable decision-makers to formulate their problems initially by means of drawings and diagrams. This is much easier for the nontechnical person than trying to formulate his problems in terms of equations. The result will be to provide increased recognition of the pervasiveness and significance of these types of problems, and thus to enlarge the number of important real world problems that are being solved by OR methodology. The second and probably more significant consequence will derive from the fact that these types of problems can often be solved with dramatic success, even in large-scale applications. Consequently, a much greater appreciation of OR by industry and government will come about, permitting the widespread disillusionment that followed on the heels of many attempted LP and IP implementations to be reversed. Indeed, it seems conceivable that such developments may spearhead a new liaison between OR and its users. We have personally had first hand experience of this upsurge of interest by industry and government when such modeling and solution approaches are used. Recent real world applications which have been successfully solved via these modeling and solution approaches are summarized in Reference 21.

Low-cost residue number systems for computer arithmetic

by BEHROOZ PARHAMI
Arya-Mehr University of Technology
Tehran, Iran

ABSTRACT

The representation of integers by their residues with respect to a set of pairwise-prime moduli is known as the residue number representation system and has been shown to have several advantages over conventional number systems for digital computers. In this paper, residue systems are considered for which each modulus is of the form 2^b-1. Such systems result in relatively high storage efficiency as well as simple algorithms for addition, subtraction multiplication, conversion, and reconversion; hence the name "low-cost." The question of existence for low-cost residue number systems is examined. It is shown that the additional storage requirement with respect to binary representation is at most one bit per word. Guidelines are given for optimal selection of the set of moduli to represent a desired range of integers. Algorithms for various operations in a low-cost residue system are described.

INTRODUCTION

When dealing with large numbers in digital computers, the computations are slowed down because of the requirement for carry or borrow propagation through many stages of logic in addition and subtraction operations and for long iterative algorithms to perform multiplication and division. Attempts to eliminate the propagation of carries and borrows have resulted in proposals for stored-carry[1] and signed-digit[2] number representation systems. The residue number system[3] does not totally eliminate carry propagation but limits it to within a few stages by representing large numbers as an ordered set of smaller numbers that can be processed independently and in parallel. This is particularly advantageous in multiplication which becomes almost as simple and as fast as addition. However, the complexity of division in residue number systems makes them unsuitable for general-purpose use.

In this paper, residue number systems are reviewed briefly and their properties are enumerated. A class of residue number representation systems which results in relatively high storage efficiency as well as simple algorithms for addition, subtraction, multiplication, conversion, and reconversion algorithms is introduced. The questions of existence, selection, storage efficiency, and algorithms for such "low-cost" residue systems are examined. The storage requirement for each word is shown to be within one bit of the binary representation. Algorithms needed for basic operations and conversions are discussed.

RESIDUE NUMBER SYSTEMS

A *residue number system*[4,5] is one in which a numerical value n is represented by a k-tuple whose components are the residues of n with respect to an ordered set of k moduli

$$p = \langle p_1, p_2, \ldots, p_k \rangle \tag{1}$$

which are relatively prime pairwise. Hence, n is represented by the k-tuple

$$r = \langle r_1, r_2, \ldots, r_k \rangle \tag{2}$$

such that

$$r_i = p_i | n \; ; \; i = 1,2, \ldots, k \tag{3}$$

where $\rho = \mu | \xi$ means that ρ is the smallest non-negative integer satisfying $\xi = \rho + \beta\mu$ for some integer β. The *range* of a residue system (i.e., the number of distinct values representable) is:

$$N = \prod_{i=1}^{k} p_i \tag{4}$$

To represent a negative integer $-n$, we simply represent the positive integer $N-n$ since we have

$$p_i | (N-n) = p_i | (-n) \; ; \; i = 1,2, \ldots, k \tag{5}$$

The integer $N-n$ is the *additive inverse* of n and is denoted by $\bar{n}$. The residue representation $\bar{r}$ of $\bar{n}$ has the following relation with the representation r of n:

$$\bar{r}_i = p_i | (p_i - r_i) \; ; \; i = 1,2, \ldots, k \tag{6}$$

If binary representation is used for the residues, the number of bits required for storing each value in the residue system is

$$B = \sum_{i=1}^{k} b_i = \sum_{i=1}^{k} \lceil \log_2 p_i \rceil \tag{7}$$

which is always greater than or equal to $\lceil \log_2 N \rceil$, the number of bits needed for the binary representation of N distinct values. Hence, a residue number system is less efficient than the binary representation in terms of storage space.

Addition and multiplication in a residue system are done by performing the corresponding operation (modulo p_i) on the i-th residues of the two numbers, independently of other residues. Hence, showing the sum and product of $x = <x_1, x_2, \ldots, x_k>$ and $y = <y_1, y_2, \ldots, y_k>$ by s and m, respectively, we can write:

$$s_i = p_i | (x_i + y_i)\ ;\ i = 1,2, \ldots, k \qquad (8)$$

$$m_i = p_i | (x_i \cdot y_i)\ ;\ i = 1,2, \ldots, k \qquad (9)$$

Subtraction is performed by adding the additive inverse, as defined by (6). Thus, the carry propagation delay for addition and subtraction is reduced and the construction of very fast multiplication circuits is made possible. However, comparison of magnitudes, and hence division, and also detection of overflow conditions are fairly complex in residue number systems. Hence, such systems are not suitable for general-purpose use.

To find the normal representation n of a residue number $r = <r_1, r_2, \ldots, r_k>$, the following equation may be used

$$n = N | \sum_{i=1}^{k} \left((r_i c_i \frac{N}{p_i} \right) \qquad (10)$$

where the coefficient c_i is selected to be the smallest integer satisfying

$$c_i = p_i (1 + \beta_i p_i) / N \qquad (11)$$

for some integer β_i.

Another reconversion process uses the following algorithm which is a formalization of the procedure given in Reference 5.

Algorithm R (12)

```
[1] $v \leftarrow r; n \leftarrow 0; w \leftarrow 1; u_j \leftarrow 1, j = 1,2, \ldots, k; i \leftarrow k$
[2] Find smallest integer d such that for some $\beta$,
                                   $d = (v_i + \beta p_i) / u_i$
[3] $n \leftarrow n + wd$
[4] For $j = 1,2, \ldots, k$ set $v_j \leftarrow p_j | (v_j - u_j d)$ and
                                   $u_j \leftarrow p_j | (u_j p_i)$
[5] $w \leftarrow w p_i$
[6] $i \leftarrow i - 1$
[7] if $i > 0$ then go to Step [2] else stop
```

LOW-COST RESIDUE SYSTEMS

A residue number representation system is *low-cost* if each modulus p_i is selected such that:

$$p_i = 2^{b_i} - 1;\ b_i > 2 \qquad (13)$$

The name "low-cost" is justified because of the relatively high storage efficiency and the simplicity of addition subtraction, multiplication, conversion, and reconversion algorithms as will be seen in the remainder of this paper. In this section, we will only concentrate on the existence of such systems and their storage efficiency.

The selection of b_i's must be made such that the resulting p_i's are pairwise prime. It can be proven that p_i and p_j are relatively prime if and only if the corresponding b_i and b_j are relatively prime (see Theorem 1 in the Appendix). Using this result, Table I has been constructed to show the maximal sets of pairwise-prime b_i's for $b_i \leqq 20$, since making b_i larger than 20 may defeat the advantage of residue number systems in breaking long numbers into several short components. We define, as a measure of this advantage, the *dissection factor:*

$$\delta = \max_i (b_i) / \Sigma_i b_i \qquad (14)$$

Table II shows possible selections of b_i's for a given total number of bits, B, which satisfy the following criteria, in the order given: (1) Minimum value of δ, and (2) Smallest number of b_i's. The second criterion is justified by the fact that once the size of the longest group is fixed at its minimum value, no speed advantage results from making the other groups shorter. Figure 1 shows the same results graphically.

We define as a measure of storage efficiency, the ratio of N to the range of the binary system with the same number of bits:

$$n = N/2^B = \prod_{i=1}^{k} (p_i / 2^{b_i}) = \prod_{i=1}^{k} (1 - 2^{-b_i}) \qquad (15)$$

It can be proven (see Theorem 2 in the Appendix) that

TABLE I—Maximal Compatible Sets of b_i's ($b_i \leq 20$) for Low-Cost Residue Number Systems

for any low-cost residue number system $0.5<\eta<1$ from which we can conclude

$$2^{B-1}<N<2^{B} \qquad (16)$$

This shows that the storage requirement for a low-cost residue system is within one bit of the most efficient representation. It also shows that N is an increasing function of B.

To select a low-cost residue system, B must be determined first. To do this, we first note that among all choices for the set of moduli for each value of B, given by Table II, the one for which $\min_i(b_i)$ is a maximum results in the largest possible range (see Theorem 3 in the Appendix). If more than one set has this maximum value for $\min_i(b_i)$, we look at the second smallest b_i in the sets, etc. Table III gives the maximum range obtainable for each value of B. Since, in a low-cost residue system, the storage requirement is dictated by B and the processing speed by $\max_i(b_i)$, the final choice for B among the values which provide adequate range may involve a tradeoff between these two factors. For example if B=51 is sufficient for some desired range, B=52 and B=53 must also be considered for the final selection, since they provide higher processing speeds at the expense of more storage space.

LOW-COST ALGORITHMS

We first note that in dealing with numbers represented in a residue system, the following operations in-

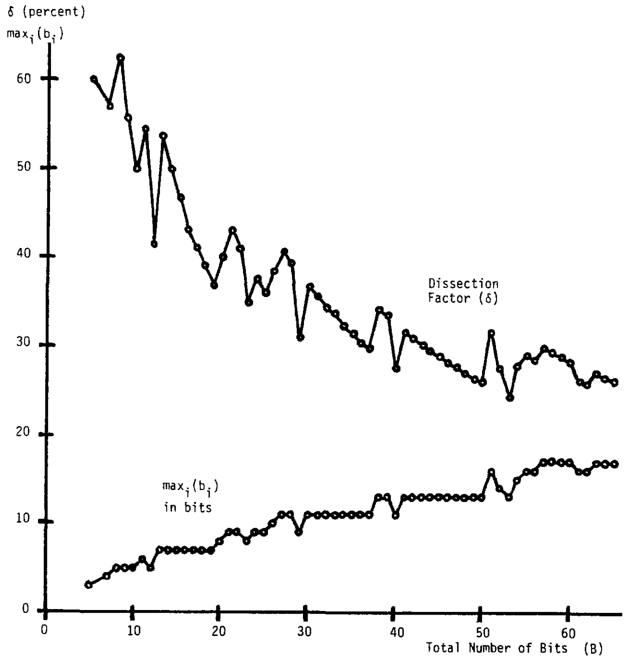

Figure 1—The values of $\max_i(b_i)$ and δ as functions of B

volving the set of moduli p are required (numbers following each operation show the equations where it is used):

1. Subtraction from p_i : (6)
2. Addition modulo p_i : (8)
3. Determination of residues with respect to p_i : (3), (6), (12)
4. Multiplication modulo p_i : (9)
5. Multiplication by p_i : (12)
6. Division by p_i : (10)

We will show that low-cost algorithms exist for performing all of the above operations in a low-cost residue number system. Here, the term "low-cost" refers to the computer implementation of algorithms, keeping in mind that in digital computers addition and subtraction are the fastest and least expensive of the four basic operations, while division is the slowest and most expensive to implement. Most of the operations to be described are also used in encoding, decoding and arithmetic operations for low-cost arithmetic error codes.[6,7]

Subtraction of a b_i-bit binary number x from p_i is quite simple since $p_i=2^{b_i}-1$ is represented in binary as b_i digits of 1. Hence, the digits of p_i-x are the logical complements of the digits of x.

Addition of two b_i-bit binary numbers modulo p_i is also simple. It consists of a simple b_i-bit binary addition with end-around carry; i.e., the carry generated by the last digit position is inserted into the first digit position. This is true since for a sum which is greater than p_i, we have to subtract $p_i=2^{b_i}-1$ in order to obtain its modulo p_i residue. This is done by subtracting 2^{b_i} (discarding the outgoing carry) and adding 1 (inserting a carry into the first digit position). The only problem arises when the sum is equal to p_i, in which case we either need special circuitry to detect this condition and insert a carry into the first digit position if it arises, or simply leave the result as it is and have two representations for zero. This latter approach will cause no difficulty since in all modulo-p_i operations the two values 0 and $2^{b_i}-1$ are entirely equivalent.

To determine the residue of a binary number x with respect to p_i, we simply break x into b_i-bit bytes, starting at the right end, and add the resulting bytes modulo p_i. This is true since the residue of 2^{b_i} with respect to p_i is equal to 1 and the value of x is a polynomial in 2^{b_i}, with the values of the b_i-bit bytes of x as the coefficients. Hence the residue of x with respect to p_i is the same as the residue of the sum of these coefficients with respect to p_i, which is the modulo p_i addition of these coefficients.

Multiplication in digital computers is usually performed through multiple additions, either sequentially by a single adder or in parallel by using a number of carry-save adders.[8] Hence, modulo-p_i multiplication of two numbers can be performed through a number of modulo-p_i additions, the algorithm for which was discussed previously.

Multiplication of a binary number x by $p_i=2^{b_i}-1$ can be done by a single subtraction $x.2^{b_i}-x$, since $x.2^{b_i}$ can be easily obtained through shifting x to the left by b_i bits (inserting b_i zero to the right of x).

Finally, division by p_i (of a number which is a multiple of p_i) can be done by a very interesting algorithm[7] which is obtained by observing that $x=x.2^{b_i}-x.p_i$. Now, the first b_i bits of $x.2^{b_i}$ are known to be zero and since we have $x.p_i$, the first b_i bits of x can be obtained by subtraction. These b_i bits of x now form the second b_i bits of $x.2^{b_i}$ and, hence, the second b_i bits of x are obtained by another subtraction, taking into account a borrow which may have been generated by the first subtraction. This process is continued until all the digits of x are computed.

CONCLUSION

In this paper, we have introduced the class of low-cost residue number representation systems and studied their properties. It appears that such systems alleviate the storage inefficiency normally associated with residue number systems and simplify many of the basic algorithms. The division process, however, remains complex. Therefore, such systems are useful only for special applications.

One disadvantage of the low-cost residue number system is that the moduli, and hence the residues, are larger than those for conventional residue systems with no restriction on p_i's. Therefore, carry propagation delay is not reduced by as much. However, this

APPENDIX

THEOREMS AND THEIR PROOFS

Theorem 1: $p_i=2^{b_i}-1$ and $p_j=2^{b_j}-1$ are relatively prime if and only if b_i and b_j are relatively prime.

Proof: (Only if part)—Let $b_i=zx$ and $b_j=zy$ with $z>1$. Then, since a^n-1 is divisible by $a-1$, p_i and p_j are both divisible by 2^z-1 and, hence, they are not relatively prime.

(If part)—Suppose there exist pairs of integers of the form $2^{b_i}-1$ and $2^{b_j}-1$ which are not relatively prime while b_i and b_j are. Let 2^x-1 and 2^y-1 be one such pair with $x>y$ and $x+y$ a minimum among all such pairs. Let the odd prime number z divide 2^x-1 and 2^y-1. Then, z must also divide their difference

$$2^x-2^y=2^y(2^{x-y}-1). \qquad (17)$$

Since z cannot divide 2^y, it must divide $2^{x-y}-1$. But now z divides $2^{x-y}-1$ and 2^y-1 with $x-y$ and y relatively prime (since, by assumption, x and y are relatively prime) and $(x-y)+y$ smaller than $x+y$ which was assumed to be a minimum among all such pairs; clearly a contradiction.

Theorem 2: If $b_i\geq 2$ for all i and if for $i\neq j$, we have $b_i\neq b_j$, then

$$\eta=\prod_{i=1}^{k}(1-2^{-b_i})>1-2^{-(\min_{i\leq k}(b_i)-1)}\geq 1/2 \qquad (18)$$

Proof: The second inequality is obvious upon noting that $\min_i(b_i)\geq 2$. To prove the first inequality, we first show, by induction on k, that:

$$\prod_{i=1}^{k}(1-2^{-b_i})\geq 1-\sum_{i=1}^{k}2^{-b_i} \qquad (19)$$

Clearly this is true for $k=1$. To show that if the inequality holds for k it will also hold for $k+1$, we multiply both sides of (19) by the positive value $(1-2^{-b_{k+1}})$ to get:

$$\prod_{i=1}^{k+1}(1-2^{-b_i})\geq 1-\sum_{i=1}^{k+1}2^{-b_i}+b_{k+1}\cdot\sum_{i=1}^{k}2^{-b_i} \qquad (20)$$

The right-hand-side of (20) is clearly greater than the right-hand-side of (19) with k replaced by $k+1$. Next, denoting $\min_{j\leq K}(b_i)$ by m, we write:

$$1-\sum_{i=1}^{k}2^{-b_i}>1-\sum_{x=m}^{\infty}2^{-x}=1-2^{-(m-1)} \qquad (21)$$

Combining (21) with (19), we get the desired result.

Theorem 3: Given $b_1<b_2<\ .\ .\ .\ <b_k$ and $b'_1<b'_2<\ .\ .\ .\ <b'_k$ with $b_1>b'_1$

and

$$\sum_{i=1}^{k}b_i=\sum_{i=1}^{k}b'_i=B, \qquad (22)$$

we have

$$\prod_{i=1}^{k}(2^{b_i}-1)>\prod_{i=1}^{k}(2^{b'_i}-1). \qquad (23)$$

Proof: Using Theorem 2 and the fact that $b'_1\leq b_1-1$, we can write:

$$\begin{aligned}\prod_{i=1}^{k}(2^{b_i}-1)&=2^B\prod_{i=1}^{k}(1-2^{-b_i}) \qquad (24)\\ &>2^B(1-2^{-(b_1-1)})\\ &\geq 2^B(1-2^{-b'_1})\end{aligned}$$

On the other hand:

$$\prod_{i=1}^{k}(2^{b'_i}-1)=2^B\prod_{i=1}^{k}(1-2^{-b'_i})\leq 2^B(1-2^{-b'_1}) \qquad (25)$$

Combining (24) and (25), we get the desired result.

Very fast computation of polynomial remainder sequence coefficient signs*

by JAMES R. PINKERT
University of Tennessee
Knoxville, Tennessee

ABSTRACT

Polynomial remainder sequences are the basis of many important algorithms in symbolic and algebraic manipulation. In a number of these algorithms, the actual coefficients of the sequence are not required; rather, the method uses the signs of the coefficients. Present techniques, however, compute the exact coefficients (or a mixed radix representation of them), and then obtain the signs. This paper discusses a new approach in which interval arithmetic is used to obtain the signs of the coefficients without computing their exact values. Comparisons of this method with analogous standard techniques show empirical computing time reductions of two orders of magnitude for even relatively small cases.

INTRODUCTION

Two occurrences at Mathematical Software II[1] were especially important to this paper. One was Oliver Aberth's presentation of some very interesting techniques in interval arithmetic. The other was a discussion with George E. Collins regarding potential time reductions in algorithms of symbolic and algebraic manipulation if approximate or interval arithmetic could replace some of the exact arithmetic.

One of the author's main interests is the computation of polynomial roots using algebraic algorithms. A major tool in such work is the integer polynomial remainder sequence.[2]

It is important to note that in this application the exact numerical values of coefficients in a given sequence are not required. Rather, one is concerned with the signs of the coefficients.

Two algorithms for computing these signs have received considerable attention.[2] In one, pseudo-division[3] is used to compute a reduced integer polynomial remainder sequence; the signs are then obtained from the integer coefficients. (A greatest common divisor algorithm can be added to obtain a primitive integer polynomial remainder sequence.) In the other algorithm, modular methods are used to obtain mixed radix representations[4] of the coefficients. The signs can then be obtained from these representations without actually computing the integer values.

Since signs, and not numeric values, are required, the considerations brought up in the first paragraph of this section seemed particularly relevant to these computations.

A SAC-1[2] interval arithmetic package was implemented, employing some concepts from Aberth's presentation. The standard SAC-1 algorithm for computing the pseudo-remainder of two polynomials[3] was then modified to use this interval arithmetic.

Empirical comparisons of the standard and modified versions have been very encouraging. Time reductions of two orders of magnitude have been realized on relatively small problems and extrapolations seem to indicate even greater reductions for larger cases. For example, one list of signs which could not be computed in thirty minutes using the standard pseudo-division algorithm was obtained in one second using the interval arithmetic version.

Section two of this paper discusses the interval arithmetic algorithms. The modified polynomial remainder sequence algorithms are presented in Section three. Sample empirical computing times are shown in Section four. Section five summarizes the results.

SAC-1 INTERVAL ARITHMETIC

This section discusses the SAC-1 interval arithmetic package used to compute reduced polynomial remainder sequences. Some initial comments must be made regarding these algorithms.

First, they are included for completeness of discussion and better evaluation of results presented in Section four, not on any premise of significant developments in themselves. These algorithms were designed for efficient implementation in SAC-1, and hence to expedite testing of the hypothesis that interval arith-

* Research supported by the University of Tennessee Faculty Research Fund.

metic could be used to improve polynomial remainder sequence generation. Given the successful test results, effort can now be directed to refinement and expansion of this package to form a viable SAC-1 Interval Arithmetic Module.

Second, and related to the previous paragraph, only the fundamental operations of the algorithms are shown. Actual subroutine calls, list operations, and checks for such things as zero inputs and null lists are not included. A complete listing and/or card deck of the actual system can be obtained from the author.

Finally, some notational conciseness has not been used, in the interest of clarity (e.g., deeply nested if-then-else statements).

Consider an integer $A \neq 0$, where for some integer $\beta > 1$, $\beta^m \leq |A| < \beta^{m+1}$. Then A can be written as $A = \sum_{j=0}^{m} \alpha_j \beta^j$ where $\alpha_j = 0$ or $\text{sign}\{\alpha_j\} = \text{sign}\{A\}$, $|\alpha_j| < \beta$, and $\alpha_m \neq 0$. The SAC-1 Integer Arithmetic System[5] uses this technique, representing A as the list $(a_0, a_1, \ldots, a_m)$ where a_j is the Fortran representation of α_j.

Now consider the interval $I = [\beta^\chi\{A-\epsilon\}, \beta^\chi\{A+\epsilon\}]$ where A is as above, $0 \leq \epsilon < \beta$, and $0 \leq \chi < \beta$. This interval is represented in SAC-1 as the list $((a_0, a_1, \ldots, a_m), e, x)$ where $\bar{A} = (a_0, a_1 \ldots, a_m)$ is the representation of A, e is the Fortran representation of ϵ, and x is the Fortran representation of χ.

The interval I is spoken of as "carried to m+1 β-digits." For conciseness, it will be written $\beta^\chi[A \pm \epsilon]$.

The Integer Arithmetic System representation of $A = 0$ is the null list, (). The representation of interval $I = [0, 0]$ will also be the null list.

The following algorithm is used for interval subtraction, $I - J$, where $I = \beta^{\chi_1}[A \pm \epsilon_1] = ((a_0, a_1, \ldots, a_{d_1}), e_1, x_1) = (\bar{A}, e_1, x_1)$, $J = \beta^{\chi_2}[B \pm \epsilon_2] = ((b_0, b_1, \ldots, b_{d_2}), e_2, x_2) = (\bar{B}, e_2, x_2)$, and the result is carried to n β-digits.

Subtraction:

```
Step 1: If $x_1 = x_2$ then $x_3 \leftarrow x_1$;
Step 2: If $x_1 > x_2$ then do;
          $e_2 \leftarrow 2$;
          $\bar{B} \leftarrow (b_{x_1-x_2}, b_{x_1-x_2+1}, \ldots, b_{d_2})$;
          $x_3 \leftarrow x_1$;
          end;
Step 3: If $x_2 > x_1$ then do;
          $e_1 \leftarrow 2$;
          $\bar{A} \leftarrow (a_{x_2-x_1}, a_{x_2-x_1+1}, \ldots, a_{d_1})$;
          $x_3 \leftarrow x_2$;
          end;
Step 4: $e_3 \leftarrow e_1 + e_2$;
Step 5: $\bar{C} \leftarrow \bar{A} - \bar{B} = (c_0, c_1, \ldots, c_{d_3})$;
Step 6: If $e_3 \geq \beta$ then do;
          $\bar{C} \leftarrow (c_1, c_2, \ldots, c_{d_3})$;
          $h \leftarrow 1$;
          $e_3 \leftarrow 2$;
          $x_3 \leftarrow x_3 + 1$;
          end;
        else $h \leftarrow 0$;
Step 7: If $d_3 - h + 1 > n$ then do;
          $m \leftarrow d_3 - n + 1$;
          $\bar{C} \leftarrow (c_m, c_{m+1}, \ldots, c_{d_3})$;
          $e_3 \leftarrow 2$;
          $x_3 \leftarrow x_3 + m - h$;
          end;
Step 8: Return $C = (\bar{C}, e_3, x_3)$.
```

Step 1 through Step 3 modify exponents if necessary. For example, if $x_2 > x_1$ then $\bar{A}$ would be modified to $((a_{x_2-x_1}, a_{x_2-x_1+1}, \ldots, a_{d_1}), 2, x_2)$. Since $p = \sum_{j=0}^{\chi_2-\chi_1-1} |\alpha_j \beta^j| < \beta^{\chi_2-\chi_1}$ and $\epsilon_2 < \beta$, it follows that $p + \epsilon_2 < 2\beta^{\chi_2-\chi_1}$ and $\beta^{\chi_1}\left[\sum_{j=0}^{d_1}\{\alpha_j\beta^j\} \pm \epsilon_2\right] \subseteq \beta^{\chi_2}\left[\sum_{j=x_2-x_1}^{d_1}\{\alpha_j\beta^j\} \pm 2\right]$. Note that one could have $x_2 - x_1 > d_1$, in which case the result is $((), 2, x_2) \equiv \beta^{\chi_2}[\pm 2]$.

Step 6 insures that the resulting error term will satisfy the definition, i.e., $e_3 < \beta$. Step 7 insures that the interval will be carried to no more than the specified number, n, of β-digits.

In multiplying two intervals, the system does three multiplies of a β-digit error term, say c, times a β-integer, say $\bar{B}$. Each result is a single β-digit error term, say e, times a power of β, i.e., $|c\bar{B}| \leq e\beta^\chi$. The following algorithm performs this operation. Inputs are β-digit c and β-integer $\bar{B} = (b_0, b_1, \ldots, b_{d_2})$.

Special Multiplication, mpys:

```
Step 1: $G \leftarrow 1 + |b_{d_2-2}| + c|b_{d_2-1}| + c|b_{d_2}|\beta =$
          $(g_0, g_1, \ldots, g_k)$;
Step 2: If $k = 2$ then do;
          $x \leftarrow d_2 + 1$;
          $e \leftarrow g_2 + 1$;
          end;
        else do;
          $x \leftarrow d_2$
          $e \leftarrow g_1 + 1$;
          end;
Step 3: If $e = \beta$ then do;
          $x \leftarrow x + 1$;
          $e \leftarrow 1$;
          end;
Step 4: Return $C = (e, x)$.
```

Note that $c|\bar{B}| = c\sum_{j=0}^{d_2} |b_j|\beta^j = c\sum_{j=0}^{d_2-2} |b_j|\beta^j + c|b_{d_2-1}|\beta^{d_2-1} + c|b_{d_2}|\beta^{d_2} < c(|b_{d_2-2}|+1)\beta^{d_2-2} + c|b_{d_2-1}|\beta^{d_2-1} + c|b_{d_2}|\beta^{d_2} < (|b_{d_2-2}| + 1)\beta^{d_2-1} + c|b_{d_2-1}|\beta^{d_2-1} + c|b_{d_2}|\beta^{d_2} \leq (\beta-1)\beta^{d_2+1} + \beta^{d_2-1}$. Hence Step 1 of the algorithm will give a result which bounds $c|\bar{B}|$, and which has $k=1$ or $k=2$.

Step 2 sets the exponent and rounds up the error term. Step 3 insures that the error term is a single β-digit.

The following algorithm uses mpys to perform interval multiplication.

Multiplication:

```
Step 1:  $E_1 \leftarrow \text{mpys}\{a\bar{B}\} = (e_1, f_1)$ ;
Step 2:  $E_2 \leftarrow \text{mpys}\{b\bar{A}\} = (e_2, f_2)$ ;
Step 3:  $E_3 \leftarrow \text{mpys}\{a(b)\} = (e_3, f_3)$ ;
Step 4:  $G \leftarrow e_1\beta^{f_1} + e_2\beta^{f_2} + e_3\beta^{f_3} = (g_0, g_1, \ldots, g_f)$ ;
Step 5:  $e_4 \leftarrow g_f + 1$ ;
Step 6:  If $e_4 = \beta$ then do;
           $e_4 \leftarrow 1$ ;
           $f \leftarrow f + 1$ ;
           end;
Step 7:  $\bar{C} \leftarrow \bar{A} \bullet \bar{B} = (c_0, c_1, \ldots, c_{d_4})$ ;
Step 8:  If $f > 0$ then do;
           $e_4 \leftarrow e_4 + 1$ ;
           If $e_4 = \beta$ then do
                $e_4 \leftarrow 2$ ;
                $f \leftarrow f + 1$ ;
                end;
           end;
Step 9:  If $d_4 - f + 1 > n$ then do:
           $e_4 \leftarrow 2$ ;
           $f \leftarrow d_4 - n + 1$ ;
           end;
Step 10: $x_4 \leftarrow f + x_1 + x_2$ ;
Step 11: $\bar{C} \leftarrow (c_f, c_{f+1}, \ldots, c_{d_4})$ ;
Step 12: Return $(\bar{C}, e_4, x_4)$.
```

Step 1 through Step 5 do the standard error term multiplies, add the results, and round up the final error term. Step 6 insures that the final error term is a single β-digit.

Step 8 checks whether the error has a positive exponent. If it does, some digits of the product $\bar{C}$ must be dropped and the error term correspondingly increased by one. The increased error term must then be checked to insure that it is a single β-digit.

Step 9 computes the length of the product, to see that it is carried to no more than the specified number of β-digits.

PSEUDO-REMAINDERS AND SIGN LISTS

This section describes an algorithm for computing the pseudo-remainder of two polynomials, and an algorithm which uses pseudo-remainders to compute one standard type of coefficient sign list. The discussion is abbreviated, since the methods have appeared previously.[2,3]

A SAC-1 interval polynomial has exactly the same internal representation as an integer polynomial,[3] except that the numerical coefficients are intervals rather than integers. Hence the pseudo-remainder algorithm can be applied to either type of polynomial simply by calling the corresponding arithmetic routines.

The following algorithm computes the pseudo-remainder of two polynomials, P(v) and Q(v). Note that "deg," "ldcf," and "red" return the degree, the leading coefficient, and the reductum, respectively.

Pseudo-remainder, psrem:

```
Step 1:  $k \leftarrow \deg\{P\} - \deg\{Q\} + 1$ ;
Step 2:  For $j \leftarrow 1$ to k by 1 do;
           $d \leftarrow \deg\{P\} - \deg\{Q\}$ ;
           if $d < 0$ then $R \leftarrow \text{ldcf}\{Q\} \cdot P$
                else $R \leftarrow \text{ldcf}\{Q\} \cdot \text{red}\{P\} -$
                     $\text{ldcf}\{P\} \cdot \text{red}\{Q\} \cdot v^d$ ;
           $P \leftarrow R$ ;
           end;
Step 3:  Return R.
```

The next algorithm applies pseudo-remainders to compute the list of degrees and leading coefficient signs in the reduced polynomial remainder sequence for polynomials P and Q.

List of Signs and Degrees, lsad:

```
Step 1:  $L \leftarrow (\text{sign}\{\text{ldcf}\{P\}\}, \deg\{P\}, \text{sign}\{\text{ldcf}\{Q\}\},$
         $\deg\{Q\})$ ;
Step 2:  While $(R \neq 0)$ & $(d \neq 0)$ & $(0 \notin r)$ do;
         $R \leftarrow \text{psrem}\{P, Q\}$ ;
         if $R \neq 0$ then do;
              $r \leftarrow \text{ldcf}\{R\}$ ;
              if $0 \notin r$ then do;
                   $s \leftarrow \text{sign}\{r\}$ ;
                   $d \leftarrow \deg\{R\}$ ;
                   $L \leftarrow L \| (s, d)$ ;
                   end;
                else $L \leftarrow ()$ ;
              end;
         $P \leftarrow Q$ ;
         $Q \leftarrow R$ ;
         end;
Step 3:  Return L.
```

Note that there are two return conditions. A successful return is executed when the pseudo-remainder is zero or is of degree zero. A failure return is executed when the sign of the leading coefficient cannot be determined. By definition, if $R \neq 0$ then $r = \text{ldcf}\{R\} \neq 0$. Hence if $0 \in r$ then the failure condition has occurred. The cause, of course, is that the intervals have not been carried to a sufficient number of β-digits.

The latter algorithm can be used with integer arithmetic simply by removing the test for $0 \in r$:

```
Step 2:  While $(R \neq 0)$ & $(d \neq 0)$ do;
         $R \leftarrow \text{psrem}\{P, Q\}$ ;
         if $R \neq 0$ then $L \leftarrow L \| (\text{sign}\{\text{ldcf}\{R\}\}, \deg$
           $\{R\})$ ;
         $P \leftarrow Q$ ;
         $Q \leftarrow R$ ;
         end;
```

COMPARISON OF EMPIRICAL COMPUTING TIMES

The algorithm for computing the list of signs and degrees, lsad, was applied to randomly generated poly-

nomials, first using integer methods and then using interval methods. The empirical results are shown in this section.

Random polynomial P, of specified degree and infinity norm, was obtained. Since lsad{P, P′} is used often,[2] this case was run first. Then, for $1 \leq j < \deg\{P\}$, random polynomial Q of degree j was generated, and lsad{P, Q} was computed.

This process was repeated for another polynomial P of the same degree and norm. The exact number of repetitions for a given entry depended on the time required for each repetition.

The average results are shown in Tables I, II, III, and IV. In each comparison, the first entry of the pair is the time (in milliseconds) required for the integer method. The second entry is the time (in milliseconds) required for the interval method, using the minimum possible number of β-digits. A question mark indicates that the set of runs could not be completed in a reasonable amount of time.

	59					33

The time comparisons were made with reduced rather than primitive integer techniques because of the direct analogy in algorithms. Modular methods were not included because, unlike many other instances, they have not resulted in any consistent improvements over integer methods.[2]

Note that the times shown are with intervals carried to the minimum number of β-digits. How does one determine this minimum? As yet, the author has found no way of deriving any theoretical answers to the question. For the sample runs discussed, the minimums were determined experimentally. Given this situation, the times shown for the interval method should include overhead resulting from using too few or too many β-digits.

A small percentage of the test runs required five β-digits; all others required four or fewer. This result is very interesting, since coefficients of a hundred β-digits were not uncommon in the integer computations. It suggests an algorithm which simply starts with one β-digit, and increments by one until the list is computed. This approach was tried, and it gave an average increase of two to three times the illustrated results.

The observed minimum number of β-digits seemed to depend mainly on the degree of Q (or the degree of P'). Hence the author started at this value and doubled the number of β-digits used each time a failure occurred. This approach yielded almost exactly the same set of times as shown in the tables.

SUMMARY

Interval methods appear to have great potential in the computation of polynomial remainder sequence coefficient signs.

Obviously, more reseach needs to be done in determining how many β-digits to carry for the intervals. However, significant improvements seem to be possible even with simplistic approaches.

It is hoped that these results, in addition to being useful per se, might suggest further applications of interval methods in symbolic and algebraic manipulation.

System theoretic implications of numerical methods applied to the solution of ordinary differential equations

by T. G. WINDEKNECHT and H. D'ANGELO
Memphis State University
Memphis, Tennessee

ABSTRACT

This paper presents a system-theoretic analysis of numerical methods used in approximating solutions of ordinary differential equations. By representing ordinary differential equations with system block diagrams (i.e., interconnections of static elements and integrators), a numerical method can be viewed as a process in which the integrators of a continuous system are replaced by discrete approximations to the integrators (i.e., by discrete subsystems made up of interconnections of static elements and delays). The main result of the paper establishes that if the system block diagram corresponding to the original differential equation has no static loops and if the discrete subsystems used to replace the integrators have no static loops and no static through paths, then the resulting discrete system can be characterized by explicit difference equations. A system-theoretic study is conducted of several of the more commonly used numerical methods (the Euler, trapezoidal, Runge-Kutta, and predictor-corrector methods) and the limitations of using these numerical methods in the real-time analysis of input-output systems are examined.

INTRODUCTION

Important insight into numerical methods used in the solution of ordinary differential equations can be obtained by studying these numerical methods from a system theoretic standpoint. The system block diagram (an interconnection of static and dynamic elemental components) has proved to be particularly helpful in this regard. With this point of view, a useful categorization of numerical methods is obtained.

THE PROBLEM

The problem addressed in this paper is the following: Determine a numerical solution to the system of ordinary differential equations given in the standard canonical form

$$\frac{dx(t)}{dt} = f(x(t),u(t)),\ x(t_o) = x_o,\ t\epsilon[t_o,t_f] \qquad (1)$$

where x is an n-vector, u is an m-vector, and f is a function such that $f: R^{n+m} \rightarrow R^n$.

The ultimate objective in applying a numerical method is to compute a sequence

$$\hat{x}(t_o), \hat{x}(t_o+\delta), \hat{x}(t_o+2\delta), \ldots, \hat{x}(t), \ldots, \hat{x}(t_f) \qquad (2)$$

which is, in some sense, a good approximation to the sequence

$$x(t_o), x(t_o+\delta), x(t_o+2\delta), \ldots, x(t), \ldots, x(t_f) \qquad (3)$$

where the continuous variable x, defined on the interval $[t_o,t_f]$ is the solution of equation (1).

It is generally computationally advantageous to be able to compute sequence (2) as a solution to a set of difference equations in the standard state-variable form

$$v(t+\delta) = f_a(v(t),u(t)) \qquad (4a)$$

$$,\ v(t_o) = g(x_o),\ t\epsilon Td$$

$$x(t) = E\, v(t) \qquad (4b)$$

where x is an n-vector, v is an N-vector $(N \geq n)$, u is an m-vector, and f_a is a function such that $f_a: R^{N+m} \rightarrow R^N$, g is a function such that $g: R^n \rightarrow R^N$, E is an nxN matrix of rank n whose elements are either 0 or 1 with one and only one 1 in each row (thus, the components of x are a subset of the components of v), and T_d is the discrete time set $\{t_o, t_o+\delta, t_o+2\delta, \ldots, t_f\}$.

The form of difference equations (4), in which f_a does not depend on $v(t+\delta)$, is said to be *explicit.* Explicit difference equations are computationally attractive since, for most functions f_a, they allow the approximation sequence (2) to be generated in a straightforward iterative fashion. More precisely:[1]

Theorem 1 Explicit difference equation (4) has a unique solution provided only that f_a is defined at each stage of iteration. The solution can be generated on a computer provided that f_a is a computer function and that $|v(t+\delta)|$ is no larger than the largest number in the computer.

However, under certain severe modeling constraints, it may be necessary to settle for less attractive numerical methods in which the approximation sequence (2) is computed as a solution to a set of difference equations of the form

$$v(t+\delta)=f_s(v(t),v(t+\delta),u(t)) \quad , v(t_0)=g(x_0),\ t\epsilon T_d \tag{5a}$$

$$x(t)=E\,v(t) \tag{5b}$$

where f_s is a function such that $f_s:R^{2N+m}\rightarrow R^N$. Difference equations of this form, in which f_s depends on $v(t+\delta)$, are said to be *implicit.* The computational difficulties associated with implicit difference equations stem from the fact that, depending on the nature of the function f_s, it may not be possible to solve for $v(t+\delta)$ and thus obtain the desirable recursive form of equations (4). In such cases, where the solutions are known to exist, and they may not exist, computing $v(t+\delta)$ from a knowledge of $v(t)$ and $u(t)$ is not straightforward. Often, an iterative method of solution, such as a Newton method, with generally unknown convergence properties, is required to approximate $v(t+\delta)$. Certainly, one should avoid this latter form if possible.

SYSTEM BLOCK DIAGRAMS

In system theory it is sometimes convenient to represent sets of equations characterizing dynamic systems by interconnections of elemental components. Systems characterized by differential equations, and thus defined on the continuous time set $[t_0,t_f]$, $t_f>t_0$, are called *continuous systems*; systems characterized by difference equations, and thus defined on the discrete time set T_d, are called *discrete systems.* A sufficient set of elemental components for synthesizing the necessary interconnections consists of the general static element and two fundamental dynamic elements, the delay and the integrator. Each elemental component defines a causal relationship between an *output variable* and one or more *input variables.* The set of elemental components is defined:

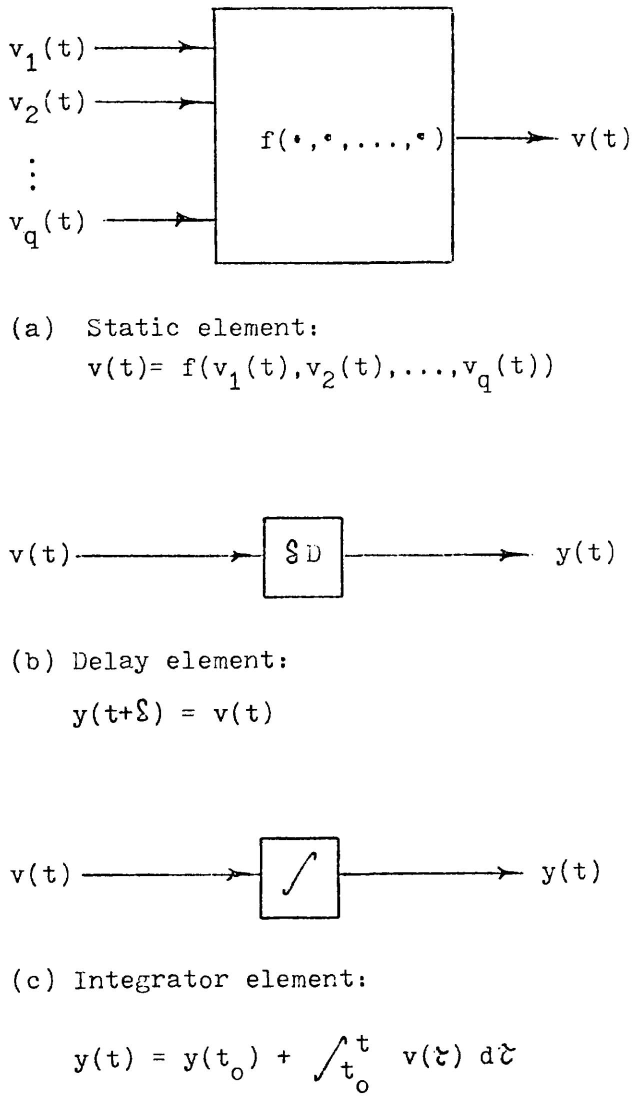
a. A general static element, represented graphically in Figure 1a, is a functional relationship between q input variables and an output variable. It has the form

$$v(t)=f(v_1(t),v_2(t),\ldots,v_q(t)) \tag{6}$$

where f is a function such that $f:R^q\rightarrow R$.

b. A δ-delay element, represented in Figure 1b, is a single-input, single-output element satisfying the quasi-functional relationship between two dynamic variables v and y

$$y(t+\delta)=v(t),\ t\epsilon T_d \tag{7}$$



(a) Static element:
$v(t)= f(v_1(t),v_2(t),\ldots,v_q(t))$

(b) Delay element:
$y(t+\delta) = v(t)$

(c) Integrator element:
$y(t) = y(t_0) + \int_{t_0}^{t} v(\tau)\, d\tau$

Figure 1—Fundamental elemental components

c. An integrator element, represented in Figure 1c, is a single-input, single-output element defined so that the output is the integral of the input (or, equivalently, the input is the derivative of the output):

$$y(t)=y(t_0)+\int_{t_0}^{t} v(\tau)\,d\tau \tag{8}$$

Note that the initial condition $y(t_0)$, as well as the input variable v on the interval (t_0,t), is required to determine the output $y(t)$.

A fixed-structure discrete dynamic system is any *consistent* interconnection of delays and static elements. An interconnection is consistent if no two outputs of elemental components are connected together (i.e., no two outputs should represent the same variable). Similarly, a fixed-structure continuous dynamic system is any consistent interconnection of integrators and static elements. Such interconnections of elemental systems are called *system block diagrams.*

It is important to establish the conditions under which system block diagrams are characterized by canonical state variable equations, i.e., by equations of the form

$$\begin{aligned} x(t+\delta) &= f(x(t),u(t)) \\ y(t) &= g(x(t),u(t)) \end{aligned}, \; t\epsilon T_d \qquad (9)$$

for discrete systems or by equations of the form

$$\begin{aligned} \frac{dx(t)}{dt} &= f(x(t),u(t)) \\ y(t) &= g(x(t),u(t)) \end{aligned}, \; t\epsilon[t_o,t_f] \qquad (10)$$

for continuous systems. Toward this end, the concept of a *proper interconnection* is introduced. An interconnection is proper provided every closed path (in the direction of the arrows) on the system block diagram contains at least one delay element (or, in the case of a continuous system, one integrator). A closed path that does not contain a delay (or integrator) is called a *static loop.* Thus, a system with no static loops is a proper interconnection.

Two important results relating to system block and canonical state equations are found in References 2 and 3.

Theorem 2 Every proper interconnection of static elements and delays admits a state-variable characterization of the form of equations (9); every proper interconnection of static elements and integrators admits a state-variable characterization of the form of equations (10).

Theorem 3 Every set of difference equations in state-variable canonical form (equations (9)) can be represented by a proper interconnection of static elements and delays; every set of differential equations in state-variable canonical form (equations (10)) can be represented by a proper interconnection of static elements and integrators.

COMPUTATIONAL IMPLICATIONS OF STATIC LOOPS

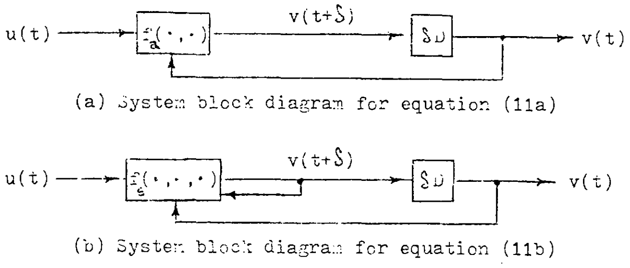
Consider the system block diagrams in Figure 2 corresponding to the following two first-order difference equations, the first explicit and the second implicit:

$$v(t+\delta) = f_a(v(t),u(t)) \qquad (11a)$$

$$v(t+\delta) = f_s(v(t),v(t+\delta), u(t)) \qquad (11b)$$

Note that the explicit first-order difference equation can *always* result in a proper system block diagram (i.e., one without static loops), whereas the implicit first-order difference equation *always* results in a system interconnection with a static loop.

For higher order systems, the results are almost the same: Explicit difference equations (4a) can *always* result in a proper system block diagram, whereas implicit difference equations (5a) *generally* result in system interconnections with a static loop. The exceptional case where an implicit difference equation does not result in any static loops is the somewhat trivial case where a simple reindexing of variables renders the set of difference equations in the following "lower triangular form":



(a) System block diagram for equation (11a)

(b) System block diagram for equation (11b)

Figure 2—System block diagrams for explicit and implicit first-order difference equations

$$\begin{aligned} v_1(t+\delta) &= f_1(v(t),u(t)) \\ v_2(t+\delta) &= f_2(v(t),v_1(t+\delta),u(t)) \\ &\vdots \\ v_i(t+\delta) &= f_i(v(t),v_1(t+\delta),v_2(t+\delta),\ldots, \\ &\qquad v_{i-1}(t+\delta),u(t)) \\ &\vdots \\ v_N(t+\delta) &= f_N(v(t),v_1(t+\delta),v_2(t+\delta),\ldots, \\ &\qquad v_{N-1}(t+\delta),u(t)) \end{aligned} \qquad (12)$$

where v is an N-vector consisting of the scalar components $v_1,v_2,\ldots,v_N$, and f_i, $i=1,2,\ldots,N$, is a function such that $f_i:R^{N+i}\rightarrow R$. Note that this is a rather exceptional implicit form in that

a. The sequence $v(t_o),v(t_o+\delta),\ldots,v(t_f)$ can be computed in a simple iterative fashion.

b. This form admits a system block diagram representation with no static loops.

That the above statements a and b are equivalent statements is easily established by showing that equations (12) can always be put into explicit form by substituting the first equation into the second equation to eliminate $v_1(t+\delta)$, then substituting the first and new second equation into the third equation to eliminate $v_1(t+\delta)$ and $v_2(t+\delta)$, etc. Therefore, the computationally desirable form can be associated with system block diagrams having no static loops and, with the exception of the "lower triangular forms", the computationally difficult implicit form can be associated with block diagrams having at least one static loop.

DISCRETE APPROXIMATIONS TO CONTINUOUS SYSTEMS

It can be shown that every ordinary differential equation in canonical state-variable form can be represented by a proper system block diagram (i.e., an interconnection of static elements and integrators containing no static loops). For example, the first-order differential equation

$$\frac{dx(t)}{dt}=f(x(t),u(t)) \qquad (13)$$

is represented by the system block diagram shown in Figure 3. Similarly, the set of two simultaneous first-order differential equations

$$\frac{dx_1(t)}{dt}=f_1(x_1(t),x_2(t),u(t))$$
$$\frac{dx_2(t)}{dt}=f_2(x_1(t),x_2(t)) \qquad (14)$$

is represented by the system block diagram shown in Figure 4.

One may, taking a system-theoretic viewpoint, interpret most numerical methods for approximating solutions to ordinary differential equations to be equivalent to substituting discrete subsystems for the integrators in the system, thus converting the continuous system to a discrete system. In some numerical methods integrators are replaced by single-input, single-output discrete subsystems on an individual basis whereas in other numerical methods all the integrators are considered to make up a single subsystem and this subsystem is replaced as a single entity. In the latter case, the n integrators in a system are considered to be an n-input, n-output subsystem consisting of n parallel non-interacting integrators; this subsystem is then replaced by an n-input, n-output discrete subsystem. We speak of these subsystems which replace the integrators in a system as discrete approximations to integration or simply as discrete integrators. If the resulting discrete system has no static loops, such a substitution for the integrators in the system leads to explicit difference equations (4); if static loops are present then implicit difference equations (5) are obtained. As far as computational efficiency is concerned, we prefer those discrete approximations to integration which result in discrete systems with no static loops. Since one can always obtain a system block diagram with no static loops to characterize the canonical state-variable differential equations, a condition for the discrete approximations to integration sufficient to assure that the resulting discrete system also has no static loops is easily obtained.

Theorem 4 If the system block diagrams of the discrete approximations to the integrators in a proper system block diagram of a continuous system have

(i) no static loops
(ii) no static through paths (i.e., paths from input to output without a delay element)

then the system block diagram of the resulting discrete system is also proper and can therefore be characterized by the set of explicit difference equations (4).

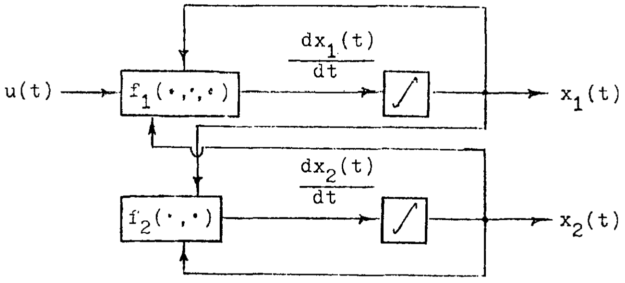


Figure 4—System block diagram for equations (13)

As an example, consider using the Euler zero-order approximation to integration[4] in obtaining a numerical solution to the following first-order differential equation:

$$\frac{dx(t)}{dt}=\cos(x(t)\ u(t)),x(0)=1 \qquad (15)$$

The system block diagram corresponding to equation (15) is shown in Figure 5. An integrator with input v(t) and output x(t), shown in Figure 6a, is characterized by the equation

$$x(t+\delta)=x(t)+\int_t^{t+\delta}v(\tau)d\tau \qquad (16)$$

The Euler method approximates the definite integral by a rectangle:

$$\int_t^{t+\delta}v(\tau)d\tau\cong\delta v(t) \qquad (17)$$

Thus, using the Euler approximation in equation (16) gives the discrete approximation to integration:

$$x(t+\delta)=x(t)+\delta v(t) \qquad (18)$$

The system block diagram for this discrete approximation to integration is shown in Figure (6b). Note that

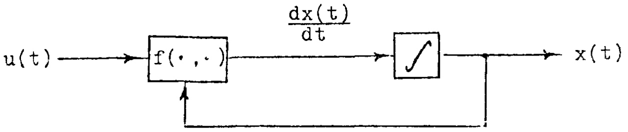

Figure 3—System block diagram for equation (13)

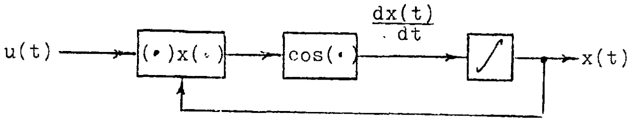

Figure 5—System block diagram for equation (15)

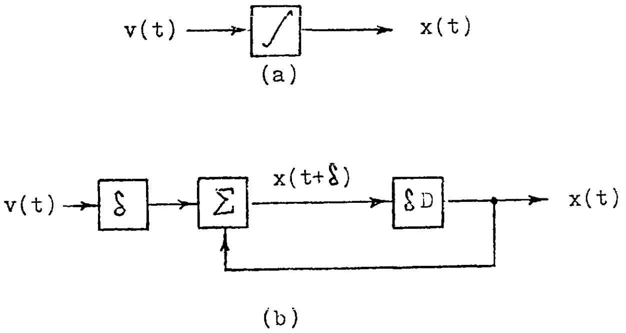

Figure 6—An integrator, (a), and the Euler discrete approximation to it, (b)

the Euler discrete approximation to integration has neither static loops nor static through paths.

Replacing the integrator in the system block diagram of Figure 5 by the Euler discrete approximation to it, Figure 6b, results in the discrete system shown in Figure 7. Importantly, the resulting discrete system has no static loops and is thus characterized by an explicit difference equation:

$$x(t+\delta)=x(t)+\delta\cos(x(t)\ u(t)) \qquad (18)$$

Some other well-known discrete approximations to integration and their system theoretic interpretations are given in the following section.

EXAMPLES OF SOME FREQUENTLY USED NUMERICAL METHODS

In this section some well-known numerical methods will be studied from a system theoretic viewpoint. Much of the literature on the numerical analysis of ordinary differential equations deals with the problem of finding solutions to the class of differential equations defined by

$$\frac{dx(t)}{dt}=f(x(t),t) \qquad (18a)$$

Note that the class of differential equations defined by equation (18a) is somewhat narrower than the class defined by equation (1). Specifically, equation (1) is equivalent to equation (18a) only for the special case that

$$u(t)=t$$

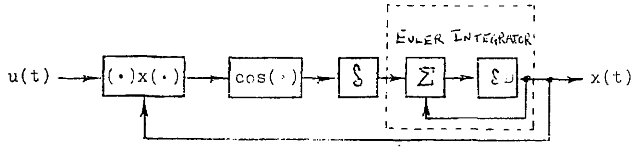

Figure 7—The discrete approximation to equation (15)

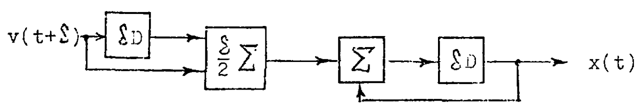

Figure 8—System block diagram for equation (20)

From a systems standpoint, this is unfortunate since much of system theory deals with systems defined in an input-output sense and restricting all inputs u to be defined by u(t)=t is quite unsatisfactory. As we shall see, the problem of extending a numerical method designed for equation (18a) so that it can be used for equation (1) is not always straightforward and, in a systems sense, not always possible. Some of the examples in this section will illustrate this.

For simplicity, but with no loss of generality, the examples will deal with finding solutions of a first-order differential equation, i.e., equation (13).

(i) *The trapezoidal rule:* Here the definite integral is approximated by a trapezoid:

$$\int_t^{t+\delta} v(\tau)\,d\tau=\frac{\delta}{2}(v(t)+v(t+\delta)) \qquad (19)$$

Thus, the relation between the input v and the output x of the trapezoidal approximation to integration is

$$x(t+\delta)=x(t)+\frac{\delta}{2}(v(t)+v(t+\delta)) \qquad (20)$$

A system block diagram of the system characterized by equation (20) is shown in Figure 8. The difficulty with this system is that although it provides x(t) as an output, it requires v(t+δ) as an input; v(t) should be the input if this discrete system is to be used as a substitution for integration. This difficulty can be resolved by introducing a time shift in the original continuous system which is to be discretized for computational purposes. For example, the continuous system shown in Figure 5 can be relabeled with the necessary time shift as shown in Figure 9. With such a time shift we can consider using a discrete approximation to an integrator with input v(t+δ) and output x(t+δ). Such a subsystem is easily achieved with the trapezoidal approximation to integration of Figure 8 simply by considering the output to be the input of the rightmost delay element (i.e., x(t+δ) rather than the output of that delay (i.e., rather than x(t)). Figure 10 shows this rearranging.

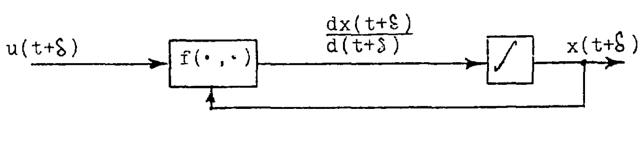

Figure 9—Time-shifted system block diagram for system of Figure 3

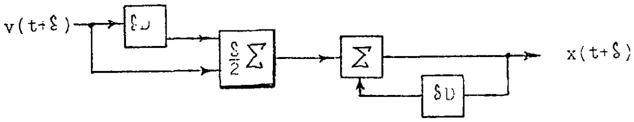

Figure 10—System block diagram for trapezoidal integrator (Figure 8) redrawn to show x(t=δ) as the output

It can be seen that with v(t+δ) as the input and x(t+δ) as the output, the trapezoidal approximation to integration has a static through path. Substituting the trapezoidal integrator into the time-shifted original continuous system results in a discrete system with one static loop (Figure 11) which in turn results in implicit difference equations.

Note that two delay elements are used in the approximation to one integrator. Thus, two initial values are required for the resulting discrete system and the single initial value provided for the first-order continuous system is not sufficient to provide a unique solution for the approximating discrete system. For example, if the discrete process is started at t = −δ, one must have the two initial values f(x(0),u(0)) and x(0). In this case, computing the initial value f(x(0), u(0)) from the original initial value x(0) and the initial value of the input u(0) is relatively straightforward. However, in a systems sense, the time shift from t to t+δ is a severe modification. As a result of the time shift, the discrete system operates in *future time* (i.e., at time t, the system requires input u(t+δ)). If such an approximating system were required to operate in *real time*, then the time shift would represent an impossible realization. Of course one may decide to use the system, which as an interconnection of elements is realizable, in real time nevertheless. This implies shifting time back again from t+δ to t and starting the process at t=0. The difficulty with this is that the initial values required now are x(δ) and f(x(δ),u(δ)) which, of course, are not generally known at time t.

(ii) *Runge-Kutta methods:* The Runge-Kutta methods are based on computing x(t+δ) as a perturbation of x(t) by approximating the terms in a truncated Taylor series with comparable terms which do not involve derivatives. The Runge-Kutta methods are typically given as a means to approximating solutions to the class of differential equations defined by equation (18) (i.e., the special case of equation (1) where u(t)=t). Although this is not the class of primary interest in system theory, let us present the systems implications of the method in its normal context. We will consider modifying it later.

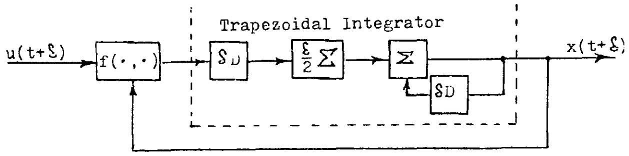

Figure 11—Discrete approximation to system of Figure 3 using a trapezoidal integrator

Perhaps the most widely used Runge-Kutta method is of order four:[4]

$$x(t+\delta)=x(t)+\frac{\delta}{6}(k_1+2k_2+2k_3+k_4) \tag{22}$$

where

$$\begin{aligned} k_1&=f(x(t),u(t)) \\ k_2&=f\left(x(t)+\frac{\delta}{2}k_1,\ t+\frac{\delta}{2}\right) \\ k_3&=f\left(x(t)+\frac{\delta}{2}k_2,\ t+\frac{\delta}{2}\right) \\ k_4&=f(x(t)+\delta k_3,\ t+\delta) \end{aligned} \tag{23}$$

Thus, in this Runge-Kutta method, integration is approximated as follows:

$$\int_t^{t+\delta} x(\tau)\, d\tau=\frac{\delta}{6}(k_1+2k_2+2k_3+k_4) \tag{24}$$

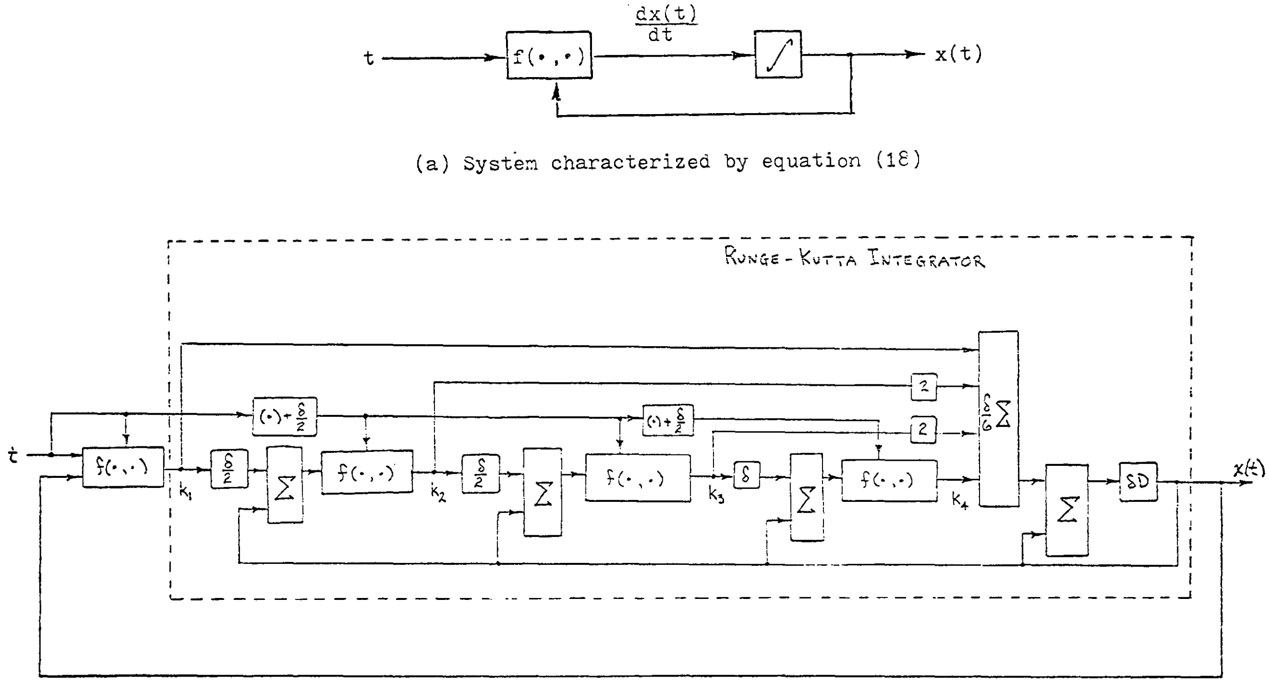
Figure 12 shows the original continuous system and the Runge-Kutta discrete approximation to it. It is noteworthy that:

(i) the Runge-Kutta integrator has only one delay element and no static loops or static through paths. Thus, only one initial value is required and, if the original continuous system contains no static loops, the resulting discrete system contains no static loops and an explicit set of difference equations results.

(ii) the Runge-Kutta integrator depends on the function f, unlike the Euler and trapezoidal integrators considered earlier. Thus, the Runge-Kutta integrator is *adaptive* in the sense that the integration process varies as a function of the signal being integrated.

(iii) the values of $t+\frac{\delta}{2}$ and t+δ are obtained in the system simply by adding $\frac{\delta}{2}$ and δ to t, respectively.

The point to the seemingly trivial observation (iii) is that static components are used to obtain future values of time. In particular, the computation of x(t+δ) $\left(\text{for the subsequent evaluation of } f\left(x(t)+\frac{\delta}{2}k_i,\ t+\frac{\delta}{2}\right),\ i=1,2, \text{ and } f(x(t)+\delta k_3,\ t+\delta)\right)$ does not require the knowledge of any function of time for values of time greater than t. In trying to use this Runge-Kutta method for finding the solutions of equation (1) (u(t)≠t), one is faced with evaluating $f\left(x(t)+\frac{\delta}{2}k_i,\ u\left(t+\frac{\delta}{2}\right)\right)$, i=1,2, and f(x(t)+δ, u



(a) System characterized by equation (18)

Figure 12—A continuous system and its Runge-Kutta discretization

(t+δ)). This means that at the time x(t+δ) is computed, the input u must be known for times $t+\frac{\delta}{2}$ and t+δ as well as for time t. Thus, if a real-time continuous system starts at time t=0, the corresponding real-time Runge-Kutta discrete system cannot start until time t=δ, at which time the values u(0), u $\frac{\delta}{2}$, and u(δ) are available, in addition to the original initial condition x(0).

IMPLICIT METHODS (THE PREDICTOR-CORRECTOR)

The class of predictor-corrector methods for solving differential equations provides an excellent example of how an implicit method can sometimes be utilized in numerical analysis. In this section the typical predictor-corrector is defined. The system-theoretic implications of the predictor-corrector integrator are noted. In particular, the predictor-corrector approach to the analysis of discrete systems with static loops is examined.

The predictor-corrector method is perhaps best introduced with respect to finding solutions of the no-input, time-invariant, one-variable system characterized by

$$\frac{dx(t)}{dt}=f(x(t)) \qquad (25)$$

Since some of the more accurate numerical integration methods, such as the trapezoidal method, are implicit methods (i.e., x(t+δ) is used in the computation of x(t+δ)), one may be forced to decide between computational expediency and computational accuracy. In spite of the computational difficulties associated with static loops encountered in using implicit methods, one may still decide to use them.

Most commonly used implicit methods can be represented by the following difference equation:

$$x(t+\delta)=x(t)+c(f(x(t+\delta)),f(x(t)),\ldots,f(x(t-k\delta))) \qquad (26)$$

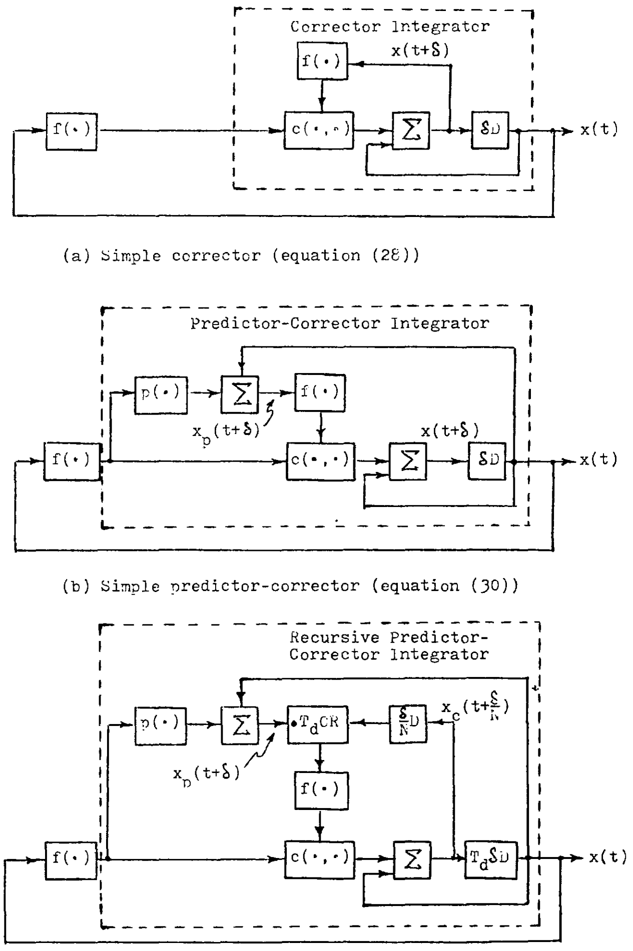
where x(t+δ), x(t), and the last k values of x are used to compute x(t+δ). Thus the function c provides the approximation to integration; it is called the *corrector*. If the trapezoidal method is used to solve equation (25), the result, in a form corresponding to that of equation (26), is

$$x(t+\delta)=x(t)+\frac{\delta}{2}(f(x(t+\delta))+f(x(t))) \qquad (27)$$

To simplify what follows, but with no loss of generality, consider a corrector which depends only on x(t+δ) and x(t) (e.g., that of the trapezoidal method):

$$x(t+\delta)=x(t)+c(f(x(t+\delta)),f(x(t))) \qquad (28)$$

Figure 13a shows a block diagram corresponding to the simple corrector system of equation (28). Note that a static loop exists in the corrector integrator.



(a) Simple corrector (equation (28))

(b) Simple predictor-corrector (equation (30))

(c) Simple recursive predictor-corrector (equation (33))

Figure 13—Corrector and predictor-corrector discretizations

The essence of the predictor-corrector method lies in the approach used to eliminate the static loop in the corrector integrator. An approximation to $x(t+\delta)$ is used in the corrector function c rather than $x(t+\delta)$ itself (which causes the static loop). The approximation to $x(t+\delta)$, $x_p(t+\delta)$, is obtained by using an explicit method requiring only $x(t)$ and the last k values of x:

$$x_p(t+\delta)=x(t)+p(f(x(t)),f(x(t-\delta)),\ldots,f(x(t-k\delta))) \qquad (29)$$

The function p used to anticipate the value of $x(t+\delta)$ for use in the corrector is called the *predictor*. For example, one might use the trapezoidal integrator as a corrector (equation (27)) and the Euler integrator $(x(t+\delta)=x(t)+\delta f(x(t)))$ as a predictor. Again, for simplicity, consider a predictor which depends only on $x(t)$ (e.g., that of the Euler method):

$$x_p(t+\delta)=x(t)+p(f(x(t))) \qquad (30)$$

Figure 13b shows a block diagram corresponding to the simple predictor-corrector system defined by equations (28) and (30). Note the predictor-corrector integrator has no static loops or static through paths.

For the case that a predictor-corrector method is to be used for a continuous system with an arbitrary input (i.e., equation (13)), the situation is again more complicated. Specifically, in real-time situations where a time-shifted system is not tolerable, one is faced with the problem of having to predict at time t the value of input $u(t+\delta)$, as well as the value of $x(t+\delta)$. In theory, since nothing is known about the exogenous system generating the input u, such a prediction is not possible. Practically, however, if the input u is not a totally random signal and δ is not too large, some method of extrapolation using past values of u might be used to predict $u(t+\delta)$.

The predictor-corrector configuration is also frequently used as the basis for an iterative scheme in which the predictor provides the first approximation to $x(t+\delta)$ and then the corrector, starting with the predictor's value, is used to iteratively generate a sequence of subsequent approximations to $x(t+\delta)$. The final value of this sequence of approximations to $x(t+\delta)$ is then taken to be the best approximation. The iterative scheme for generating the sequence of approximations to $x(t+\delta)$, for the simple predictor-corrector defined by equations (28) and (30), is as follows:

$$\begin{aligned}
x^{(1)}(t+\delta)&=x(t)+p(f(x(t)))\\
x^{(2)}(t+\delta)&=x(t)+c(f(x^{(1)}(t+\delta)),f(x(t)))\\
x^{(3)}(t+\delta)&=x(t)+c(f(x^{(2)}(t+\delta)),f(x(t)))\\
&\vdots \qquad\qquad\qquad\qquad\qquad\qquad (31)\\
x^{(N-1)}(t+\delta)&=x(t)+c(f(x^{(N-2)}(t+\delta)),f(x(t)))\\
x(t+\delta)&=x(t)+c(f(x^{(N-1)}(t+\delta)),f(x(t)))
\end{aligned}$$

The *lower-triangular form* of equations (31) is sufficient to assure that the system block diagram corresponding to this set of equations can be constructed so as to contain no static loops. However, an alternate representation, resulting in a significantly smaller block diagram, can be obtained by defining a new time set T_d' such that

$$T_d'=\left\{t_0, t_0+\frac{\delta}{N}, t_0+2\frac{\delta}{N}, \ldots, t_0+\delta, t_0+\delta+\frac{\delta}{N}, \ldots, t_f\right\} \qquad (32)$$

Note that $T_d \subset T_d'$. With respect to the new time set T_d' we write the following set of difference equations:

$$x_c\left(t+\frac{\delta}{N}\right)=x(t)+\begin{cases}c(f(x(t)+p(f(x(t)))),\\ \quad f(x(t))),\ t\epsilon T_d\\ c(f(x_c(t)),f(x(t))),\ t\notin T_d\end{cases}$$

$$(33)$$

$$x\left(t+\frac{\delta}{N}\right)=\begin{cases}c(f(x(t)+p(f(x(t)))),\\ \quad f(x(t))),\ t\epsilon T_d\\ x(t),\ t\notin T_d\end{cases}$$

where $x_c\left(t+\frac{\delta}{N}\right)$ is the corrector estimate of $x(t+\delta)$.

Figure 13c shows the system block diagram corresponding to equations (33). Note the subsequence $\{x(t_o), x(t_o+\delta), x(t_o+2\delta), \ldots, x(t_f)\}$, corresponding to the time set T_d, obtained from the output sequence of this system defined on time set T_d', is the same sequence one would obtain from the iterative predictor-corrector scheme defined by equations (31).

It is significant that an iterative scheme used to solve the nonlinear algebraic equations resulting from the existence of static loops in a discrete dynamic system corresponds to another dynamic system with no static loops. In essence, then, the static loop of the corrector system is eliminated by inserting a $\frac{\delta}{N}$ delay within it. To complete the iterative scheme, sufficient logic must be added to initiate the iterative scheme with the predictor estimate of $x(t+\delta)$ for every t such that $t \notin T_d$ and to assure that on this new time set, T_d', $x(t)$ changes only for times t such that $t \in T_d$. In Figure 13c this logic is conveniently achieved using the time-varying static element, the T_dOR, and the time-varying dynamic element, the T_d delay.

The T_dOR is a two-input (v_1 and v_2), single-output (v) static element defined such that if the *dot input* (i.e., the input associated with the arrow pointing to the dot) is v_1, then

$$v = \begin{cases} v_1, & t \notin T_d \\ v_2, & \text{otherwise} \end{cases}$$

In Figure 13c it is seen that a T_dOR is used to decide whethe̊r the predictor estimate of $x(t+\delta)$ or the corrector's own previous estimate of $x(t+\delta)$ is to be used in the corrector.

The T_d delay is a subsystem which is used to replace the δ delays in the original corrector system (defined on the time set T_d—Figure 13a). The T_d delay is, in effect, a δ delay defined on the new time set T_d'. The T_d delay with input v and output x is defined as follows:

$$x(t+\delta) = \begin{cases} v(t), & t \in T_d \\ x(t), & t \notin T_d \end{cases}$$

Figure 14 shows how a T_d delay can be realized using a T_dOR and two $\frac{\delta}{N}$ delays.

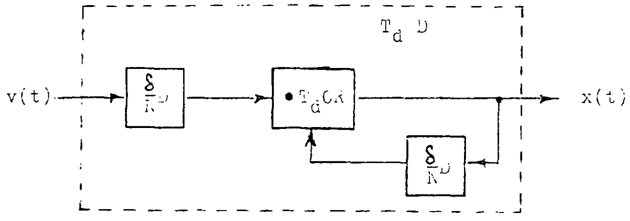


Figure 14—A realization of a T_d delay

Note there are three $\frac{\delta}{N}$ delays in the predictor-corrector recursive system shown in Figure 13c (two are within the T_d delay and thus not shown explicitly in the figure). The initial value of the $\frac{\delta}{N}$ delay within the T_d delay which provides the input to the T_dOR must be set to the same initial value given for the state variable x of the original continuous system (i.e., set to x_o); the initial values of the remaining two $\frac{\delta}{N}$ delays can be set to any values.

CONCLUSIONS

This paper presents a system-theoretic analysis of numerical methods used in approximating solutions of ordinary differential equations. By representing ordinary differential equations by system block diagrams (i.e., interconnections of static elements and integrators), a numerical method can be viewed as a process in which the integrators of a continuous system are replaced by discrete approximations to integrators (i.e., by discrete subsystems made up of interconnections of static elements and delays). Of special concern are questions concerning existence, uniqueness, and computability by digital computer of the solutions of the resulting difference equations which characterize the discrete system approximating the original continuous system.

A study is made of the properties of the system block diagrams characterizing canonical state-variable differential and difference equations. It is noted that proper interconnections of delays and static elements (i.e., discrete interconnections with no static loops) can always be characterized by explicit difference equations. Thus, a proper interconnection represents a computationally attractive form and as such is a goal in devising a numerical method. The main result of the paper establishes that if the system block diagram corresponding to the original differential equation has no static loops and if the discrete subsystems used to replace the integrators have no static loops and no static through paths, then the resulting discrete system has no static loops (and can thus be characterized by explicit difference equations).

With the main result in hand, a system-theoretic study is conducted of several of the more commonly used numerical methods: the Euler, trapezoidal, Runge-Kutta, and predictor-corrector methods. For each of these methods the discrete subsystem used to replace the integrators of the continuous system is detailed. The limitations of using these numerical methods in real-time analysis are examined, particularly with respect to the problem often encountered in which inputs must be anticipated. The system-theoretic implications of using the iterative predictor-corrector scheme are examined.

Memory conserving efficient methods for solving large sets of stiff differential equations

by GRUIA-CATALIN ROMAN, DAVID GARFINKEL and CARL B. MARBACH
University of Pennsylvania
Philadelphia, Pennsylvania

ABSTRACT

Solution of large systems of stiff differential equations by the most widely used method, that of Gear, is limited by its requirement for the presence in memory of a Jacobian matrix, which may become intolerably large. Methods of alleviating this situation, believed to be broadly applicable, have been worked out with large metabolic models. One general tactic is to remove from the set of differential equations elements which can be represented instead by algebraic equations: rate equations for enzymes and equilibrium relations for very rapid reactions. Another general tactic is to store efficiently only a part of the sparse Jacobian matrix containing the non-zero elements, which requires the presence of a preprocessor, using algorithms which are given in the paper. The Jacobian matrix may sometimes be represented by a diagonal approximation; this works better with the algebraic methods. Examples of the savings are given. These methods have been incorporated into BIOSSIM, a machine-independent simulation language designed for large biological systems, and in our hands have considerably reduced the cost and difficulty of solving large systems of stiff differential equations.

Methods of solving "stiff" differential equations have received considerable attention within the last few years, and important improvements have recently been made.[1] The most important of these is the predictor-corrector method of Gear.[2] This appears to be the most widely used "stiff" differential equation solver, and is widely considered to be the best one. This implicit method requires that the Jacobian matrix of the differential equation variables be present in core memory. Unfortunately the size of this matrix can become intolerably large when modeling complex systems. We describe here an economical method of computing the behavior of large systems based largely on modifications of Gear's method, which we have thus far applied to biochemical systems. The most important such modification requires the presence in memory only of the non-zero elements of the Jacobian matrix, usually a small part of the total for the systems we have worked with.

Biological systems are often inherently quite complicated. Accurate representation of such systems in terms of differential equations ordinarily results in "stiffness"; this is widely believed to hold true for natural systems generally. A common problem in simulating them is that simplification for the sake of mathematical tractability often leads to biologically unrealistic results. Representing a system in terms of n differential equations (where often $n > 100$) may lead to the following serious dilemma:

(1) n must be large enough for biological realism;
(2) n^2 (the size of the Jacobian matrix) must be small enough for available core memory.

The methods we have developed reduce core memory requirements to a practical range and also save computer time. While they are based on the structure of the biological systems which we have investigated, the methods can be extended in varying degree to other complex systems of stiff differential equations.

We have used two main approaches:

(1) Replace some of the differential equations with algebraic equivalents when this is possible.
(2) Reduce the number of elements of the Jacobian matrix required to be stored in memory for the Gear method to solve the remaining differential equations.

While these two approaches can be combined for a given system, as exemplified later, they are described separately in the two following sections.

SUBSTITUTION OF ALGEBRAIC RELATIONSHIPS

The general approach employed is to separate out from the total system those components whose behavior can be calculated by algebraic equations rather than differential equations, thus greatly reducing the number and possibly the "stiffness" of the latter.

In metabolic models enzyme mechanisms and reactions at equilibrium can be separated out and dealt with by specialized algebraic means:

(1) Individual enzyme behavior in a complex model can be represented by an algebraic rate law[3] which can be determined by standard systems analysis procedures.[4] The differential equations for these enzyme forms are converted to explicit algebraic equations. The concentrations of the enzyme forms and the rate at which the enzyme reactions go are calculated by matrix inversion.[5] Only the small molecules involved need be represented by differential equations. The saving of CPU time and memory is indicated by the last two columns of Table 1, although a little space is required for the algebraic equations.

(2) Some chemical reactions (e.g., inorganic chelations) are very rapid compared to others in the model and can be represented as always being at equilibrium. Techniques for calculating these equilibria, which have existed for some time[6] have been adapted for joint use with differential equations solving[7,8] and incorporated into the program described here. As these reactions (here referred to as "fast reactions") are the ones with the fastest time constants, removing them from the system of differential equations reduces the "stiffness".

The differential equations which remain after the above elements have been separated out are then solved by the Gear method. The efficiency of Gear's differential equation solver is independent of stiffness over a wide range of stiffness, although we have been able to slow it down by making the equations very stiff. However, if a diagonalized approximation is used[9, 10] for the Jacobian matrix in Gear's method, the sensitivity to stiffness appears to increase considerably. Separating out the fast reactions alleviates this situation by reducing the stiffness. The diagonalized approximation may also be aided by the fact that the elements removed from the Jacobian matrix in this process are commonly off-diagonal elements as well as being the (absolutely) largest ones.

MODIFICATION OF THE GEAR METHOD

In the course of considerable experimentation with various versions of the Gear method we found it to be more than satisfactory. We made efforts to improve its performance by reducing its execution time as well as the space requirements. These changes can be considered "tuning" of the Gear method, which speeded things by 10-15 percent. Analysis of the program's behavior revealed that a large percentage of the differential equation solving time is spent in solving a linear system of equations of the form:

$$X * J = B \tag{1}$$

where J is the Jacobian or partial derivative matrix mentioned above. Furthermore the *size* of the J is the factor determining the time spent in finding the solution for X, and reducing the size of J will reduce execution time as well as space requirements.

It is a fortunate situation that the Jacobian matrix for biological models representing metabolic systems is normally quite sparse, so that sparse-matrix techniques are applicable. These were applied by Curtis and Chance in the CHECK and CHECKMAT program.[11] It is possible to go further because the sparseness is structured so that most of the non-zero elements of the matrix are near the main diagonal, as shown in Figure 1. Furthermore, the non-zero elements which are not near the main diagonal may also have a structure which can be exploited; this is in fact done by the removal of fast reactions described in the preceding section. It would be desirable to eliminate the zero elements of the sparse Jacobian matrix from storage in the most efficient way. However, this could not be achieved initially due to the method used by Gear to solve the linear system—backward decomposition with partial pivoting. The pivoting is dependent upon the value of the elements of J at each given point. This makes it impossible to predict how the sparseness of J is changed by the decomposition algorithm. On the other hand, we discovered that the partial pivoting made little difference in the behavior of the Gear's method and could be replaced by a simpler backward decomposition procedure. Once pivoting is eliminated, predicting the effect of the decomposition upon the sparseness of J becomes possible.

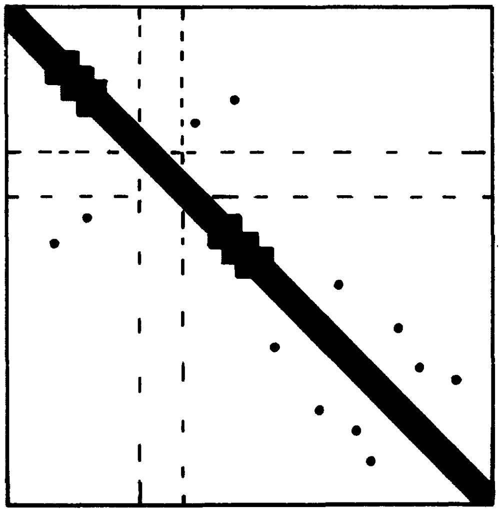

Figure 1—Typical sparseness pattern of the Jacobian matrix representing a metabolic system (non-zero elements are indicated in black)

PROCEDURE FOR SPARSE MATRICES

The sparseness prediction algorithm is:

1. $i=1$ (*the sparseness of the first row will never be altered* by the decomposition process).
2. $i=i+1$ and $j=1$ (consider the next row).
3. if $i>N$ go to step 9 (if all N rows of the Jacobian J have been analyzed, exit the loop).
4. increment j until the next non-zero element is encountered (all zero elements skipped so far on the row i will always remain zero).
5. if $i=j$ go to step 2, (*the sparseness of row i was determined*).
6. if $j>i$ stop—the matrix J is not a Jacobian.
7. all elements $J(i, t)$ for which $t>j$ and $J(j, t) \neq 0$ will be marked as non-zero, unless they are already marked as such.
8. go to step 4.
9. the algorithm stops:
   all elements of J which have not been marked as non-zero will in no circumstances become non-zero as a result of the decomposition process. The decomposition algorithm will be described below.

Example: application of the sparseness prediction algorithm to a sample Jacobian. In the following, '*' will indicate original non-zero elements, while a '+' will signify that the given element was marked as non-zero during the application of the algorithm. All elements left unmarked by the sparseness prediction algorithm need not be present in core during the integration process.

row 1	row 2	row 3	row 4	row 5
*0*0*	*0*0*	*0*0*	*0*0*	*0*0*
	0*0*0	0*0*0	0*0*0	0*0*0
0*0*0		*0*0+	*0*0+	*0*0+
*0*00	*0*00		00**+	00**+
00**0	00**0	00**0		0*0+*
0*00*	0*00*	0*00*	0*00*	

Subsequently, the sparseness prediction algorithm is used to create two arrays WI and WJ. For each non-zero element in J an entry (indicating the column number of the non-zero element) is made in WJ. All entries in WJ are ordered by rows and the elements in each row ordered in increasing order (by column numbers). Furthermore, for each row a pointer in array WI is set to indicate its beginning (e.g., the column of the first non-zero element of row i is given by WJ(WI(i))). An additional pointer binds the last row. In the case of the Jacobian used in the previous example, the arrays WI and WJ take the following form:

WI: 1 4 6 9 12 15
WJ: 135 24 135 345 245

The preprocessor will pass to the simulator not only the dimensions of WI, WJ, and WPW (the Jacobian dimensioned to the same size as WJ), but also the content of WI and WJ.

The saving of memory space resulting from this process becomes more significant in the case of our implementation, described below, which is composed of two programs: a preprocessor (called the generator), and the simulator program which actually solves the differential equations. The generator receives as input the set of chemical reactions to be represented by a set of differential equations and, on analyzing it, dimensions the simulator's arrays to the exact length required by the specific system. It then derives the set of differential equations themselves, following which the task of determining the initial sparseness of the Jacobian becomes trivial.

Whenever required, the simulator will compute the values of the Jacobian elements and store them in the appropriate locations of WPW. The following decomposition routine will replace WPW by a triangular matrix (stored in the upper corner of the Jacobian) and a triangular multiplication factor matrix (stored in the lower side of the Jacobian). The decomposition algorithm is quite similar to the sparseness prediction algorithm since the latter mimicks the actions of the former (N is the number of variables involved; J is the conceptual Jacobian, not to be identified with its program implementation WPW):

1. $i=1$ (the first row is unchanged).
2. $i=i+1$ and $p=0$ (consider the next row).
3. if $i>N$ go to step 9 (the triangularization is complete).
4. find next non-zero element on row i: $J(i, j) \neq 0$, i.e., repeat $j=WJ(WI(i+p))$ and $p=p+1$ until $WPW(WI(i+p)) \neq 0$ (note that j steps over the elements which are known to be zero).
5. if $i=j$ go to step 2.
6. if $j>i$ stop—programming error.
7. (a) set $J(i,j)=K$ (i.e., $WPW\ (WI(i+p))=K$) where $K=-J(i,j)/J(j,j)$.
   (b) add row j to row i starting with the column $j+1$.
8. go to step 4.
9. stop—algorithm is completed.

By using the result of this decomposition routine, the solution routine will compute the value of the unknowns of the equation (1) for each given B.

In accordance with our expectation, the predictive sparseness method resulted not only in substantial savings in core but also in a significant improvement in the speed of Gear's method: the time required to solve the differential equation system decreased considerably. The advantages resulting from this method become more important with increasing system size. To our knowledge, the only other successful research of this type resulted in a (DEC-10) machine-dependent program (M. Pring, to be published) which is not yet available for consultation.

The predictive sparseness method is the last of a large series of experimental methods which unfortunately could not pass our acceptance criteria—they had to prove themselves faster than the regular Gear method. In our first attempt, we tried to use a variation of Gear's method where the Jacobian is replaced by a diagonal approximation, and this was excessively slow for large stiff systems and suffered a loss in accuracy when the same relative error parameter was used. We also tried a new version of Gear's package, GEARB[10] which replaced the Jacobian by a diagonal band of chosen width. Since most of our systems involve Jacobians which are concentrated around the diagonal (Figure 1), the chances of success seemed good. Furthermore, our experiments showed improvements in the execution speed when the Jacobian indeed had all the non-zero elements inside such a band. However, the method was rejected on further testing, which revealed that as soon as elements outside the band became slightly significant the behavior of the program is adversely affected.

A second group of experiments followed in an attempt to use a Gauss-Seidel iteration procedure to solve the set of linear equations (1). In the belief that the slowdown encountered in the previous cases was due to a poor approximation of the Jacobian, we attempted to use the solution given by the diagonal band as a starting point for the iteration process. However, the convergence was much too slow, especially for large systems.

POSSIBLE ALTERNATIVE METHODS

As mentioned before, the predictive sparseness method gives good results and the larger the number of differential equations, the greater the improvements appear to be. However, alternative differential equation solving methods are available to the user of our program: Euler, regular Gear, or Gear with the Jacobian replaced by a diagonal approximation. All of these methods may also be combined with the fast reaction method mentioned above.

The Euler method is rarely used to integrate stiff differential equations, but past experience has shown it to work as well—or as badly—as the more sophisticated non-stiff methods when faced with a stiff system. Since decreasing stiffness improves the behavior of Euler, it may sometimes be used in conjunction with the fast reaction method; if the latter greatly reduces the degree of stiffness, this combined method will give an accurate solution in a reasonable time for systems where Euler alone would fail. Since the Gear method is "slow-starting" the Euler method is at a relative advantage for short-time calculations, as seen in the first two columns of Table 1 (the second column includes editing time, the first does not).

TABLE 1

Computing times to solve three different test systems on the PDP-10 computer. Except for the first column, these include a considerable computer expenditure for graphing and tabulating the solutions. The programs involved are all in FORTRAN except for the ones to algebraically handle enzymes, which are in assembly language (here the advantage in speed over FORTRAN is particularly great). J is Jacobian size (unaffected by fast reactions).

Test Systems

Size	N=9		N=65	N=66
Description	No fast reactions, no enzymes, not very stiff		No fast reactions, not very stiff, enzymes represented by differential equations	Fast reactions, enzymes represented algebraically
Method of Solution	time=1500	time=15		
Euler with fast reactions	29.3 sec J=0	15.5 sec J=0		67.9 sec J=0
Gear diagonal approximation	26.1 sec J=9	15.9 sec J=9		unworkable —
with fast reactions				18.6 sec J=20
Regular Gear	8.8 sec J=81	24.5 sec J=81	12 min 25.9 sec J=4096	22.2 sec J=400
with fast reactions				41.4 sec J=400
Gear-predictive sparseness	6.6 sec J=34	20.8 sec J=34	6 min 43.3 sec J=1715	17.0 sec J=47
with fast reactions				40.8 sec J=47

The diagonal approximation of the Jacobian suffers from many of the same weaknesses as Euler, but to a lesser degree. However, when *properly* combined with the fast reaction method, surprisingly enough, it is faster than the regular Gear method, for some medium-sized systems tested. This is very significant when we think that only N locations are needed for the Jacobian in place of N*N. This method is still under investigation, but we do not hope for equally good results with larger systems. Moreover, the fast reaction method has applicability restrictions (e.g., it requires a clean distinction between fast and non-fast reactions) which make it unsuitable in many cases.

The predictive sparseness method will not work where the user interferes with the derivative evaluation routine (written by the preprocessor) by inserting additional (FORTRAN) coding and artificially creating partial derivatives of significant size, which cannot be predicted since they are not derived from the original differential equations. The unmodified Gear method does work in this situation.

A short comparative study of the various methods available in the system is summarized in Table 1 (CPU time for integration and the size of core used for the Jacobian).

DEPENDENCE ON WORDLENGTH

During our investigations[12] we were able to run our program on three different machines, the Control Data 6400, the IBM 370/165, and the Digital Equipment PDP-10 (with which the bulk of the work was done). We were investigating the effect of wordlength of the accuracy and number of calculations required to solve a test problem. As expected, the 32 bit processor (IBM) gave slightly less precision and performed more calculations in reaching a solution than did the PDP-10. Surprisingly the 6400 (60 bits) performed even more calculations than did the 32 bit IBM 370. Further investigation showed that a minimum number of calculations occurred at wordlengths of 36 to 40 bits.

Since the Jacobian is formed by numerical differencing within the Gear program, increased wordlength will lead to some elements being very small but finite where shorter wordlength would result in such elements being set to zero. If too many are set to zero, accuracy can be lost in forming the Jacobian, thus requiring more evaluations for convergence. If too few are set to zero, there should be no problem. The pivoting strategy used in the matrix decomposition routine in the original Gear program employed no scaling, so that these small elements affected the pivot with a similar loss in accuracy causing additional matrix evaluations. An earlier version with scaling did not demonstrate this phenomenon. Since our latest method does not employ pivoting, the problem has been eliminated. This is mentioned here because this result is so unexpected: increased wordlength is generally believed to improve the efficiency of matrix computations.

IMPLEMENTATION IN A SIMULATION LANGUAGE: BIOSSIM

Application of these methods of handling the Gear matrix necessarily requires a preprocessor of some kind to determine what non-zero derivatives are possible in the Jacobian matrix and to construct pointers for them. We have combined the Gear method into a machine-independent two-pass language biochemical simulation language which we have been using for some time.[13] This language which writes and solves differential equations can perform the necessary operations in its first pass. Our research into methods for solving stiff differential equations grew out of the need to make this language more efficient. It has otherwise been updated considerably, and a report of this will be submitted elsewhere. A most important aspect of this updating is that the program implementing the language have been "structured" to permit modification by the user.[14] Given the capability of such modification and the ability to write as well as solve ordinary differential equations, this language can probably be applied to systems of equations far removed from those for which it was designed. It has already been used for problems which are more nearly physiological than chemical in their definition and for ecological problems. As communication about such usages would be considerably facilitated by having an acronym for the language, we have named it BIOSSIM (for BIOlogical Structured SIMulator).

The ability to solve large numbers of stiff differential equations is expected to considerably assist the study of biological systems by mathematical means, because the equations can be sufficiently complex to meet the need for realism. It has been difficult to develop such computer models in the past because of the cost of computer time, and the unfavorable running restrictions (e.g., nighttime access only, because of the large core requirement). There is reason to hope that the biological models that are feasible to compute with the methods here described will be realistic enough to be of value for clinical and industrial applications.

The BIOSSIM program will be available, as its predecessors for some time have been, through the SHARE Program Library Agency (Library No. 360D-03.2.008), and possibly in other ways as well.

SUMMARY

A method of decreasing both the running time and the core occupancy of the Gear stiff differential equation solver by "compacting" its large Jacobian matrix with a preprocessor and auxiliary programs is described. This may be further assisted by separating out appropriate subelements of a large set of stiff differential equations and treating them by algebraic methods instead. In our hands these methods have had a very large impact on the difficulty and cost of solving complex systems of stiff differential equations.

This project was supported by NIH grants GM 16501, HL 15622, and RR 15.

A geometric analysis of heuristic search

by GORDON J. VANDERBRUG
University of Maryland
College Park, Maryland

ABSTRACT

Search spaces for various types of problem representations can be represented in one quadrant of the coordinate planes. This geometric representation is used to prove some formal properties of heuristic search strategies involving completeness, admissibility, optimality, consistency, and the use of the perfect heuristic. The geometric analysis provides an intuitive alternative to the algebraic analysis which appears in the literature.

INTRODUCTION

To specify a state-space representation for a problem, one must specify a start state, the general structure of a state, a characterization of a goal state, and a set of operators which map states into states. To solve a problem using such a representation one successively applies operators to currently generated states to obtain new states until a goal state is generated. This process is called searching the search space (or state-space), and can be done in many different ways. The manner in which it is done is called a search strategy. The solution to the problem is the sequence of operators which transforms the start state into the generated goal state.

The graph model for searching a state-space is based on associating states in the representation with nodes of the graph, and operators of the representation with arcs of the graph. With this model we can view a state-space representation as an implicit definition of a graph. It defines a start node and procedures for generating other nodes of the graph.

A search strategy can be thought of as a process of making explicit part of this implicitly defined graph. In this paper we will be dealing with a frequently occurring class of search strategies called ordered search strategies. An ordered search strategy determines the manner in which the state-space is generated by assigning a merit ordering to the nodes. A merit ordering is a procedure for ranking the nodes. The search process occurs in stages, and at each state the merit ordering specifies which node is to be expanded (i.e., which node is to have its successor nodes generated by applying all applicable operators). An ordered search algorithm is presented in Figure 1. It is equivalent to the algorithms presented in Hart, Nilsson, and Raphael;[1] Pohl;[2] and Kowalski.[3]

Usually merit orderings are defined by evaluation functions. Evaluation functions use selected features of a state to assign it a number, and thus rank it relative to all the other states. One possible evaluation function assumes that the operators have associated costs, and assigns to each node the sum of the costs of the operators used to generate it. This evaluation function is usually denoted by g, and the search resulting from its use is called the uniform cost search strategy. In terms of the graph which represents the

  Exit with failure
```

Figure 1—An ordered search algorithm. S is the set of nodes which have been expanded, $\tilde{S}$ the set of nodes which are candidates for expansion, and $\Gamma(n)$ the finite set of successors of the node n. The algorithm forms a tree of the nodes in the problem space, with the nodes in $\tilde{S}$ at the tips of the tree. When the algorithm exits with success the solution path can be found by tracing the pointers from the goal node to the start node

state-space, the uniform cost strategy uses the cost of the path from the start node to the node n as the merit of n. Pure heuristic search uses and estimates, h(n), of the cost of a path from n to the nearest goal node as the merit of n. Frequently h(n) is based on the extent to which selected features of the node n differ from these same features of a goal node. This cost is frequently referred to as the distance from n to a goal. We will insist that $h(n)=0$ whenever n is a goal node. An ordered search strategy which uses an evaluation function $f(n)=g(n)+h(n)$, with both a cost and a heuristic component, is called diagonal search. Various weights on the cost and heuristic components can be achieved with the function $f(n)=(1-\omega)g(n)+\omega h(n)$, for $\omega\epsilon[0,1]$. $\omega=0$ and $\omega=1$ are uniform cost and pure heuristic search respectively; while $\omega=\frac{1}{2}$ is diagonal search, since the two evaluation functions, $\frac{1}{2}g(n)+\frac{1}{2}h(n)$ and $g(n)+h(n)$, define the same merit ordering.

DEFINITIONS

An ordered search strategy is said to be complete if whenever there exists a solution to the problem the strategy will find one. An admissible strategy is one which terminates with a minimum cost solution whenever one exists. The concept of optimality applies to strategies which are admissible and is defined as follows. Let h_1 and h_2 be two heuristic functions such that $h_2(n)<h_1(n)\leq h_p(n)$ for all nongoal nodes n, where h_p is a perfect heuristic function (the heuristic which gives the exact cost to the nearest goal). An admissible strategy is said to be optimal if searching with h_2 expands all of the nodes that searching with h_1 expands. Admissibility can be viewed as the optimality of the solution, whereas optimality is really the optimality of the search process.

In order to prove that ordered search strategies possess the above properties certain assumptions on the heuristic function and the graph of the search space must be made. A heuristic h satisfies the lower bound condition if $h(n)\leq h_p(n)$ for all n, where h_p is the perfect heuristic. A heuristic h is said to be consistent if any n and n′ such that there is a path from n to n′, $h(n)-h(n')\leq k(n,n')$, where k(n,n′) is the cost of the path from n to n′. The concept of a δ-graph will also be used in the theorems. We will define a δ-graph to be a graph which does not contain a path with an unbounded sequence of partial sums of arc costs.

GEOMETRIC REPRESENTATION

The proofs of the theorems in this section are geometrically-based proofs, in that they use a method of representing the search space in one quadrant of the coordinate plane. Each node n has a cost g(n) and a heuristic h(n) associated with it (for uniform cost search $h\equiv0$). Thus we can represent the node n at the point (i,j), where $i=h(n)$ and $j=g(n)$. This representation maps the entire search space into one quadrant of the plane (many nodes can be mapped into the same point, but this is of no consequence), and gives us the basis for geometrically describing the search process.

Figure 2 provides an example of the geometric representation of a search space. Note that the node n is represented at the point (h(n), g(n)), and that the h-axis extends horizontally to the right while the g-axis extends vertically downward. Since the g-component of any start node is zero, all start nodes lie on the h-axis. Similarly, all goal nodes lie on the g-axis since their h-components are zero. The nodes n_6 and n_7 could be placed in more than one position in the plane since there is more than one path from n_0 to each. In Figure 2 we have chosen the position which corresponds to the shortest path.

The heuristic used in Figure 2 satisfies the lower bound condition since it can be verified that the $h(n_i)$ is less than or equal to the distance between n_i and n_7 for $i=1,...,7$. However, this heuristic is not con-

Figure 2—An example of the coordinate representation of a search space

sistent since (for example) $h(n_1)-h(n_4)=5-2=3$, while $k(n_1,n_4)=2$.

Each choice of ω in $f_\omega=(1-\omega)g+\omega h$ determines the direction in which the space will be searched. Search with $\omega=\frac{1}{2}$ is called diagonal search because it defines all nodes which lie on the same diagonal to have equal merit and attempts to expand nodes in the direction indicated in Figure 3(a). Upwards diagonal search differs from diagonal in that node n has better merit than a node n′ iff $f(n)<f(n')$, or $h(n)<h(n')$ when $f(n)=f(n')$; and attempts to expand nodes in the same direction as diagonal search except that the search proceeds up successive diagonals as indicated in Figure 3(b). Figures 3(c)-3(f) illustrate the direction of search for various values of ω. If the distinction between the h-components is made for nodes with the same f-value as is done in upwards diagonal search, then along each line in these figures the search proceeds in the direction of the h-axis.

As the process of searching the space proceeds, the region of the quadrant which has been covered grows. As any stage of the search process all nodes which lie inside the covered region (including the boundary) can potentially be expanded. A node n lying inside such a region will be expanded if there is a path from the start node to n such that all the nodes on this path also lie within the region. Note that n lying within the region covered by the search is not sufficient reason for it to be expanded. Note also that a node which is expanded does not necessarily lie on the diagonal of the triangular region, but may lie strictly within the region.

An alternative to specifying an evaluation function in the form $f_\omega=(1-\omega)g+\omega h$ for $\omega\epsilon[0,1]$ is to use the form $f_\alpha=g+\alpha h$ for $\alpha\epsilon\ [0,\infty)$. Since scaling the evaluation function does not change the merit ordering defined by it, the relationship between these two forms is given by $\alpha=\omega/(1-\omega)$. For example, diagonal search is specified by setting either $\omega=\frac{1}{2}$ or $\alpha=1$ in these respective formulas.

When the first form is used, changes in the value of ω correspond most naturally to changing the direction of search as illustrated in Figure 3. However, the parameter α in the second form can be thought of as being part of the heuristic component of the evaluation function. When this is done, it is most natural to think in terms of the direction of search remaining diagonal, but all the nodes being moved either towards the g-axis if $\alpha<1$, or away from the g-axis if $\alpha>1$. Thus the above two forms point out the two ways in

which a change in an evaluation function can be viewed; either as a change in the direction of search or as a change in the position of the nodes. In this paper we will use the $f_\omega = (1-\omega)g+\omega h$ alternative.

THEOREMS

Now that we have explained the geometric representation of the search space, we turn to the statements and proofs of the theorems. The proofs of the theorems refer to the illustrations in Figure 4. The term search strategy will mean an ordered search strategy which uses the evaluation function $f_\omega = (1-\omega)g+\omega h$.

THEOREM 1. [Completeness] A search strategy is complete for all δ-graphs iff $\omega \epsilon [0,1)$.

PROOF: Assume that there is a solution, that is, a path from the start node s to a goal node t, and that $\omega \epsilon [0,1)$. Thus, the direction of search is not parallel to the g-axis (the case where $\omega = 1$). This case is illustrated in Figure 4(a). Suppose that the solution is not found. Then the search strategy never reached all of the nodes on the solution path because some region in the plane encountered by the search strategy contains an infinite number of nodes. Since $\omega \neq 1$, such a region must be either an infinite strip parallel to the h-axis (the case where $\omega = 0$), or an finite triangular region (the case where $0 < \omega < 1$). In either case, since some region contains an infinite number of nodes, there exists a path in the graph whose g-values are unbounded. A path of unbounded g-values is the only condition which can give rise to an infinite number of nodes in either a region parallel to the h-axis or a finite triangular region. However, a path of unbounded g-values is impossible because the graph is δ-finite. Hence, if $\omega \epsilon [0,1)$ then all the nodes along the path from s to t will eventually be expanded; that is the search strategy is complete.

Now suppose that $\omega = 1$. Then since there can be an infinite path in the graph whose h-values are bounded above, one of the infinite strips which are encountered by the search strategy before it covers all of the nodes from s to t can contain infinitely many nodes. Such a strip would prevent the search strategy from finding the solution. Thus search with $\omega = 1$ is incomplete.

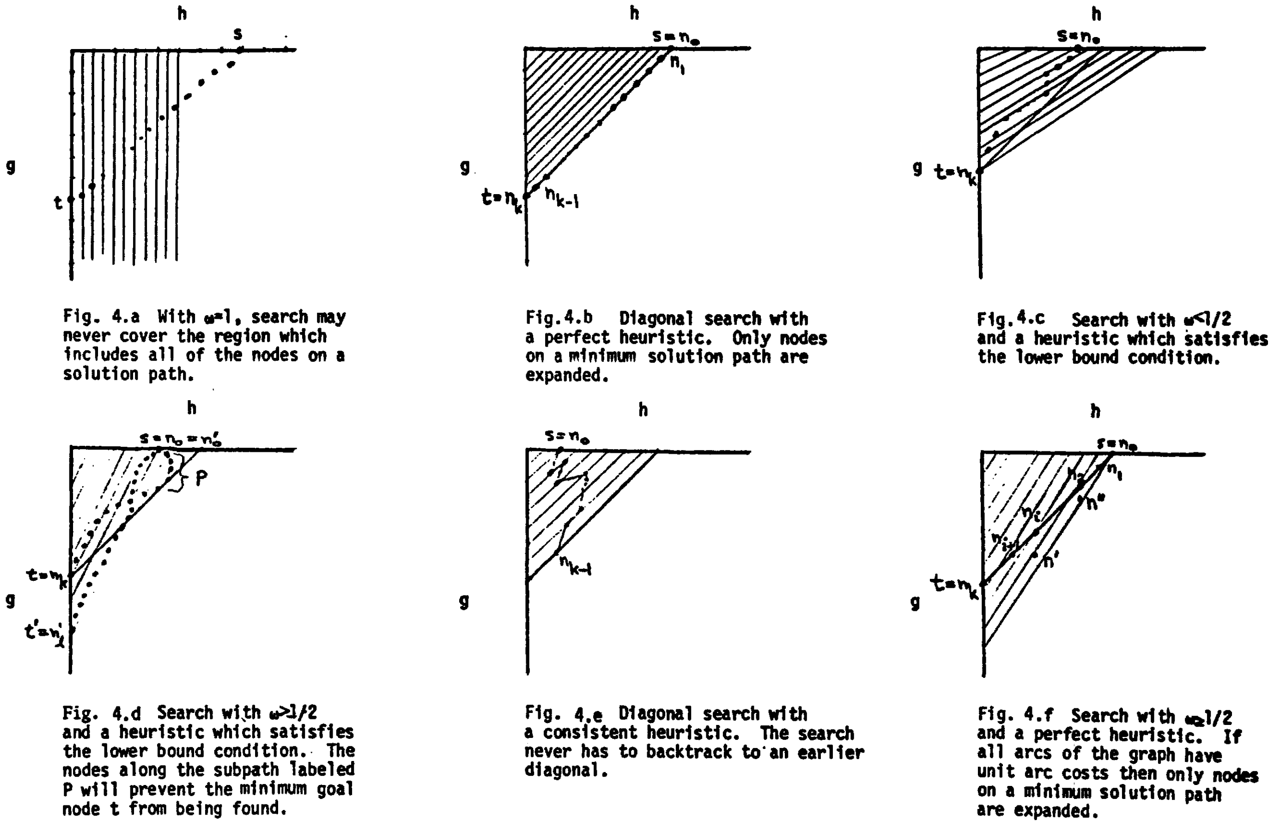

Fig. 4.a With $\omega=1$, search may never cover the region which includes all of the nodes on a solution path.

Fig. 4.b Diagonal search with a perfect heuristic. Only nodes on a minimum solution path are expanded.

Fig. 4.c Search with $\omega<1/2$ and a heuristic which satisfies the lower bound condition.

Fig. 4.d Search with $\omega>1/2$ and a heuristic which satisfies the lower bound condition. The nodes along the subpath labeled P will prevent the minimum goal node t from being found.

Fig. 4.e Diagonal search with a consistent heuristic. The search never has to backtrack to an earlier diagonal.

Fig. 4.f Search with $\omega\geq 1/2$ and a perfect heuristic. If all arcs of the graph have unit arc costs then only nodes on a minimum solution path are expanded.

Figure 4—Illustrations of different search strategies with various conditions on the heuristic. Although not explicitly shown in the figures, all modes which lie in a region of search and have ancestors forming a path back to the start node which also lie in the region of search are expanded

The admissibility theorem tells us the conditions under which the first solution found is a minimum cost solution.

THEOREM 2. [Admissibility] Let h satisfy the lower bound condition, $h \leq h_p$, where h_p is the perfect heuristic. Then search with h is admissible for δ-graphs iff, $\omega \epsilon [0,\frac{1}{2}]$.

PROOF: Let us begin by thinking in terms of the nodes positioned in the plane as defined by the perfect heuristic h_p. Since $g(n_i)+h_p(n_i)$ equals the minimum solution cost for each node n_i which is on a minimum solution path $s=n_0, \ldots, n_k=t$, all such n_i must lie on the minimum cost diagonal of the plane (see Figure 4(b)). Since $g(n')+h_p(n')$ is greater than the minimum solution cost for each node n' which does not lie on a minimum solution path, all such n' lie outside the triangular region defined by the minimum cost diagonal. Thus, no nodes lie within this triangular region. If the heuristic is not perfect, but does satisfy the lower bound condition, then the nodes $n_0, \ldots, n_k$ are all pulled to the left and lie in the triangular region (some may lie on the boundary). Thus, diagonal, upper diagonal, and any search with $\omega \geq \frac{1}{2}$ (see Figure 4(c)) will have expanded $n_0, \ldots, n_{k-1}$ by the time search reaches the location of the minimum goal node t, and therefore t will be found before any other goal node. Hence if $\omega \epsilon [0,\frac{1}{2}]$ the search is admissible.

However, if $\omega > \frac{1}{2}$ (see Figure 4(d)) the region covered by the search can include all of the nodes on a nonminimum path like $s-n_0', \ldots, n_l'=t'$ (and thus find a nonminimum solution), before it covers all of the nodes on the minimum path $s=n_0, \ldots, n_k$. In Figure 4(a) the nodes along the subpath (of the minimum solution path) labeled P lie outside the region which includes all of $s=n_0', \ldots, n_l'=t'$. These nodes (and all of the successors along the minimum path) will not be expanded, and the minimum goal node will not be found. Thus in $\omega \epsilon [0,\frac{1}{2}]$ the search is not admissible.

The optimality theorem tells us that for all of the values of ω which give admissible searches, the use of better heuristics will result in improved searches.

THEOREM 3. [Optimality] Let $\omega \epsilon [0,\frac{1}{2}]$, and $h_2 < h_1 \leq h_p$. Then search with h_2 expands every node expanded by search with h_1 for all δ-graphs that contain a minimum solution.

PROOF: Again let us begin with the nodes positioned in the plane for the perfect heuristic, where nodes on a minimum solution path lie on the minimum cost diagonal and all others lie outside the triangular region. Now think in terms of the movement of the nodes in the plane which results from using the heuristics h_1 and h_2 instead of h_p. Since $h_2 < h_1$, h_2 pulls all of the nodes into the triangular region which are pulled there by h_1, and others besides. Not all of the nodes which lie inside the triangular region will be expanded. Only those for which there exists a path back to a start node such that all of the nodes on this path also lie in the triangular region will be expanded. However, all of the nodes pulled in by h_1 that are expanded by h_1 will also be expanded by h_2, because those paths back to a start node whose nodes are placed in the triangular region by h_1 will also be placed there by h_2. Thus search with h_2 expands all of the nodes expanded by search with h_1, and diagonal search (i.e., $\omega=\frac{1}{2}$) is optimal.

For $\omega < \frac{1}{2}$ the reason for optimality is similar. The poorer heuristic pulls more nodes inside the triangular region than the better heuristic, only now the triangular region in question is as shown in Figure 4(c).

The completeness and admissibility theorems were stated as iff conditions in terms of the subinterval of [0,1] in which the properties held. This is not done for the optimality theorem because optimality is defined for admissible heuristics, and admissibility holds only in the subinterval $[0,\frac{1}{2}]$. Thus since $\omega \epsilon [\frac{1}{2},1]$ eliminates admissibility, optimality in this subinterval is not a queston.

If the hypothesis of the optimality theorem is changed from $h_2 < h_1 \leq h$ to $h_2 \leq h_1 \leq h$, then it is possible that search with h_2 may not expand a node n which lies on the minimum cost diagonal which is expanded by search with h_1. This is because a search strategy resolves ties arbitrarily, and search with the poorer heuristic h_2 may choose to expand a node n which is tied for merit with a minimal goal node, while search with the better heuristic h_1 chooses not to expand n. Thus, if $h_2 \leq h_1 \leq h$ then search with h_2 expands all the nodes expanded by search with h_1 except possibly for a set of nodes which have the same merit as a minimum goal node.

Let us now turn to the consistency property of a heuristic function. It has been pointed out that in general a search strategy does not expand the nodes of the graph according to the merit ordering. Thus, in general, diagonal search does not expand a node as soon as it falls within the region which has been searched. It must continually backtrack to earlier diagonals to expand nodes. Consistency of the heuristic is a sufficient condition to prevent this from happening.

THEOREM 4. If h is consistent then diagonal search (i.e., $\omega=\frac{1}{2}$) never has to backtrack to an earlier diagonal to expand a node.

PROOF: If h is consistent, then if $k(n,n')$ exists then $h(n)-h(n') \leq k(n,n')$. What does this condition mean in terms of the coordinate representation of the search space?

$$\begin{aligned} & h(n)-h(n') \leq g(n')-g(n) \\ \Leftrightarrow\ & g(n)+h(n) \leq g(n')+h(n') \\ \Leftrightarrow\ & h(n)-h(n') \leq k(n,n') \\ \Leftrightarrow\ & f(n) \leq f(n') \end{aligned}$$

Thus consistency means that if n precedes n' in the graph (which is a necessary and sufficient condition for $k(n,n')$ to exist), then $f(n) \leq f(n')$. In terms of the coordinate representation this means that n appears on the same or an earlier diagonal. Hence diagonal search moves from diagonal to diagonal to expand nodes, and never has to backtrack to an earlier diagonal to expand a node (see Figure 4(e)).

An important consequence of Theorem 4 is that if a heuristic is consistent then an ordered search strategy will never have to expand a node more than once; the first path found to any node is the minimum cost path to that node. Thus, when the heuristic is consistent, Case 3 (in the algorithm given in Figure 1), where $m \epsilon S$ and the new merit is better than the old merit, will not arise.

Sometimes the concept of a monotonic evaluation function is used instead of consistency. An evaluation function f is monotonic if for all n and n', $n \leq n' \Rightarrow f(n) \leq f(n')$, and $h(n') = 0$ when n' is a goal node; where $n < n'$ means that n precedes n' in the graph, and $n \leq n'$ means that either n precedes n' or n equals n'. For $\omega = \frac{1}{2}$ the concept of monotonicity is equivalent to that of consistency.

At one time it was thought that the optimality property required the consistency assumption. Recall that the proof of the optimality theorem depended on the poorer heuristic h_2 pulling all of the nodes into the triangular region which are pulled in by the better heuristic h_1. Thus all of the nodes pulled in and expanded by h_1 were pulled in and expanded by h_2. If the consistency of h_1 is assumed, then every node pulled in by h_1 is also expanded by h_1. Thus we can say every node pulled in by h_1 is pulled in and expanded by h_2. However, it is clear that the optimality property does not depend on h_1 expanding every node which it pulls into the triangular region. That is, the consistency assumption is not necessary for optimality.

THEOREM 5. [Perfect Heuristic] Suppose that all arcs of the graph have unit costs. Then search with $f_\omega = (1-\omega)g + \omega h$ only expands nodes on a minimum solution path iff $[\frac{1}{2}, 1]$.

PROOF: As indicated earlier, a perfect heuristic places no nodes inside the triangular region defined by the minimum cost diagonal, and places all nodes on all minimum solution paths on the minimum cost diagonal itself. No nodes will be expanded until the area covered by the search includes the start node (see Figure 4(f)). To prove the theorem we must show that at each stage of the search the node that is expanded lies on the minimum cost diagonal.

Let $s = n_0, n_1, \ldots, n_k = t$ be a minimum solution path. Clearly the first stage expands a node on the minimum cost diagonal since the node expanded is n_0. Suppose that $n_0, n_1, \ldots, n_i$ are the only nodes which have been expanded at the ith stage. Then since all arcs have unit arc costs the successor of n_i which is on the minimum solution path namely n_{i+1}, lies on the diagonal and a successor n' which is not on the minimum solution path lies off of the diagonal to the right of n_{i+1} (see Figure 4(f)). Thus n_{i+1} has better merit than the other successors of n_i. n_{i+1} has better merit than any previously unexpanded successor n'', because n_i has better merit than n'', and n_{i+1} has better merit than n_i. Hence, n_{i+1} will be expanded at stage i+1, and only nodes on the minimum solutions path are expanded.

If $\omega \epsilon [\frac{1}{2}, 1]$ then it is possible for the previously unexpanded successor n'' to have better merit than n_{i+1}. Hence a node not on the minimum solution path may be expanded.

If the unit arc costs assumption is removed from the hypothesis of Theorem 5 the conclusion is not true. This is because the node n' may be in the region which gives it a better merit than n_{i+1}, and thus a node off of the minimum solution path will be expanded. It is clear that the unit arc cost assumption can be replaced by a constant arc cost assumption. Figure 5 illustrates that Theorem 5 does not generalize to arbitrary arc costs.

All values of $0 \leq \omega \leq \frac{1}{2}$ are equally good in the sense that completeness, admissibility, and optimality all hold for $\omega \epsilon [0, \frac{1}{2}]$ provided h satisfies the lowerbound condition. However, it is clear from an examination of the regions expanded by searching with various values of $\omega \epsilon [0, \frac{1}{2}]$ that $\omega = \frac{1}{2}$ is best, because it expands fewest nodes.

Ignoring admissibility and optimality for the mo-

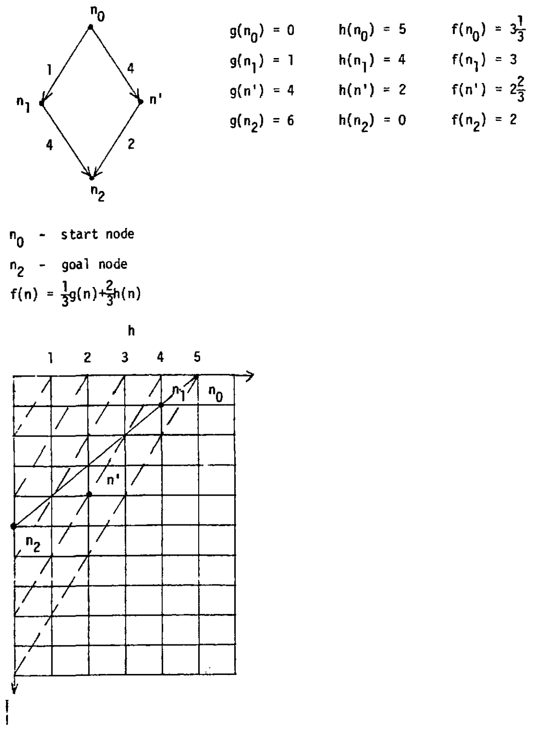

Figure 5—An illustration that Theorem 5 does not generalize to arbitrary arc costs. Searching the above graph with the perfect heuristic using $\omega = 2/3$ not only expand the node n' which is off of the minimum solution path, it even finds the nonminimal solution n_0, n', n_2

ment, there seem to be intuitive reasons for choosing $\omega=1$, or at least for choosing $\omega>\frac{1}{2}$. Recall that g is the cost-to-date component of the evaluation function, and that h estimates the cost to the nearest goal. An intuitive reason for choosing $\omega=1$ is as follows. Since the search has progressed to the point of generating n, why should we concern ourselves with the cost that has been incurred to get there? Perhaps we should only concern ourselves with what is the expected cost to get to a goal.

On the other hand, in addition to the fact that we may desire a minimum solution, which is not guaranteed when $\omega>\frac{1}{2}$, there is the following reason for including a g-component in the evaluation function. Sometimes it is difficult to construct a good heuristic function for a problem, and in these cases the presence of a g-component does not hinder the search, and sometimes helps it. Consider, for example, a heuristic function h which is of bounded error ($h_p(n)-\epsilon\leq h(n)\leq h_p(n)+\epsilon$, for some $\epsilon>0$ and all n), and which is defined in a way that deliberately misleads the search by being as optimistic as possible for nodes off the minimum solution path and as pessimistic as possible for nodes on the minimum solution path. It has been shown that for such a heuristic, diagonal search ($\omega=\frac{1}{2}$) expands fewer nodes in obtaining a solution than does pure heuristic search ($\omega=1$). This is an extreme example, but it does illustrate how a g-component can act as a stabilizing source when a poor heuristic is used.

BIBLIOGRAPHICAL REMARKS AND CONCLUSION

Graph representations have long been recognized as important models in problem solving. Discussion of both early and more recent use of graph representations can be found in the books by Ernst and Newell,[4] Barnerji,[5] Nilsson,[6] and Slagle.[7] These books along with the articles by Amarel,[8] Michie,[9] and Sandewall[10] also contain general discussions of ordered search strategies.

The admissibility and optimality of ordered search strategies and the concepts related to these theorems are due to Hart, Nilsson, and Raphael.[1,11] Algebraic proofs of these theorems also appear in Nilsson.[6] In this reference a δ-graph is defined to be a graph whose arc costs are bounded away from zero. The definition used in this paper which restricts the partial sums of the arc costs along an infinite path from being unbounded is more general, since it allows finitely many arcs of zero cost. This definition is based on the concept of a δ-finite merit ordering which was used by Kowalski,[3] who also was the first to use the geometric representation. Pohl[12] investigated the evaluation function $f_\omega=(1-\omega)g+\omega h$ in some experiments on the 15-puzzle. Doran and Michie[13] also experimented with the 15-puzzle. The theorem on completeness was proved by Pohl.[2] The theorem on the perfect heuristic and the argument for including a g-component in evaluation function are also due to Pohl.[12] To the best of our knowledge, the fact that the theorem on the perfect heuristic does not generalize to arbitrary arc costs has not previously been pointed out.

Hart, Nilsson, and Raphael,[1,11] developed ordered search strategies for directed graphs, which are used to represent state-space representations. Chang and Slagle[14] developed ordered search strategies for AND/OR graphs, which are used for problem-reduction representations. Ordered search strategies for theorem-proving graphs, which are used to represent state-space representations with multiple-input operators, were developed by Kowalski,[3] and also by Michie and Siebert.[15] An illustration of how the direction in which a problem space is searched determines whether a single problem representation is viewed either as a state-space or a problem-reduction representation appears in VanderBrug and Minker.[16]

The formal properties of ordered search algorithms, which we proved using the geometric representation, are of limited interest to the developers of a practical problem solving system. Completeness is rarely a big consideration in the design of such a system. Usually what keeps a search from being successful is exhaustion of the available resources, not the incompleteness of the search strategy. Admissibility is only sometimes an important consideration, since often a solution which is approximately minimum is sufficient. Thus, one can use a heuristic which only approximately satisfies the lowerbound condition (i.e., $h\leq h_p+\epsilon$), and expect to get a solution which is approximately minimum. Such a search is less conservative (in the sense that it takes more chances) than an admissible one, and frequently will find an approximately minimum solution before the admissible search finds a minimum one.

Nonetheless, the theorems are important formal properties, and help to unify the work done in this area. We believe that the geometric approach to the presentation of these formal properties is an intuitive alternative to the algebraic approach.

Another algorithm for reducing bandwidth and profile of a sparse matrix

by W. F. SMYTH
International Labor Office
Geneva, Switzerland

and

ILONA ARANY
Computing Center of the Ministry of Labor
Budapest, Hungary

ABSTRACT

The paper describes a new bandwidth reduction method for sparse matrices which promises to be both fast and effective in comparison with known methods. The algorithm operates on the undirected graph corresponding to the incidence matrix induced by the original sparse matrix, and separates into three distinct phases: (1) determination of a spanning tree of maximum length, (2) modification of the spanning tree into a free level structure of small width, (3) level-by-level numbering of the level structure. The final numbering produced corresponds to a renumbering of the rows and columns of a sparse matrix so as to concentrate non-zero elements of the matrix in a band about the main diagonal.

INTRODUCTION

As electronic computers make possible computations on ever larger data sets, it has come to be realized [1,p17,2] that most large matrices are, in the nature of things, sparse; more precisely, that a matrix of (large) order n will generally contain only Kn non-zero elements, where K tends to decrease as n increases (K is often as little as 2 or 3 and only rarely greater than 20). There has been, accordingly, during the last ten years, a good deal of research into techniques for efficient computer handling of large sparse matrices. These techniques may be separated into two classes:

T_1: techniques which deal with the given sparse matrix, more or less directly, in a sparse form (some typical approaches are surveyed in [2] and [3]);

T_2: techniques which transform the given sparse matrix into a band form (which may then be processed further by efficient and well-known band matrix algorithms).

Initially "direct" techniques T_1 attracted more interest, and the utility of "band" techniques T_2 was occasionally questioned.[4] Research into T_2 techniques was spurred however by the work of Cuthill-McKee,[5] who described an effective bandwidth reduction algorithm with execution time linear in Kn. Instead of dealing directly with the given matrix, Cuthill-McKee (hereafter called CM) dealt with the numbered graph whose connections correspond to the given matrix's zero/non-zero structure; they renumbered the vertices of this graph, and this renumbering therefore defined the interchanges of rows and columns required to transform the original sparse matrix into a band matrix.

The CM method was later modified in various ways, especially by Rose,[6] who also contributed an important analysis of the application of Gaussian elimination to band matrices, showing in particular the importance of the profile.

The algorithm presented here, called the SA algorithm, is of class T_2. It results from efforts to improve on previous work,[7] and has been directly stimulated by the approach suggested by Smyth-Benzi (hereafter called SB)[8] as well as by the related algorithm published independently by Gibbs-Poole-Stockmeyer (hereafter called GPS).[9] Like the CM and GPS algorithms, SA renumbers the vertices of a given numbered graph with the objective of minimizing the maximum difference between numbers assigned to connected vertices. Also in common with these algorithms, SA reduces profile as well as bandwidth[6] and may be applied to non-symmetric as well as to symmetric matrices.

TERMINOLOGY

We use the term *graph*, and the symbol G or G(V, E), to denote a finite connected * undirected graph without

* The algorithm may easily be modified to deal separately with the disjoint components of a single graph.

loops or multiple edges defined on a *vertex* set V of cardinality $n=|V|>1$ and an *edge* set E of cardinality $m=|E|$. For any distinct pair of vertices $u, v \epsilon V$, we define the usual *distance* function $\rho(u,v)$ to be the number of edges on the shortest *path* from u to v. For a single vertex u, we adopt the convention $\rho(u,u)=0$; for unconnected vertices u,v, we set $\rho(u,v)=\infty$; if $\rho(u,v)=1$, then u and v are said to be *adjacent*. The *diameter* of G is defined by

$$\text{diam}(G)=\max_{u,v\epsilon V}[\rho(u,v)].$$

Since we assume G is connected, $\text{diam}(G)\leq n\text{-}1$.

Apart from such basic terms, we need for our purposes here to define four main concepts: level structure, free level structure, numbering, and bandwidth.

A *level structure* LS of a graph G(V,E) is an assignment of the vertices of V into sets, called *levels* $L_1, L_2, \ldots, L_\lambda$, such that

(1) L_1 contains at least one vertex;
(2) for each $k=2,3,\ldots,\lambda$, L_k contains every vertex not in a previous level which is adjacent to some vertex of L_{k-1}.

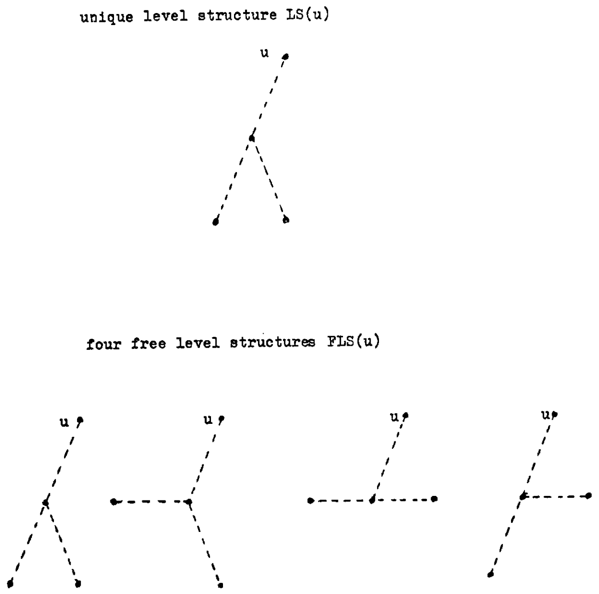
It follows from this definition that if G is connected, LS contains all n vertices of V; that the levels are disjoint; that $1\leq\lambda\leq\text{diam}(G)+1$; and that LS is determined uniquely by the choice of vertices in L_1. We may therefore unambiguously denote LS by $LS(L_1)$ or, when $L_1=\{u\}$, by LS(u). We observe in fact that level L_k of $LS(L_1)$ consists of exactly those vertices which occur in the kth level of every *spanning forest* (SF) grown from the vertex set L_1 (for a description of this process see Reference 5). $LS(L_1)$ therefore corresponds (one-many) to the $SF(L_1)$, and LS(u) to the *spanning trees* ST(u). Whenever edges are not important, then, we may refer to LS and SF/ST interchangeably.*

A *free level structure* FLS of a graph G(V,E) is an arrangement of all n vertices of V into λ levels $L_1, L_2, \ldots, L_\lambda$, such that

(1) no level is empty;
(2) if $u \epsilon L_k$ then all vertices adjacent to u are in either L_{k-1}, L_k, or L_{k+1}.

We note that in this case also $1\leq\lambda\leq\text{diam}(G)+1$, but that FLS(u) is no longer uniquely determined (Figure 1). For either LS or FLS we speak of the *width of level k*, $w(L_k)=|L_k|$, and the *width of the structure*, w(LS) or $w(FLS)=\max_{1\leq k\leq\lambda}w(L_k)$. λ is called the *length* of the structure.

Following GPS, we now define a *numbering* $\alpha=\alpha(V)$ of G(V,E) to be a one-one map of V onto the first n natural numbers $\{1,2,\ldots,n\}$. For a given numbering α, we may define $\delta_\alpha(G)$, *the bandwidth of the graph G relative to the numbering* α, to be



unique level structure LS(u)
u
four free level structures FLS(u)
u
u
u
u

Figure 1

$$\delta_\alpha=\delta_\alpha(G)=\max_{(u,v)\epsilon E}|\alpha(u)-\alpha(v)|.$$

The *bandwidth of G* is then

$$\delta=\delta(G)=\min_{\text{all}\,\alpha}[\delta_\alpha(G)].$$

GENERAL DESCRIPTION OF THE SA ALGORITHM

Our goal is therefore, given G(V,E), to find a numbering $\alpha=\alpha(V)$ such that $\delta_\alpha=\delta(G)$. Our (heuristic) algorithm approaches this problem in three distinct phases:

I *Find LS*
Using the SB method,[8] a level structure LS $=LS(u)$ is found such that $\lambda=\text{diam}(G)+1$.

II *Find FLS*
Using a subset M ($|M|=\min\{|L_\lambda|, |\overline{n}/\overline{\lambda}|\}$) of the vertices of level L_λ in LS(u), a new level structure, denoted $LS'=LS'(M)$, is grown. LS′ is also of length λ. LS and LS′ are systematically compared, and an FLS is determined such that $w=w(FLS)$ is small (if possible, $w=|\overline{n}/\overline{\lambda}|$).

III *Number FLS*
FLS is numbered on a level-by-level basis; that is, first, the integers $\{1,2,\ldots,w_1\}$ are assigned to the vertices of the first level of FLS (w_k denotes the width of the kth level of FLS);

* We dwell on this point to avoid confusion. The definition of LS given here is more restrictive than the original definition given in Reference 7, but is compatible with the SF/ST usage of Reference 8. The GPS definition of LS Reference 9 is compatible with Reference 7, and what GPS call the "level structure rooted at u" is identical to our LS(u).

second, the integers $\{w_1+1, w_1+2, \ldots, w_1+w_2\}$ are assigned to the vertices of the second level; and so on, until all vertices have been numbered. The algorithm makes use of knowledge of the edges joining vertices of successive levels in an effort to minimize bandwidth: it searches for a level-by-level numbering α such that the corresponding bandwidth satisfies

$$\delta_\alpha \leq w+\Delta,$$

where Δ successively takes the values $0,1,\ldots, w-1$. The first numbering found which satisfies this condition is the required numbering α.

The justification of algorithms such as this is partly theoretical, partly experimental, and numerous variations in strategy are possible. In practical terms, we are trying to find a "reasonably good" numbering without needing to investigate all of the n! different possible numberings; our strategy therefore is always influenced by estimates, often very rough in nature, of the additional benefit to be expected from the additional effort expended. We will find an example of this kind of strategic thinking in Phase II of SA: we do not carry out an exhaustive search to find the FLS of truly minimum width, even though such a search might not on the average be too laborious, simply because (1) it seems that an exhaustive search would not be likely to decrease w; (2) the result might be merely to decrease w by 1, but not decrease δ_α, and in addition make numbering more lengthy and difficult. On the other hand, in Phase I, we propose using the SB algorithm [8] instead of the GPS pseudo-diameter algorithm,[9] because the former guarantees finding a longest spanning tree at (apparently) no additional cost. On the theoretical side, the basic justification for level-by-level numbering is the result of Arany-Szóda [10] that corresponding to every numbering α of G there exists at least one FLS whose width $w=\delta_\alpha$, and which may be numbered on a level-by-level basis to yield the numbering α. Since the case $\delta_\alpha=\delta$ is included in this result, it follows that level-by-level numbering of an FLS is an acceptable approach to bandwidth reduction, in that it does not exclude any minimum case. The result however does not point to any particular FLS-growing or FLS-numbering algorithms.

PHASE I OF SA: FIND LS

As noted above, the SB diameter algorithm is proposed here, because it guarantees finding $\lambda=\text{diam}(G)+1$ and apparently is comparable to the GPS pseudo-diameter algorithm in execution time. The SB algorithm is described fully in Reference 8 and is not included here*.

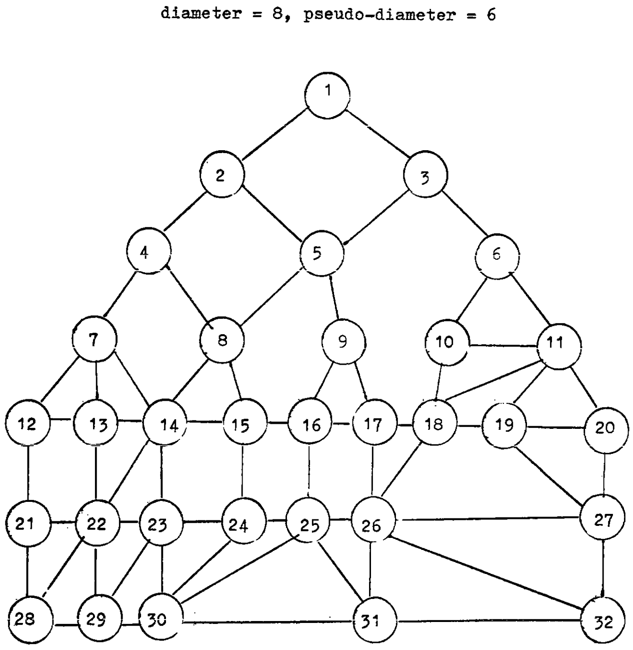


Figure 2

GPS state in Reference 9 that their pseudo-diameter algorithm found the true diameter in all test cases. Figure 2 illustrates a graph of diameter 8 whose GPS pseudo-diameter is 6. The GPS algorithm would require the growth of 6 spanning trees to achieve this result, the SB algorithm 3 spanning trees (starting vertex ①). Removal of edges (4,8) and (5,9) from Figure 2 and insertion of edge (4,5) would permit GPS to find a pseudo-diameter 7 at a cost of growing 4 spanning trees. For a symmetrized version of the Curtis matrix[4] (Figure 3), SB finds diameter 7 at a cost of 6 spanning trees (starting vertex ①), and GPS finds pseudo-diameter 7 from each of six starting vertices of minimum degree at an average cost of 5.5 spanning trees. See Table I.

A more detailed analysis of the application of the GPS pseudo-diameter algorithm to the Curtis matrix

TABLE I—Comparison of SB and GPS

	(pseudo-) diameter		number of LS grown	
example	SB	GPS	SB	GPS
Figure 2	8	6	3	6
Figure 2 (mod.)	8	7	3	4
Curtis matrix	7	7	6	5.5

* We do however provide a correction to the algorithm SPAN (h,i) given in the Appendix of Reference 8. In step 7 replace the ending "." with "gotoll.". Step 8 should read "[Is the vertex connected to jorig in level g+1?] *If h=1* and level (h, elist(j)) =g+1, goto10; otherwise gotoll.". Interchange steps 9 and 10.

FLS corresponding to Curtis matrix

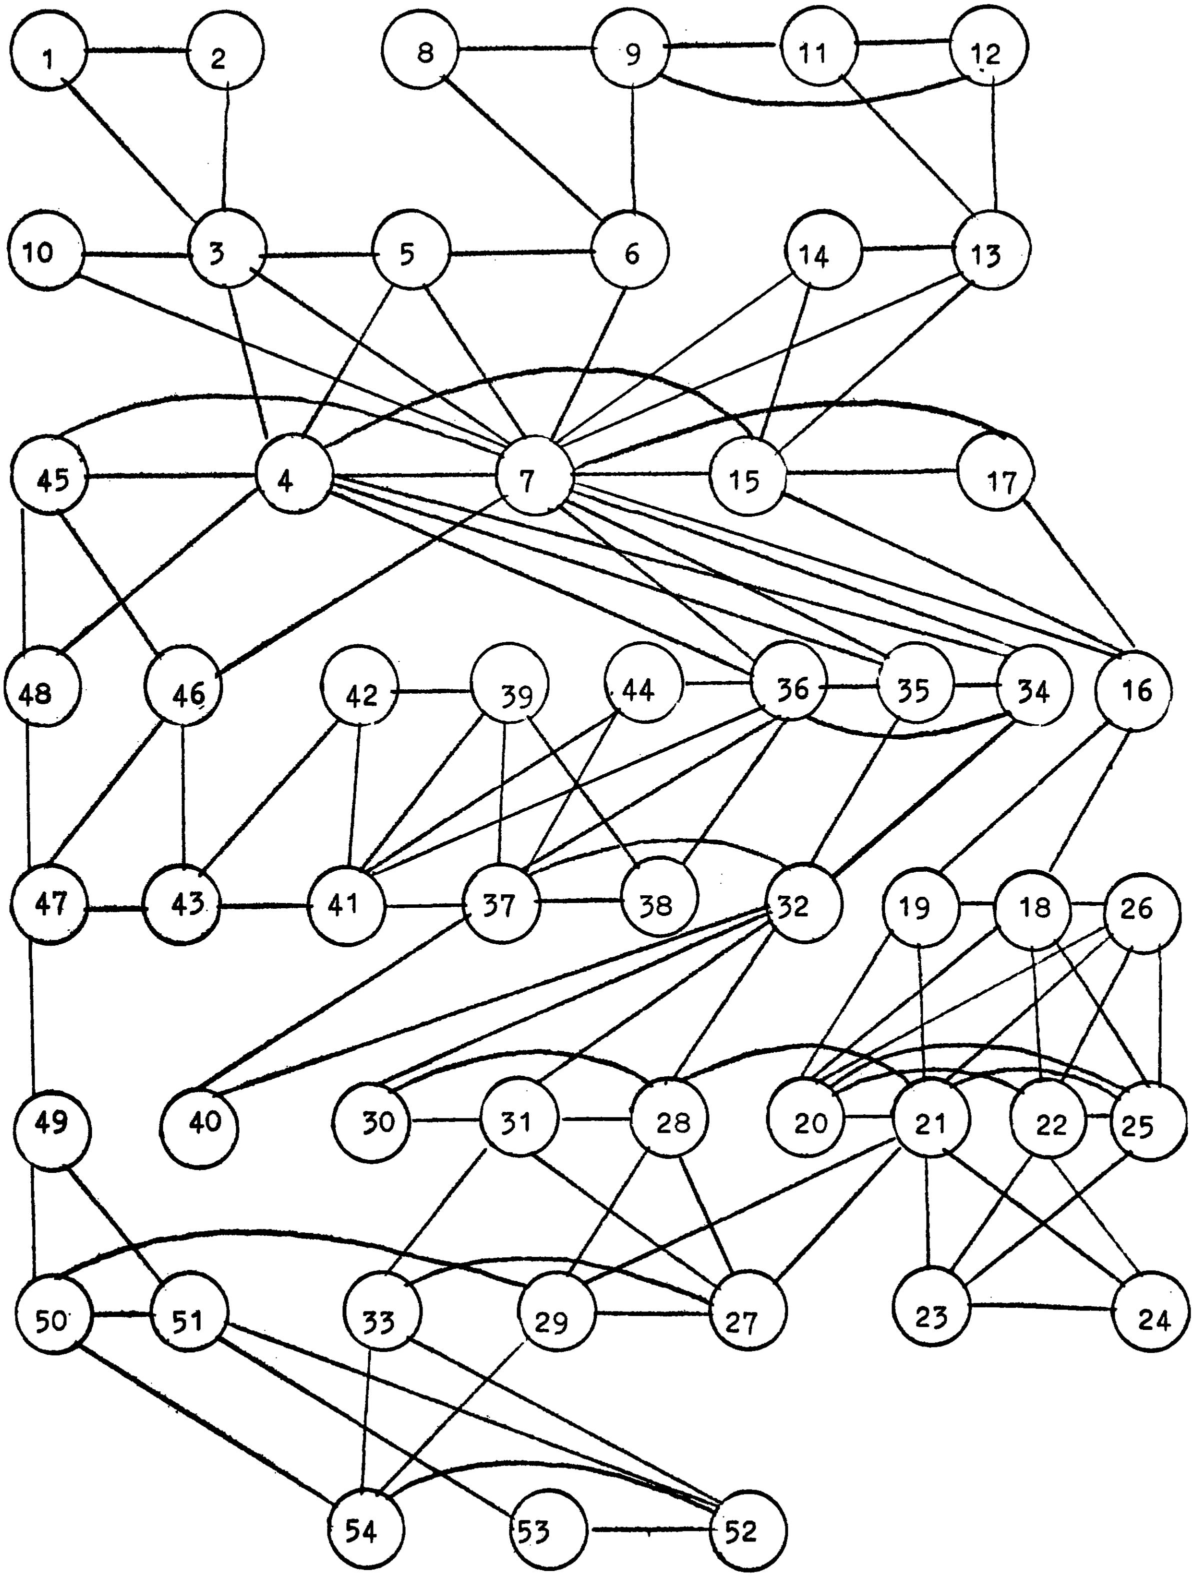

Figure 3

shows that 48 of the 54 vertices would, used as starting root vertices, yield maximum pseudo-diameter 7; of these 48 vertices, the 9 extreme vertices yield $\lambda=8$ immediately, 22 yield $\lambda=7$ but contain an extreme vertex in L_7, and 15 yield $\lambda=6$ with an extreme vertex in L_6 (there are two other special cases). These statistics appear to be related to the success of the GPS algorithm, and it would be interesting to know if for much larger graphs also ($n=500$ to 5000) such a high percentage of optimal starting root vertices occurs.

GPS initially searches V for a vertex of lowest degree as starting root vertex, and from the corresponding L_λ selects additional root vertices in increasing order of degree. SB includes no such searches.

PHASE II OF SA: FIND FLS

The algorithm described below is an attempt to deal efficiently with difficult cases which may arise when G is not "well" connected (Figure 4); that is, when a number of vertices swing into different levels in the level structure LS′ grown from vertices of L_λ in LS(u). It seems that the growing of this "reverse" level structure (step (1) of the following algorithm) will normally accomplish what GPS accomplish in phase II of their algorithm; the other steps in the algorithm given below make use of the same information proposed by GPS, but in a more flexible manner.

Given LS(u) of length $\lambda=\mathrm{diam}(G)+1$, phase II proceeds as follows:

(1) [Grow "reverse" LS′.] For $R=|\bar{n}/\bar{\lambda}|$,* choose a set of vertices $M<L_\lambda$ such that $|M|=\min\ [R, w(L_\lambda)]$ and grow LS′(M) with levels L_k' of width $w'(k)$, $k=1,2,\ldots,\lambda$ ($L_1'=M$).

(2) [Calculate initial value of T.]
$T\leftarrow\Sigma_{1\leqq k\leqq\lambda}\min\ [R-w'(k),0]$; if $T=0$, goto (16).
[Two criteria are used to determine whether the movement of a vertex of FLS(M) from one level to another yields a "better" FLS: the value T given here and the value $T'=\Sigma[R-w'(k)]^2$. The FLS is "better" if the vertex movement increases T (by unity) or decreases T′. T is also an "absolute" criterion, since any FLS for which $T=0$ is accepted; T′ is not calculated explicitly because it is not "absolute", so that only $\Delta T'$ is required (see step (12)). Both T and T′ may be used since T′ decreases iff T does not increase.]

(3) [Calculate level pairs.] As in Reference 9, associate with each vertex $v\in V$ a *level pair* (g_v,h_v), where g_v is the level of v in LS′(M), where $h_v=\lambda-k_v+1$, and k_v is the level of v in LS(u).

(4) [Separate "movable" vertices into r connected components.] As in Reference 9, separate all vertices such that $g_v=h_v$ into r disjoint connected components $C_1,C_2,\ldots,C_r$ of cardinality $c_1,c_2,\ldots,c_r$, respectively, arranged so that $c_1\leq c_2\leq\ldots\leq c_r$.

(5) If $r=0$, goto (16).

(6) [Organize storage for vertices in component C_r.] Associate with each vertex $x_{rj}\epsilon C_r$, $j=1,2,\ldots,c_r$, an *identifier* $[v(j),g(j),h(j)]$, where $v(j)$ is a pointer to the level pair of the vertex $v=x_{rj}$, and $[g(j),h(j)]$ is the level pair of x_{rj} (that is, $g(j)=g_{v(j)}$, $h(j)=h_{v(j)}$); order the vertices so that $g(1)\geq g(2)\geq\ldots\geq g(c_r)$.

(7) [Initialize vertex movement parameters for C_r.] $j\leftarrow 1$; $\Delta T\leftarrow 0$, $\Delta T'\leftarrow 0$; for each $k=1,2,\ldots,\lambda$, $w(k)\leftarrow w'(k)$.
[For each C_r, we need to provide temporary storage for the level widths $w'(k)$: this temporary storage into $w(k)$ is used to keep track of moves made since the last acceptance of a vertex movement (last increase of T or decrease of T′).]

(8) [Move vertex x_{rj} from level $g(j)$ to $g(j)-1$.] Perform MOVE-VERTEX(j,γ) as follows:
(8.1) $\gamma\leftarrow g(j)\leftarrow g(j)-1$;
(8.2) $w(\gamma)\leftarrow w(\gamma)+1$, $w(\gamma+1)\leftarrow w(\gamma+1)-1$;
(8.3) let j' successively take the values $j+1,\ldots,c_r,1,\ldots,j$; for the first value j' such that $g(j')>h(j')$, set $j\leftarrow j'$;
(8.4) if there is no such j', set $j\leftarrow 0$.
[Given j, MOVE-VERTEX(j,γ) returns the new level γ of the moved vertex x_{rj}, together with the next admissible value of j. The vertex movements take place in a "cascade" from higher-level vertices to lower-level vertices, in accordance with the observation that under these circumstances a vertex x_{rj} may always be moved to the preceding level, provided that $g(j)>h(j)$ (initially, of course, $g(j)>h(j)$ for every $j=1,2,\ldots,c_r$). Note that not all possible configurations of C_r are necessarily covered by the movements included here.]

(9) [Calculate ΔT.] $\Delta T\leftarrow\Delta T+$ (if $w(\gamma+1)>R-1$, 1; otherwise, 0) $-$ (if $w(\gamma)>R$, 1; otherwise 0).
[The full expression for ΔT is
$$T=-\min\{R-[w(\gamma)-1],0\}+\min\{R-w(\gamma),0\}-\min\{R-[w(\gamma+1)+1],0\}+\min\{R-w(\gamma+1),0\}.]$$

(10) [For increased T, store present arrangement of vertices into levels.] If $\Delta T=1$, $T\leftarrow T+1$, $\Delta T\leftarrow 0$, and perform STORE-PATTERN; otherwise, goto (12).
[STORE-PATTERN does the following: for $j=1,2,\ldots,c_r$, $g_{v(j)}\leftarrow g(j)$; for $k=1,2,\ldots,\lambda$, $w'(k)\leftarrow w(k)$; $\Delta T'\leftarrow 0$. Note that $\Delta T'$ is reset after every increase of T, but that acceptance based on $\Delta T'$ does not reset ΔT (step (13)).]

(11) If $T=0$, goto (16).

(12) [Calculate $\Delta T'$.] $\Delta T'\leftarrow\Delta T'+[w(\gamma)-w(\gamma+1)-1]$.

(13) If $\Delta T'<0$, perform STORE-PATTERN.

* SB propose rather $|\bar{n}/\bar{\lambda}|$.

(14) [More vertex movements possible?] If $j>0$, goto (8).

(15) [More components of "movable" vertices?] $r \leftarrow r-1$, goto (5).

(16) Exit.

[The FLS(M) which best satisfies the T and T' criteria has now been determined. Each vertex v of FLS(M) is placed into the level specified by g_v, and the width of each level L_k' is given by $w'(k)$.]

Figure 4 illustrates the result of the application of the algorithm to an LS with many movable vertices. In this case only three vertices would need to be moved before FLS became acceptable ($T=0$). In the example of Figure 2, an FLS of width 5 would be accepted ($T=-3$) after movement of two vertices. For the two dimensional grid discussed in detail by GPS, phase II yields an optimal FLS=LS(M) after step (1), and no vertex movements are required. For the Curtis matrix, on the other hand, consideration of the connected components in decreasing order of size actually inhibits bandwidth reduction: for starting vertex u=① and a corresponding LS(M) of width 11 ($T=-9$), the algorithm requires 56 vertex movements to yield an FLS of width 10 ($T=-7$). Although this result leads to an optimum numbering ($\delta=10$), much unnecessary work is done. Clearly, in order to evaluate the efficiency and utility of phase II of the SA algorithm, considerable computational experience, especially with large matrices, is desirable.

PHASE III OF SA: NUMBER FLS

We propose here a somewhat more sophisticated numbering algorithm than has previously been employed,[5,7,9] but which retains the property of having execution time approximately linear in n. Indeed, as we shall see, the numbering algorithm has the interesting property of being rather more efficient in the more difficult cases.

Suppose we are given an FLS(M) of length λ and width w', with levels L_k' of width $w'(k)$, $k=1,2,\ldots,\lambda$. Suppose further that corresponding to each $v \epsilon V$, we may identify g_v, the level of v, and A(v), the set of vertices adjacent to v; and that corresponding to each level L_k' of FLS, we may identify the vertices $x_{kj} \epsilon L_k'$, $j=1,2,\ldots, w'(k)$. Phase III assigns numbers to the vertices on a level-by-level basis, with the objective of arriving at a numbering α of G which corresponds to a suitably small bandwidth δ_α. In the large, phase III proceeds as follows:

(1) $\Delta \leftarrow 0$.

(2) $\delta_\alpha \leftarrow w' + \Delta$.

(3) For each $k=1,2,\ldots,\lambda$, try to assign numbers to the vertices $x_{kj} \epsilon L_k'$ in such a manner that the *number* n(x) of each vertex x satisfies

$$|n(x) - n(y)| \leq \delta_\alpha,$$

for every $y \epsilon A_x$.

(4) If for some k, it turns out that the vertices cannot be numbered to satisfy this condition, then $\Delta \leftarrow \Delta + 1$, goto (2).

We observe that, in principle, this algorithm will terminate sooner or later; indeed, as CM remark,[5] for $\delta_\alpha = 2w'-1$, *any* level-by-level numbering of FLS will satisfy the condition given in step (3). We observe further that, in practice, the algorithm will normally terminate at some value δ_α close to w'; in fact, in the great majority of cases, for $\delta_\alpha = w'$.*

We give now a more detailed description of step (3). Since the same procedure is used for the numbering of each level, we confine ourselves to describing the numbering of the k^th level L_k'. Certain basic values need to be defined and calculated:

$$W'(k) = \Sigma_{1 \leq k' \leq k} w'(k'), \; 1 \leq k \leq \lambda;$$
$$= 0, \; k=0.$$

$A_{\pm 1}(j) = \{v \mid x_{kj} \epsilon L'_k \wedge v \epsilon A(x_{kj}) \wedge v \epsilon L_{k\pm 1}'\}$, the set of vertices of L'_{k+1} (L'_{k-1}) adjacent to the j^th vertex in L'_k.

* However an unpublished example due to Arany-Szóda has the following characteristics: $n = 60$, $m = 112$, $w' = 9$, $\delta(G) = 14$.

$a_{\pm1}(j) = |A_{\pm1}(j)|$.

$\text{lown}(j) = \min_{x \in A_{-1}(j)} n(x),\ a_{-1}(x) > 0;$
$\quad = W'(k-1),\ a_{-1}(x) = 0;$
the lowest number assigned to any vertex in L_{k-1}' which is adjacent to the j^{th} vertex in L_k'.

The processing required for each level falls naturally into two stages, which we call INITIALIZE L_k' and NUMBER L_k':

```
INITIALIZE $L_k'$
(1) For each vertex $x_{kj}$, $j=1,2,\ldots,w'(k)$, calculate
    (1.1) xmin(j)←max[$1+W'(k-1)$, $W'(k)+a_{+1}(j)-\delta_\alpha$], the least number assignable to $x_{kj}$
          which is compatible with bandwidth $\delta_\alpha$;
    (1.2) xmax(j)←min[$W'(k)$, $\delta_\alpha$+lown(j)], the greatest number assignable to $x_{kj}$ which is
          compatible with $\delta_\alpha$;
    (1.3) xrange(j)←xmax(j)−xmin(j)+1; if xrange(j)≤0, goto INCREMENT Δ (step (4) in the general
          outline of phase III given above).
(2) nrangeclass(j)←0, $j=1,2,\ldots,w'(k)$.
    [The number of vertices to which a number $W'(k-1)+j'$, $j'=1,2,\ldots,w'(k)$, may be assigned will
    be determined; nrangeclass(j) will then contain a pointer to the first of the numbers $W'(k-1)+j'$
    which may be assigned to exactly j vertices.]
(3) For each number $j'=1,2,\ldots,w'(k)$:
    (3.1) calculate
          nr(j'), the number of values of j for which
            xmin(j)≤j'≤xmax(j);
          nlist(j',1) to nlist(j',nr(j')), a list containing the values of j for which
            xmin(j)≤j'≤xmax(j);
    (3.2) if nr(j')=0, goto INCREMENT Δ;
    (3.3) np(j')←nrangeclass(nr(j')), nrangeclass(nr(j'))←j'.
          [np(j') is a pointer to the next number in nrangeclass(nr(j')).]
NUMBER $L_k'$
(4) J←1, counter←0.
(5) If nrangeclass(J)=0, J←J+1, goto (5).
    [The numbers to be assigned are chosen in increasing order of nrangeclass.]
(6) j'←nrangeclass(J), nrangeclass(J)←np(j').
    [j' is the number to be assigned.]
(7) [Determine j, the vertex to which j' is assigned.]
    (7.1) h←1, j←nlist(j',h);
    (7.2) h←h+1, $j_1$←nlist(j',h); if $j_1$=0,
          goto (7.6);
    (7.3) if range($j_1$)<xrange(j), xrange(j)←
          xrange(j)−1, j←$j_1$, goto (7.2);
    (7.4) xrange($j_1$)←xrange($j_1$)−1; if xrange
          ($j_1$)=0, goto INCREMENT Δ;
    (7.5) goto (7.2);
    (7.6) exit.
(8) [Assign j' to j.]
    (8.1) n($x_{kj}$)←$W'(k-1)$+j';
    (8.2) counter←counter+1; if counter=w'(k),
          goto (11);
    (8.3) xrange(j)←∞, nr(j')←0.
(9) [Delete j and j' from storage.] For every J'=xmin(j), xmin(j)+, ..., xmax(j) such that
    nr(J')=0, do the following:
    (9.1) rold←nr(J'), nr(J')←nr(J')−1;
    (9.2) if rold=1, goto INCREMENT Δ;
          if rold=J, J←nr(J');
    (9.3) pold←np(J'), np(J')←nrangeclass
          (nr(J')), nrangeclass(r(J'))←J';
    (9.4) if nrangeclass(rold)=J', nrangeclass(rold)
          ←pold, goto (9.7); otherwise,
          $j_2$←nrangeclass(rold);
    (9.5) if np($j_2$)=J', $j_2$←np($j_2$), goto (9.5);
    (9.6) np($j_2$)←pold;
    (9.7) exit.
(10) Goto (5).
(11) Exit.
```

Table II displays results obtained using the above algorithm on a few examples; these results [δ(SA)] are compared with optimum numbering [δ(FLS)] and with results [δ(GPS)] obtained by the GPS numbering algorithm. δ(FLS) was attained neither by SA nor GPS, primarily because more than single-level lookahead was required.

It appears that, in phase III as in the other phases, SA produces results at least as satisfactory as those of GPS. The execution time of phase III is bounded above by a value proportional to $\Sigma w'(k)^2$, and depends essentially on the size of the variables xrange(j) and nr(j'): when these variables are small—that is, when the numbering is more difficult—execution time will correspondingly be small. Storage required for phase III is of the order of $w'(w'+6)$.

CONCLUSIONS

We have described a bandwidth reduction algorithm which appears to be competitive in effectiveness and efficiency with presently known algorithm. Systematic testing on large matrices encountered in practice is re-

TABLE II—Numbering FLS using SA

FLS	δ(SA)	δ(FLS)	δ(GPS)

quired. Some of the more important questions remaining to be clarified, either by experiment or by analysis, are as follows:

(1) The execution time of SB (phase I of SA) is proportional to 2Hm. What can be said about the magnitude of H?

(2) In what (more efficient) way can vertex movements be evaluated during phase II, in order to yield an optimum FLS?

(3) Given two FLS of G of widths w_1 and $w_2 > w_1$, denote by δ_1 and δ_2 the least bandwidths obtainable by level-by-level numbering of the first and second FLS, respectively. Does it follow that $\delta_2 \geq \delta_1$?

Business opportunity analysis

JOHN P. DOLAN

University of Puget Sound
Tacoma, Washington

ABSTRACT

Opportunity analysis is proposed as a technological forecasting method for assessing monetary profit to a firm. The method can employ use of the Delphi committee, the Bayesian algorithm, computer conferencing, and impact analysis, with certain suggested modifications.

INTRODUCTION

Opportunity analysis involves the assessment, in terms of its monetary potential for profit, of any single or series of potential developments affecting the business. The potential developments could be a set of exogenous events, such as a reduction of taxes or the passage of favorable legislation. On the other hand, it can look at endogenous events such as a proposed cost reduction program. Finally, it can be used to evaluate such things as investment proposals which contain both internal and external variables. This paper presents the concepts underlying opportunity analysis and a suggested procedure for conducting an opportunity analysis.

UNDERLYING CONCEPTS

Opportunity analysis combines the Bayesian decision process with the Delphi method, with modifications discussed in this paper.

The Bayesian process[1] involves making a roster of future possible events; assigning a subjective probability to each event; making a list of alternative actions; setting a payoff for each matrix action cell; calculating the expected value for each action; and, finally, choosing that alternative with the highest value.

The Delphi method, as originally designed[2] and developed at the RAND Corporation,[3-7] is a technique for obtaining group opinion. The method has three features; opinions of group members are anonymous; group members have the opportunity to change individual opinions through iteration and feedback; and, group opinion emerges (and perhaps converges) as a statistical summary of individual responses. The Delphi method was designed to overcome the effect of individual decision maker bias that might be found in the Bayesian decision process. In implementing the Delphi method, the first step is to obtain a panel of experts to whom a coordinator mails a questionnaire. Anonymity of individual panel members' opinions is preserved as the questionnaire is returned directly to the coordinator. In the second step, the coordinator summarizes opinions and mails the summary to the panel for review. The process may be iterated as members review the responses of others and the summary causing a reconsideration of opinion. Finally, a group consensus unfolds as a statistical summary of opinion.

RESEARCH AND REFINEMENTS

Within the past decade, applications of Delphi have proliferated. To mention but a few, Delphi has been used to forecast data processing technology,[8] communications technology,[9] European political events,[10] food and nutrition technology,[11] automobile tire technology,[12] international affairs,[13] computer developments and applications,[14] biomedical research and drug therapy,[15] and weaponry technology.[16] Delphi has also been used for policy making. Applications have been in civil defense,[17] and in teacher education.[18] Concomitant with the applications research have been refinements to the Delphi method. Of particular interest to us in developing opportunity analysis have been four types of refinements:

(a) Use of the Bayesian process. It has been suggested[19] that probabilities be assigned to events. This refinement has been applied to assessing threats to an organization,[20] wherein it was felt that time periods are not necessarily mutually exclusive and that a particular event might occur in any of several time periods, each with its own probability, within the forecasting horizon.

(b) Use of the computer. The computer has been used to produce the statistical summaries of the Delphi iterations,[20] and has been used as the medium for transmitting questions to the panel and for receiving responses.[21,22]

(c) Use of a preliminary panel. The question has been raised[23] as to the source of the questions posed to the Delphi committee. One approach[20] is to have an exploratory conference of knowledgeable individuals who produce a grocery list of issues for subsequent consideration by the Delphi panel.

(d) Consideration of dependent or interrelated events. Referred to as cross correlations[24] and cross-impact analysis[10,25-28] this refinement to the Delphi method considers the likelihood of one particular event in the forecast, given the occurrence of one or more other forecasted events.

Opportunity analysis proposes to adopt these four refinements.

THE OPPORTUNITY ANALYSIS PROCESS

In developing business plans, one of the most difficult assessments is what projects or businesses a company should engage in. Commonly this work is handled by a new idea gathering unit of some type, or may be the result of approaches from outside the organization. In any case, a series of judgments must be made as to the viability and profitability of suggested new products, and this often is done for each project standing on its own.

Not uncommonly, related projects occur at one or more research locations remote from the corporate headquarters, and so the researchers and corporate staff personnel operate without benefit of each other's insight. This is particularly costly to the problem of project selection and new business development. An alternative to the deterministic discounted cash flow capital budgeting approaches is opportunity analysis. This is a five part process which utilizes the principles of the Delphi process and Bayesian algorithm as outlined previously.

Step One. Idea input.—During this stage of the process, there would be a general survey of the members of the corporation dealing with technology development. The survey can be conducted by mail or by conferencing on a computer terminal. The important element is that the technology be spelled out in terms of what need it fulfills, i.e., savings in unit labor costs, decreased raw materials cost, increased performance, the estimated cost of commercializing the technology, and the length of time it is expected to take to achieve it.

At this phase of the investigation it is best not to identify the donor in order to help overcome the "not invented here" problem. It is also important that all offerings are invited without imposing criteria so that a free flow is inspired.

This approach is contrasted with the method employed in[20] where threats to the organization were identified as a result of a series of face-to-face committee meetings.

Step Two: Idea exchange.—From the array of inputs is assembled a master list of the developments, without the time or money figures shown. This list is then fed back to the group, via mail or computer conferencing, for estimation of what ideas would be likely to complement others, and what would be likely to supplant others. For each overlap area, the degree of overlap would be estimated. This degree of overlap is used to establish cross-impacts from one idea to another. This is necessary so that later in the process we can establish the total impact of an event across time, rather than its simple, immediate effect.

Step Three: Critical factor analysis.—Each group of ideas is tested for cross correlation and cross-impact. We view cross correlation analysis being appropriate for two simultaneous and related events. By contrast, we view cross-impact analysis being used for the circumstance of temporal priority when one event (or more than one event) precedes and is a prerequisite to another event. When either of the above conditions is found, a private meeting is held between the coordinator and each panel member internal to the organization to probe the key assumptions underlying the ideas. In the case of the labor saving device, this might be that wage rates will rise. For increased performance, the assumption may be that the result will be a higher price for the finished product. The factors which could change and impact these assumptions must be probed. For the critical factor analysis to be effective, the panel member should sort out in his/her mind whether events are dependent or related.

Once this is done, a series of testable statements is made by the coordinator which relate to the factors. In the case of a labor saving device, E_{11} (See Table I) this might read "Labor rates for this class of labor will rise six percent per year" E_{12}. As a statement measuring the overall effect, we would also need to evaluate the event "Labor rate adjustment by union contract reflecting six percent productivity increase" E_{13}. For the product with improved performance E_{21}, we might say "A product with this feature can be marketed at a $5.00 premium to current competitive items" E_{23}. A related event would be "Introduction of a competitor's product with this feature" E_{22}. These events must be clear enough to allow an evaluation of their probability of being true.

TABLE I

	Unconditional Probability	Cross Correlation	Cross Impact
Event Set 1: Labor Saving Device	E_{11}	E_{12}	E_{13}
Event Set 2: Product Improvement	E_{21}	E_{22}	E_{23}

Further, we should point out that it is possible for E_{23} and E_{12} to be cross-impacted, given that the union might ask for a wage increase due to larger business revenues.

The analyst might want to plot the probabilities for each sample space above, as illustrated in Figure 1, to show an increasing probability over time.

Step Four: Likelihood assessment.—For each of the statements made a suitable group of experts, most of whom would be external to the firm, is selected capable of weighing the probability of occurrence. For the labor-saving device, this might be labor economists or personnel specialists. For the product whose performance is enhanced, this could be a sales group or a panel of consumers of the product. These should be people knowledgeable in the area; seeking a single "expert" is to be avoided. It will be necessary to employ the Delphi procedure of resubmitting those events which do not achieve a reasonable consensus on the first pass.

Step Five: Opportunities Matrix.—The assessment is made in terms of probability of occurrence within selected time frames. For each time frame, the Bayesian algorithm is applied by multiplying the probability times the dollar value of the event. The details for this procedure have been given in Reference 29.

The summary of the above steps produces a final product grouping which shows the collected ideas, their estimated costs and benefits, and a probability of the revenues from those benefits being achieved. This is arrayed from top down, with the package of ideas having the highest probabilistic revenue relative to costs (from the Bayesian algorithm) on top and downward to those with lower and perhaps negative returns. With such a list in hand, it is much simpler for management to probe for new product ideas, and to discuss with those in research those areas with the highest promised returns. It may also be possible to discuss, using the earlier estimates, the possible tradeoff of additional expenditures on favorable projects in order to reduce the time necessary to produce the benefits.

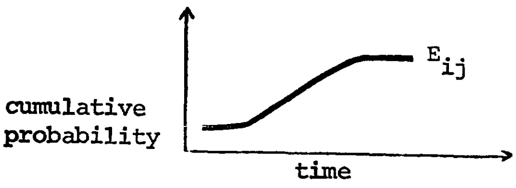

Figure 1

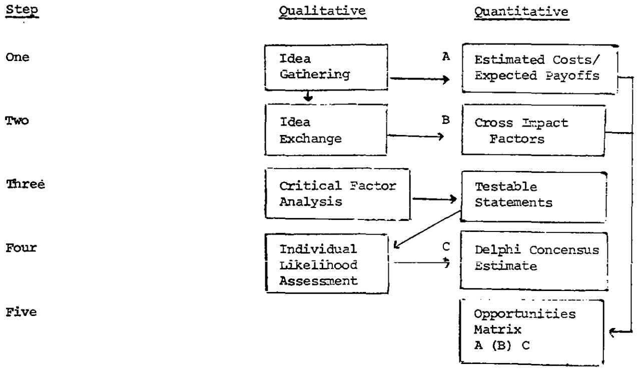
The five steps could be represented as a flow chart:

OPPORTUNITY ANALYSIS PROCESS



SUMMARY

We have outlined a procedure for assessing in monetary terms the likely value of an innovation or group of innovations to a corporation. This is done using the principles of the Bayesian algorithm and the [illegible] technique, as modified. The extension of the procedures from those used in impact analysis[20] has required certain changes which are discussed.

ACKNOWLEDGMENT

The authors thank Dr. Mitchel F. Bloom, University of Puget Sound, for his review and constructive critique of the original draft of this paper.

A "unique number" generator

by ARMEN NAHAPETIAN
Arya-Mehr University of Technology
Tehran, Iran

ABSTRACT

In many computer systems and applications, the need arises for the software to generate unique numbers or names for the identification of dynamically generated entities.

Such a generator is described here which produces new numbers and reuses numbers released by the system.

An analysis is carried out to determine the storage requirements of the generator in relation to the number of requests that can be accommodated.

INTRODUCTION

In computer applications, situations often arise where the software dynamically generates entities that must be named for future reference.

Examples of such cases are compilers that generate names for temporary locations in assembly language, graphic systems that generate names for created subpictures, operating systems that generate internal names for jobs submitted or files created, etc.

The generation of unique names for such cases can, of course, be accomplished by incrementing a counter each time a new name is requested. The resulting integer can directly be used as a name or converted to an appropriate base if an alphabetic or alphanumeric name is needed.

For example, to generate five-character Fortran identifiers, the number can be converted to a mixed radix integer

$$a_{26}\, b_{36}\, c_{36}\, d_{36}\, e_{36},$$

the first digit representing a letter and the rest alphanumeric characters.

The method just described has the following drawback. Since in most applications the names generated are used for a period of time and then released; eventually the counter will be incremented to its limit, even if the set of names currently in use has a much smaller size than this limit.

With additional restrictions imposed on the names, the limit of the counter might be reached even sooner. If, for example, names were restricted to one letter followed by one digit, this limit would be 260.

To somewhat overcome this inefficiency, the number generator to be described can be used which not only generates new names, but also tries to reuse as many of the names released as possible.

THE GENERATOR

The generator works by simply storing the released numbers (names) in a fixed-size stack. If a new number is requested the stack is tried first and only in case of an empty stack is the counter incremented to generate a new number.

Since the size of the stack is finite, cases might arise where a returned number cannot be pushed onto a full stack. Thus, the reuse of such numbers is eliminated. The results obtained in section three can be used for choosing an appropriate stack size based on the counter limit and the total number of requests anticipated.

The algorithms that follow represent the "request" and "return" operations for the unique number n. The initial value of the variable "pointer" should be zero and "counter" must initially be set to the smallest integer that can be represented or is appropriate for a name. "Stacksize" and "countlimit" represent the maximum capacity of the stack and the maximum count of the counter, respectively. The array "stack" and integers "pointer," "countlimit" and "stacksize" are assumed to be declared globally.

```
procedure request (n);
integer n;
Begin
  if pointer>0 then begin n←stack (pointer); pointer
                 ←pointer-1 end
                 else if counter=count-
                 limit then overflow
                        else begin
                               counter←counter+1;
                               n←counter
                               end
end request;
```

```
procedure return (n);
integer n;
```

```
Begin
  if pointer < stacksize then begin
                              pointer ← pointer + 1;
                              stack (pointer) ← n
                              end
end return;
```

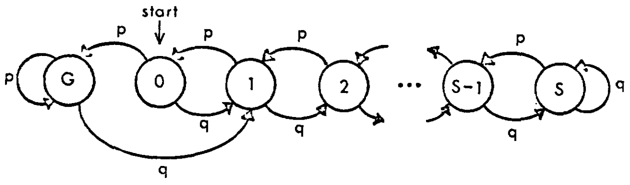
THE STACK SIZE

To determine the minimum stack size for a specific application, in addition to the number of names needed and the counter capacity, statistical information on the occurrence of the requests and returns must be provided. Of course in any case the stack size need not be larger than the number of distinct values the counter can produce.

The results of the following analysis can be used in cases where the occurrence of requests and returns (transitions) can assume to be a Markov process,[1] i.e., the probability of a transition being a request or a return is independent of previous transitions. The results can even be used in applications where a large number of request lead into a steady state Markov process, and a large number of returns terminate the process. Since to determine the stack size in such a case one need only consider the steady state (at the beginning of the process the stack is almost empty, and at the end, most numbers lost due to a full stack will not be needed again for reuse).

Assuming a probability p for a request and $q=1-p$ for a return at each transition, the state diagram and the transition probability matrix of the process are shown in Figure 1.

The number representing each state is the number of elements in the stack of size S and the state represented by G is the state where each time entered (due to a request) a new number must be generated by the counter due to an empty stack.



$$\begin{array}{c|cccccccc}
 & G & 0 & 1 & 2 & & & S-1 & S \\
\hline
G & p & 0 & q & 0 & \cdots & 0 & 0 & 0 \\
0 & p & 0 & q & 0 & \cdots & 0 & 0 & 0 \\
1 & 0 & p & 0 & q & \cdots & 0 & 0 & 0 \\
\vdots & & \vdots & & & & & \vdots & \\
S-1 & 0 & 0 & 0 & 0 & \cdots & p & 0 & q \\
S & 0 & 0 & 0 & 0 & \cdots & 0 & p & q
\end{array}$$

Figure 1

Using T_i to represent the expected number of transitions needed to reach state G from state i, and assuming C to be the number of distinct values the counter can produce, the expected number of transitions for the generator to overflow can be shown as

$$T_{over}=T_0+CT_G$$

i.e., the expected number of transitions for entering state G, $C+1$ times starting from state zero.

And the expected number of transitions before overflow occurs, being one less than T_{over} is

$$T=T_0+CT_G-1$$

T_0 and T_G can be obtained from the following set of equations

$$\begin{aligned}
&T_G=p+q(1+T_1)\\
&T_0=p+q(1+T_1)\\
&T_1=p(1+T_0)+q(1+T_2)\\
&T_2=p(1+T_1)+p(1+T_3)\\
&\cdot\\
&\cdot\\
&\cdot\\
&T_{S-1}=p(1+T_{S-2})+q(1+T_S)\\
&T_S=p(1+T_{S-1})+q(1+T_S)
\end{aligned}$$

to be

$$T_G=T_0=(1/p)\,(1+a+a^2+\ .\ .\ .\ a^S)=(1/p)\,(a^{S+1}-1)/(a-1)$$

where $a=q/p$, thus the expected number of transitions before overflow occurs is

$$T=(C+1)\,(1/p)\,(a^{S+1}-1)/(a-1)-1$$

And finally the expected number of requests that can be accommodated with a stack size of S and counter capacity of C,

$$R=pT=(C+1)\,(a^{S+1}-1)/(a-1)-p$$

which for $p=q=1/2$ reduces to

$$R=(C+1)\,(S+1)-1/2$$

CONCLUSION

A number generator was introduced that issues a unique number each time a request is made, trying to save and reissue returned number by using a stack.

The generator can be used for generating alphanumeric names by converting the generated numbers to an appropriate base.

Assuming the request and return transitions to be a Markov process, formulas were derived for the expected number of requests that can be accommodated in terms of the maximum capacities of the counter and the stack.

An on-line test program for peripheral devices

by AKIRA TANEDA, HIKARU OKU and DAIJI NAMBA
Nippon Telegraph and Telephone Public Corporation
Yokosuka, Japan

ABSTRACT

An on-line test program is a program to detect troubles in devices being used in service or to assure correctness of their operation. Therefore, it is required that the on-line test program is able to safely certify device functions without any disturbance to the service. That is, since the on-line test program interrupts usual guards of an operating system, it may cause disturbances to the service, for example, by breaking contents of media used in the service. Therefore, the requirement to the on-line test program is not only to satisfy test functions but also to remove each disturbance cause which seems to affect the service. In addition, it is necessary to test automatically to improve the capability of the program and to avoid disturbances resulting from misoperations.

This paper describes design objectives, service interruption countermeasures and automatic test techniques for an on-line test program designed mainly to test peripheral devices of DIPS (Dendenkosha Information Processing System), that is a standard data communication system in NTTPC (Nippon Telegraph and Telephone Public Corporation).

The fault detection ability of this program was confirmed at a satisfactory level, according to experiments involving artificial device troubles.

INTRODUCTION

Information processing devices carry out important missions in every social activity as well as economic activity. Therefore, it is very important to assure their reliability. Especially, higher reliability is demanded in data communication systems offering on-line services.

It is natural that a system down condition or information destruction resulting from device troubles, would cause serious damages, not only to a specific user but also to every user. Therefore, generally, device trouble detection, trouble influence prevention and trouble recovery are taken into consideration by means of countermeasures involving redundant design in a device, multiple installation of the same devices, fail soft control and so on, in a system design stage of a data communication system.

On the other hand, after the system is operational, periodic inspections and adjustments of devices to reduce the mean time between failures (MTBF) and rapid repairs to shorten the mean time to repair (MTTR) are required as maintenance operations.

In these maintenance operations, it is necessary to certify device functions after inspections and adjustments, to gather failure information about troubled devices, to locate failures and to certify device functions after repairs. Tools for these confirmations are maintenance panels, test equipment, test programs and fault locating programs. Each has individual characteristics and application fields, so they are not able to be compared simply with each other. However, on-line test programs, whose handling is easy and which do not require any special hardware for confirmation, are the most suitable for certifying device functions with the service in a short time without involving manpower.

It is not only necessary to satisfy test functions, but also to avoid disturbances to the service, because on-line test programs access together with service to devices to be tested.

The authors developed an on-line test program in DIPS (Dendenkosha Information Processing System) that is a standard data communication system in NTTPC (Nippon Telegraph and Telephone Public Corporation).

This program mainly tests functions of peripheral devices (file memories and low speed input output devices), under the configuration shown in Figure 1 for example. The reason why peripheral devices are selected is that peripheral devices have mechanical parts, so they cause trouble frequently and require many inspections and adjustments, as well as there being many devices in a system. In an example of a data communication system in NTT, maintenance tasks for peripheral devices run into 70-80 percent of all maintenance tasks in a system.

The fault detection coverage of this program is about 80 percent of all circuits in the devices according to the experiment by means of artificially induced troubles.

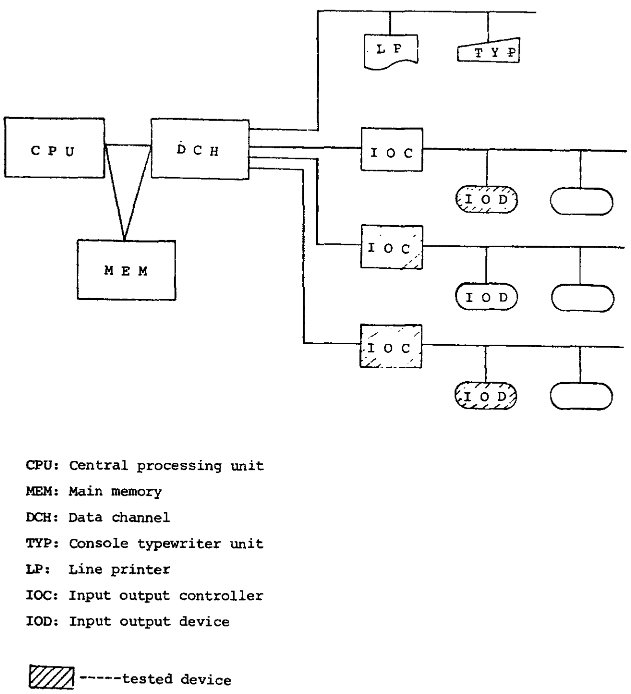

Figure 1—Test system configuration (example)

Design objectives, service interruption and misoperation prevention measures and evaluation of the program are covered in the following.

DESIGN OBJECTIVES

The following main design objectives are set for the test program:

(1) Making detailed tests
(2) Preventing service interruptions
(3) Making operation easy

(1) Making detailed tests—Generally, devices must handle many status transitions and many series of output patterns corresponding to many series of input patterns. Testing a certain function perfectly is confirmation of all status transitions and series of outputs corresponding to all inputs. It is impossible technically and economically to perform such tests for all functions of a device by program. Thus, the test program is not essentially perfect. Therefore, an important objective is how to increase the fault detection ability of the test program within technical and economical feasibilities by making detailed test items. To accomplish this objective, it is necessary to inspect a status transition and a series of outputs corresponding to at least a series of inputs for all functions which can be tested by the program.

(2) Preventing service interruptions—The test program interrupts usual guards for testing of an operating system. For example, it accesses troubled devices or uses inhibited commands to usual users. Therefore, running of the test program may seriously disturb the system service. It is necessary to try to find the cause of disturbances resulting from running the test program and to take the most suitable measures to meet any problems encountered.

(3) Making operation easy—There are many kinds of peripheral devices in a system. Even if variations of a kind of device are neglected by an operating system, the test program is aware of their varieties in many cases. In addition, it is necessary to select the most suitable program corresponding to status data tables of the operating system for devices to determine the test partition.

It is difficult for an operator to be aware of the varieties and to select the most suitable test program; in addition, he may cause disturbances resulting from misoperations. Therefore, test automation, such that a test program corresponding to these test conditions being automatically scheduled and executed, is required.

Ways to achieve these design objectives are mentioned in the following.

WAYS TO SATISFY TEST FUNCTIONS

As mentioned previously, it is necessary to test all device functions by using at least one series of inputs corresponding to each function. It is impossible to perform tests using all series of inputs.

Therefore, it is desired to test at least all functions prescribed by the logic specification of the device, by using one very severe data pattern for devices corresponding to each function. For example, when mechanical parts are tested, they shall be operated, insofar as possible, within the boundaries of their performance. When logical parts are tested, it is necessary that tested circuits be covered in more detail by being tested repeatedly with random data patterns.

SERVICE INTERRUPTION PREVENTION

Service interruption prevention is the most important problem in the design of an on-line test program. Causes which are considered to disturb the service are shown in Table I. Appropriate actions are required to remove these causes.

Incorrect access to a troubled device

In accessing to a troubled device by the on-line test program, there is a possibility of destroying the written information on the media of a correctly operating

TABLE I—Interruption Causes

ITEM	OUTLINE
Incorrect access to nomal devices	Destruction of contents in media in the service resulting from misoperations of troubled tested devices.
Garbage	Test trace which may remain after test program execution is stopped by some reasons.
Conflict with the service	Conflict with the service about system resouces which a test program is going to use.

device caused by incorrect action to it. This probability is very small. However, once incorrect access happens, the disturbance may cause widespread deleterious results on the service. Some examples of countermeasures are:

(1) In case of channel (CH) or input output controller (IOC) trouble, there is a possibility that input output operation of a testing system might cause incorrect access to an input output device (IOD), which doesn't belong to the testing system, by means of the incorrect behavior of CH, IOC and to destroy the recorded data in the media used in the service.

When the accessing route to the device consists of a dual path, assigning one path for the test and the other path for the service, it is possible to prevent trouble as shown in Figure 2. In this case, IODs in the service are reserved by using the device reserve command via the path for the service.

Functions of this command are to tie a specific IOD to a specific path. Namely, by tying the devices to the path for the service, each device for the service is free from incorrect access by the tested device.

(2) In the case of the band selector trouble in a magnetic drum memory, there is a possibility that another band could be accessed instead of the allocated band for the test and the recorded information on the correct band might be destroyed.

Accordingly it is necessary that band address information for the test must be fully checked before the test is started by the command.

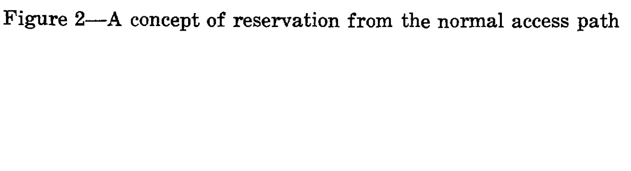

Figure 2—A concept of reservation from the normal access path

Garbage prevention

Garbage is defined as traces that may be left when running a test program is completed or interrupted. Two types of garbage are considered. One is the trace left on the control table of the operating system, for example, the discrimination flag to indicate whether each device is on test or not. The other is the trace left on the hardware of each device for example, the repeated status of the command. These traces must be cleared after the test is finished, because, later on, they will become causes of service disturbance. When a test is stopped due to the system being down, these traces are cleared at the time of restart of the operating system. However, when the test is stopped by operator command and abort is caused, the traces must be cleared by the test program itself. Moreover, in order to double the guard against service disturbance, it must have the function of clearing garbage by operator command.

Preventing service conflict concerning resources

There are conflicts with the service concerning all the system resources needed for the test.

To prevent the system from serious disturbance caused by interruption of the service by this conflict, the resources used in time sharing mode or space sharing mode, such as CPU or main memory, are to be owned by both the test system and the service. Resources which are difficult to hold in common (such as the device being tested) are owned exclusively by the test system.

Holding resources in common or exclusively for the test program results in lowering the processing power of the system. In short, it increases the overhead. Therefore, fundamental methods to deal with overhead are to shorten the testing time and to decrease the amount of resources needed for the test. They are as follows.

(1) In regard to CPU overhead, most of the test transaction is related to input-output operation, due to the nature of the test program, and the effect on CPU time is very small.

But, as some trouble might arise when the system is busy furnishing the service, a restriction must be imposed wherein a test program can't be used at such a time. Moreover, setting the test program as a background job for the service, the service should be done primarily.

By these means, overhead to CPU time for service can be made almost negligible.

(2) By avoiding the exclusive possession of devices necessary for the test insofar as possible and holding

them in common with service system, effective usage of resources can be accomplished.

However, in case the resources must be possessed exclusively due to test necessity, in order to prevent occupation for resources for a long time by hardware errors or program bug, it is necessary to watch the time while resources are used for the test. After a limited time is over, the test should be stopped, and resources must be returned to the service. Also the quantity of main memory must be minimized.

(3) The time for testing each device is usually limited to within 20 minutes. This is decided by considering avoiding exclusive possession of system resources for a long time and considering the necessary time for maintaining each device.

Accordingly some tests which need a long time to run (for example, the test for initializing the media) must be omitted, except in the case when a special order by the operator is being accomplished.

Considering the measures mentioned above, the time for the test could be shortened and system resource availability increased. After all, overhead to the service could be decreased.

OPERATION SIMPLIFICATION AND MISOPERATION PREVENTION

If an operator instigates a test which may destroy information on the active device by overwriting, for example, it may cause an extremely adverse disturbance to the service where the program runs as it is. Because a man sometimes commits careless mistakes, it is necessary to run the program as automatically as possible. When the operator intervenes, simple operation and prevention against misoperation are essential.

Test automation

For test automation, the test program should start automatically, through the detection of the trouble device by the operating system without the intervention of an operator. However, as explained in the previous section, it cannot be uniquely decided as to whether the system should be tested during the most busy time or not, and whether a long test should be performed or not. Therefore, it was decided that the program should start according to the start command by an operator.

Items that should be decided by the operator's judgment for test program execution are the tested device address number, execution of a test requiring long running time and so on.

Necessary information to select optimal test programs is classified according to the following attributes.

Attribute 1: noted on the peculiarity in running the test (whether operator intervention is necessary or not, whether the running time is long or short, and so on).

Attribute 2: based on the restriction of the I/O macro command (logical state of a tested device and its access path, whether the inhibition of the interruption is necessary or not and so on).

Attribute 3: media for tests noted (whether the volume for maintenance is necessary or not).

Attribute 4: based on peculiar conditions of the device (kinds of devices and so on).

TABLE II—Block Select Pattern

BIT POSITION	O B S P	A B S P
b_0	Block class is A	Block class A is able to run
b_1	Block class is B	Block class B is able to run
b_2	Block class is C	Block class C is able to run
b_3	Block class is D	Block class D is able to run
b_4	Block class is E	Block class E is able to run
b_5	Block class is F	Block class F is able to run
b_6 - b_{15}	Another block attribute	Parameters designated by an operator
b_{16} - b_{31}	Hardware inherent conditions corresponding to the test item	Hardware inherent conditions corresponding to designated device.

Some test items gathered due to their attributes are called Block.

A combination of these attributes decides the test items running condition (test condition). This test condition is prepared beforehand as a kind of data, called the Original Block Selected Pattern (OBSP), for every proper test item.

On the other hand, when the test running command is input, the parameters of that command and the condition of the tested devices decide the condition of the test item which can be executed. This is called the Actual Block Select Pattern (ABSP). A part of OBSP and ABSP is shown in Table II. The meaning of the block class (A—F) in the table is shown in Table III.

TABLE III—Block Class

Test condition \ Test item	Test not required interruption mask		Test required interrup tion mask*
	Test not occupying a channel	Test occupying a channel**	
Standard	F	D	B
Optional	E	C	A

* Test which occupies CPU during testing time

** Test which occupies channel during testing time

The program selects the only block which has the OBSP corresponding to ABSP.

According to such an automatic selecting function of the test items, an operator can test safely without being concerned with differences in the test programs, the states of tested devices, the kinds of devices and so on.

Protection against misoperation

Misoperation that causes extremely adverse effects to the service, include incorrect appointment of the tested device, incorrect mounting of the medium and the wrong establishment of the pseudo-trouble, for example.

For these misoperations, the following countermeasures apply.

(1) For the wrong appointment of the tested devices, it is sufficient to limit the test to the active device unless the area for test is prepared in that media.

(2) For incorrect mounting of a data storage media, a usual countermeasure is to use a specific medium for test in order to protect the media for service. Therefore, when the medium for test is not mounted, the program notifies the operator before it permits execution of the test.

(3) The test by pseudo-trouble is required to test the hard-core, such as the trouble detecting circuit and the trouble diagnosing circuit.

Misoperation in such a test is extremely adverse to the system and is not guarded by the program. Therefore, at least such a test should not be performed under the operating system in service.

Even if it can't satisfy the necessary condition, it is thought inevitable to cancel some test items in order to avoid the disturbance. By following such procedures, the safety of the test will be increased much more.

PROGRAM STRUCTURE

The structure of this test program is shown in Figure 3.

The test control part, the part of controlling and helping test execution, mainly carries out the function shown in Table IV.

The test execution part covers whole necessary test items.

EVALUATION

In previous sections, design objectives and implementation are described.

Performance of the test program and its influence on service by the test execution will be described in this section.

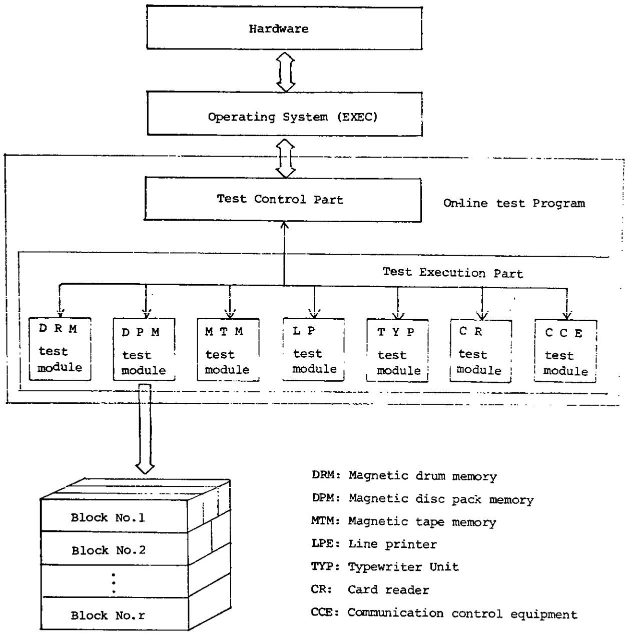

Figure 3—On-line test program structure

Performance

Incompleteness of testing functions is caused by selecting only those test items which can be executed automatically. In addition, tests using perfect data patterns are not able to be implemented. In relation to this problem, an example of results of experiments using pseudo-troubles is described for a magnetic disc pack memory (DPM) and a lineprinter (LP) in DIPS.

TABLE IV—Summary of Test Control Part Function

No.	FUNCTION OF TEST CONTROL PART
1	automatic running control
2	command processing
3	task control
4	event processing
5	prevention disturbance
6	setting up test conditions
7	resource management
8	macro processing

(1) Experimental method and results—Pseudo-troubles are made to stick logic signals at '0' or '1' at the terminals of connectors for logic circuits packages. This makes single and solid trouble.

Several hundreds of troubles are set, selected at random from logic diagrams of the devices. The test program performs each test for the pseudo-troubles and is checked to determine whether it detects pseudo-troubles or not.

Experimental results are shown in Table V.

(2) Consideration—Circuits that can't be activated by the program as shown in Table V are circuits related to the maintenance panel and so on, whose troubles can't be detected by any programs. Therefore, problems are in parts where the pseudo-troubled circuits were justified normal in Table V. These parts consist of (A) parts that can't be tested automatically by the program and (B) parts that can't be tested as a result of incompleteness of data patterns.

Since (A) parts are mainly hard-core for the diagnosis and their test requires setting pseudo-troubles, the test automation can't be implemented.

These parts form about 10 percent of all circuits in DPM and about three percent in LP.

On the other hand, about 17 percent of pseudo-troubled circuits in DPM and about four percent in LP were justified as shown in Table V.

Therefore, it is considered that the remaining seven percent in DPM and one percent in LP belong to (B). As mentioned above, it is almost impossible technically and economically for these parts to be perfectly covered. Thus it is considered that this amount of defects in fault detection is inevitable.

Defects in fault detection caused by (A) are mostly related to hard-core prepared for fault locating program. Such a hard-core is not used by the operating system or the service, so it is not essential to test them.

It was confirmed that the test program described in this paper can satisfy more than 90 percent of trouble detection ability.

TABLE V—Experiment Result Due to Pseudo-trouble

DEVICE	NUMBER OF PSEUDO-TROUBLE POINTS	PERCENTAGE OF TROUBLE DETECTION	PERCENTAGE OF TROUBLES NOT ABLE TO BE DETECTED BY ANY PROGRAM	PERCENTAGE OF TROUBLES JUSTIFIED NOMAL BY THE TEST PROGRAM
DPM	311	72%	11%	17%
LP	213	83%	13%	4%

Test influence on service

There are test items that have to occupy an access path (channel, IOC) to accomplish a test, for example the test to confirm whether a channel is busy. In the case of occupation of one of the dual paths for a test, if some troubles occur at the same time at the other of the dual paths, service for some file users connected to this path becomes impossible. When a single path is connected to some on-line devices, the path occupying test is not performed. In the case of occupation of one of the dual paths for a test, probability P_f for the other path (CH,IOC) to encounter a trouble is given by

$$P_f = 1 - e^{-\alpha t/tm}$$

$tm = 10^9/f_{ch.ioc}$ $f_{ch.ioc}$; FITs
where t; test execution time of the path
α; path occupying rate tm; MTBF

α is about 20 percent, if t is one hour per day then P_f is about 0.002.

This means that trouble in the other path during the test execution occurs once every five thousand days. Therefore, it is clear that this probability P_f is negligible.

CONCLUSION

Design objectives, methods to realize them and evaluation about the on line test program have been mentioned.

It was shown that functions required for testing devices were satisfied by using at least one severe data pattern.

Disturbances caused by devices were mentioned along with countermeasures preventing disturbances to the service, and those caused by men were discussed along with countermeasures preventing misoperations. So, it became clear that the test programs, produced by ways mentioned in this paper are able to be utilized effectively and had little adverse influence on service. These test programs are expected to allow device maintenance to become easier and the cost of maintenance will become lower by its usage.

Structure of the ELF operating system*

ABSTRACT

This paper describes the ELF operating system structure and discusses a number of considerations which influenced its design. Several applications supported by the system are presented in relation to that structure. The software tools used for constructing and maintaining the system are described, and several implementation problems which were encountered are presented.

INTRODUCTION

ELF is a multiprogrammed operating system which provides a set of programming tools for a computer network environment. The system is implemented for the DEC PDP-11 series computers and is being used to support a number of research applications at various sites in the ARPA network.[1,2]

ELF development was started in early 1973 at the Speech Communications Research Laboratory in Santa Barbara, California. An initial version of the system provided multi-user terminal support capability for network access.[3] In early 1974 that system was tested at several network sites and a decision was made to expand the system structure to provide a more general operating system environment. An initial version of the expanded system was operational at the beginning of 1975, and is currently being used at 30 network sites.

Development of the ELF** system was motivated by the need for a flexible network/user interface. The requirements for such an interface included multi-user terminal access to remote interactive systems, peripheral support for transfer of locally-stored files, real-time data acquisition facilities, and a test-bed for research problems related to computer networks. It was required that these functions be implementable with a variety of hardware and software configurations and be maintainable using the communication facilities provided by the network.

Design of the ELF system draws upon a number of techniques used in other operating systems described in the literature. For example, ELF enables sharing of hardware resources (processor, memory, and I/O devices) by providing a multiprogrammed virtual memory environment; ELF implements a tree structure of processes similar to that found in the TENEX,[4] UNIX,[5] and XDS 940[6] systems.

The ELF system has been structured in a hierarchical fashion in order to simplify its specification and testing, and to provide flexibility of system configuration. Real-time constraints imposed on the system force a compartmentalization of critical paths which disable response to interrupts; limits are placed on the maximum duration of these paths.

A robust inter-process communication facility is incorporated in the system in order to facilitate communication with remote programs (processes) in the network. Programs which utilize ARPA network protocols[7,8] to access remote resources (e.g., files) utilize this inter-process communication facility extensively.

A command language interpreter allows the system to accept requests for service from user terminals, and provides functions for controlling individual user programs in the virtual memory environment provided by the system. A library of these user programs provides capabilities for terminal access to remote systems, Input/Output of digitally-sampled data, transfer of files, or the debugging of new system facilities.

This paper describes the ELF operating system structure and discusses a number of considerations

** The name ELF is German for "eleven," and is somewhat germane to the naming of IMPs in the ARPA network.

which influenced its design. Several applications supported by the system are presented in relation to that structure. The software tools used for constructing and maintaining the system are described, and several implementation problems which were encountered are presented.

SYSTEM ORGANIZATION

At the center of the ELF system exists a set of modules, collectively referred to as the Kernel, which provides a set of primitive functions for outer-level procedures, and performs tasks which allow the system's processor, memory, and I/O devices to be shared among a set of processes. Kernel primitives perform functions such as dynamic creation of processes, process synchronization, allocation of virtual storage, scheduling of I/O requests, and sharing of an interval timer.[9]

The selection of procedures which reside above the Kernel varies somewhat and is determined by the range of applications to be supported by a system. In ELF systems which provide multi-user terminal support, a set of procedures known as the EXEC provides a mechanism for allocating system resources to users. The notion of a "Job" is utilized at this level to provide an encapsulation of the resources associated with a given user: a tree structure of processes, a collection of open files, allocated virtual storage, and so forth. EXEC procedures utilize Kernel facilities to create Jobs, interpret user commands, run user processes, and maintain the system file structure. User processes which are run under the EXEC provide a variety of functions, including terminal access to remote interactive systems on the network. An illustration of the layered system structure is shown in Figure 1.

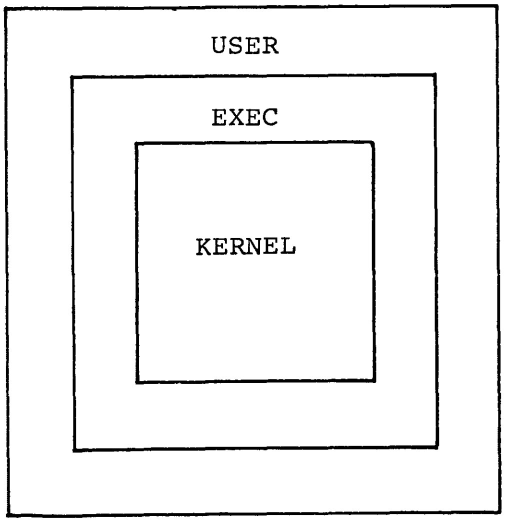

Figure 1—An example of the layered ELF system structure

The Network Control Program (NCP) is another module which may be selected. The NCP uses facilities provided by the Kernel to support a communication mechanism between local and remote processes in the ARPA network. It consists of a set of procedures which establish and control data flow on a set of connections using the ARPA network protocols [Ref].

THE ELF KERNEL

The ELF Kernel concerns itself with three primary areas. The first of these, Processor Management, controls distribution of the processor among a number of asynchronous processes and provides for process synchronization and mutual exclusion. The second major portion of the Kernel is Storage Management, which handles the allocation of physical and virtual storage available to processes in the system. The third portion, I/O management, controls the interaction between processes and external devices, and additionally provides a facility for inter-process communication.

Processor management techniques

The Kernel provides a set of system calls which allow processes to be created, compete for processor service according to priority, inter-communicate, or be terminated. A process is characterized by a virtual program counter, a set of general-purpose registers, a stack, and a queue of elements which are called event messages. Processes are created in the ready state, and remain ready until they are blocked by calling a system primitive for synchronization or mutual exclusion. A scheduling program in the Kernel maintains a list of processes which are in the ready state and transfers control to the highest priority ready process.

Process synchronization

A process synchronization mechanism similar to the message buffer scheme described by Brinch-Hansen is implemented.[10] Each process owns a queue of event messages sent to it by other processes. A process can block itself until a message is added to its event queue by issuing a system primitive called WAIT, which places the process in the "waiting" state if its event message queue is empty. If a process issues the WAIT primitive and elements exist on its event message queue, the process is left in the "ready" state, the event message at the head of its queue is removed and is returned as a parameter.

Event messages are placed on a process' event queue by another process which invokes the SIGNAL primitive, specifying a destination process name and event message. When a process awakens, it receives the 24-bit message in addition to the name of the process which signalled it. In general, the 24-bit message field is interpreted by ELF system processes as an 8-bit "event code" and a 16-bit "data" field. While this assignment of bits is a convention for system processes, higher-level (user) processes which choose to synchronize using SIGNAL and WAIT may use the 24-bit event message field arbitrarily. A system primitive exists to allow a process to wait for a specific event-code.

Examples of synchronization primitives are shown below:

WAIT→⟨PNAME, EVENT, DATA⟩
SIGNAL ⟨PNAME, EVENT, DATA⟩
WAIT-SPECIFIC ⟨EVENT⟩→⟨PNAME, EVENT, DATA⟩

Processor scheduling

Every process that is in the ready state resides in a priority queue that corresponds to a priority level that it was assigned when it was created. The ability of a process to gain control of the processor is a function of the priority queue in which it runs and its position in that queue.

The position of a process within a given queue is determined according to its behavior. A daemon process receives control at regular intervals (currently, every 250 ms.). When it receives control it re-orders the processes within each queue according to their utilization of the processor during the preceding time interval. A process' composite priority is a combination of the priority queue in which it resides and its position in that queue; the process in control of the processor at any point in time is the process at the head of the queue with the highest priority value. This scheme effects a "round-robin" scheduling technique for compute-bound processes while assigning a higher composite priority to processes that are not compute-bound.

Protection mechanisms

Because processes rely on the validity of messages received on their event queues, a protection scheme is required to prevent processes from receiving messages from other non-authorized processes. This mechanism is implemented by means of a capability value which is assigned to a process when the process is created, and may change as the process makes calls to various primitives in the operating system. The access rights of a process executing at a given capability level are a subset of the rights allowed a process with a lower capability value.

A process may be assigned a "branch name" which identifies the processes and all sub-processes in the tree below it. (The assignment of branch-names to processes is utilized by the ELF EXEC in identifying a process as a member of a particular Job.) Processes which have the maximum capability value can SIGNAL any process in the system; processes which are running with lower capability values are limited to the set of processes having identical branch-names.

Mutual exclusion techniques

Processes may request mutual exclusion by means of binary semaphores. Kernel primitives allow dynamic assignment of semaphore names, and provide Dijkstra's P and V operations on those semaphores.[11] Entries may continue to be added to a process' event message queue while the process is waiting for exclusive access to a resource.

Process creation and termination

A process is created by issuing a CREATE-PROCESS system call, specifying a starting address, set of registers, capability value, priority level, and an event code to be used to SIGNAL the creating process when the created process halts itself or encounters a system error (e.g., invalid parameter specification to a Kernel primitive). The system maintains a relationship between each process and its creator, and keeps a list of all processes created by a given process.

A process may be frozen by means of the FREEZE-PROCESS primitive. This causes the process to be blocked and its creator to be signalled with an event message containing the name of the process which was frozen. At this point, the process' registers may be examined or modified, the process may be "thawed," or the process may be terminated. Entries may continue to be added to the event message queue while a process is frozen.

A process may only be terminated by its creator. When a process is terminated, all the processes it has created are also terminated and any resources associated with it (such as outstanding event messages) are released.

Storage management techniques

The Storage Management portion of the Kernel provides a mechanism for creation of a number of virtual address spaces and controls their mapping into physical memory. An address map defines the relation between a user's virtual storage and physical storage addresses. A specific address map becomes associated with a process when the process is created. Any number of address maps may be defined for processes running in user mode; there is a single address map defined in kernel mode, and this is utilized for system (Kernel) primitives. The processor switches from kernel mode to user mode when it gives control to a process; it switches from user mode to kernel mode when a user process makes a system call or is interrupted.

Storage management data structures

There are two data structures used to maintain the relationship between virtual and physical storage. Each virtual address space is mapped as a set of 4096-word pages. A Virtual Storage Map (VSM) is an array which describes the state of each page in a virtual address space. A given page may be undefined (a "hole" in the address space), defined but non-resident, or defined and resident. Each entry in the VSM which describes a resident page contains a pointer to the page in physical storage. A virtual page may also be "read-only," in which case the hardware memory mapping facilities are utilized to prevent modification of shared or protected data. A Virtual Storage Map exists for each virtual address space. Kernel primitives exist for the creation (allocation) of a new virtual address space, and the creation of pages within an address space.

The Physical Storage Table (PST) indicates the relationship between physical pages and the (virtual) pages which occupy them. A mechanism for sharing of virtual pages is provided by the system; in the case of shared pages, the physical storage table points to the head of a linked list of VSM entries. The data structure used to implement this mechanism is shown in Figure 2.

A Virtual Storage Map identifier is included in the system state information for each process. This value uniquely identifies the user address space in which a process is running, and is a logical extension of the process' program counter, as shown in Figure 3. Hardware storage mapping register values are derived from the Virtual Storage Map when the scheduler transfers control to a process.

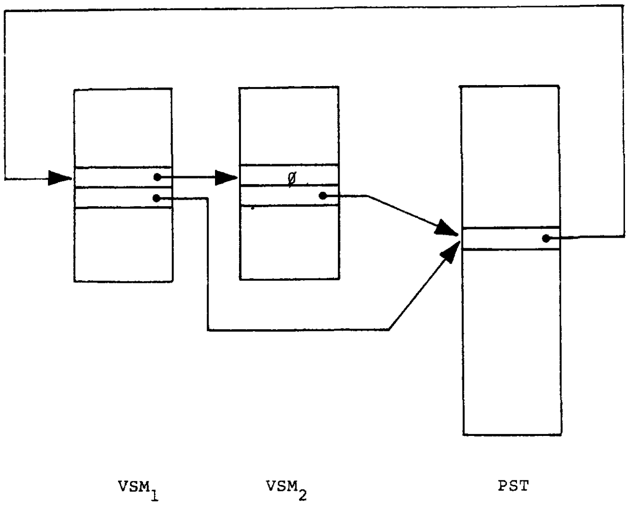

Figure 2—Storage management data structures

Storage management primitives

A set of Storage Management primitives enables a process to allocate a new virtual address space, to allocate pages within an address space, to cause pages to be shared between address spaces, or to block transfer data between address spaces. A new address space is created using the primitive CREATE-VSM, which returns an 8-bit VSM identifier for the new address space. The address space (and all physical storage associated with it) is released when a process issues a DELETE-VSM primitive or when the process which created the address space is terminated.

Creation of a new address space does not allocate any pages within it. A process may define (allocate) new pages within an address space by issuing a DEFINE-PAGE primitive, which allocates a new page in virtual storage and defines the specified page. The caller specifies the Read-Write/Read-Only status of the page. The process may optionally cause the page to be mapped into a page in another address space, causing the pages to be shared between the address spaces. For certain applications (such as system debugging) it is necessary to map a user page into an arbitrary physical page of memory. A privileged (i.e., capability-restricted) primitive allows a process to perform this function.

System primitives require the ability to access parameters which are passed as arguments by a calling process. A system call exists for transfer of a block of data between two address spaces. A primitive may request the identifier of the previous address space in order to obtain or return parameters to its caller.

Hierarchical procedures

ELF allows the establishment of a hierarchical structure of system primitives by means of a run-time binding mechanism. This permits a modular extension of system facilities, such as the addition of file system functions, without requiring modification of the Kernel. The mechanism enables a system initialization process to specify a correspondence between a set of system primitives and the procedures in a user address space which implement them.

When a process makes a call to a system primitive

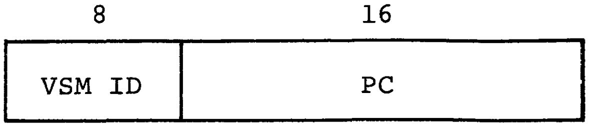

Figure 3—A process' virtual program counter

the system performs some task as an extension of that process. Control may be transferred from the calling process to a primitive in a different address space. In this case the system reloads the hardware mapping registers from the new virtual storage map and transfers control to the primitive in the new address space. The identifier of the previous address space is saved on the Kernel stack to allow restoration of mapping information when the primitive returns.

A process which runs in a user address space may utilize special instructions which "trap" through well-known address vectors on a stand-alone processor; the instructions trap through the corresponding locations in the active user space. A process which is being debugged and reaches a breakpoint, for example, causes control to be transferred to the address contained in the break-point vector (Location 14) of the user address space. This has facilitated the adaption of several debugging packages which run on a stand-alone PDP-11. It is also possible for a process to call a Kernel primitive which requests a signal in the event that a specified process reaches a break-point, and causes the break-pointed process to be placed in the frozen state. A process may thus be responsible for the debugging of a number of processes in the system. The application of this mechanism will be described later.

Input/output management

The Input/Output portion of the Kernel provides a set of system primitives which enable processes to schedule physical I/O requests to devices and to utilize the system's hardware clock. The I/O system queues requests to each device, performs a mapping from virtual to physical storage, provides an inter-process communication facility, and allows the system to be tailored for a particular hardware configuration by selection of a set of device driver modules.

Processes cause the initiation of physical I/O transfers by calling a system primitive which places their request on a queue for a particular device. An I/O process schedules I/O activity on each device, performs storage mapping functions, and causes physical I/O requests to be initiated by calls to device driver procedures.

Input/output primitives

Processes cause requests to be placed on a queue for a particular device by issuing the system primitive START-IO and specifying a device name, a buffer address, a byte count, a function code, and an optional device address. When the requested I/O operation completes, the user process is signalled by the I/O system with the requested event code. Function codes are defined for performing Read, Write, or Device-Specific (e.g., rewind tape) operations. I/O primitives exist for allocation of devices and their optional assignment on a per-process basis. When a sending process issues a write request, it is signalled when all of the bytes it has requested to be written have been transferred. When a process issues a read request, it may specify a data transfer mode (in the I/O function code). A "record" mode read request signals the process (and satisfies its request) when one or more bytes have been read; the reader is informed of the number of bytes actually transferred. A "stream" mode read request signals the reader when the number of bytes requested have been transferred.

INPUT/OUTPUT DEVICE CLASSES

There are three types of I/O devices supported by the system. The first of these classes handles character-oriented devices, such as terminals or line printers, which are used in an interrupt-driven fashion. In the case of character-oriented devices, the system moves the block of data being transferred between the Kernel and the requester's address space. This is necessary to allow interrupt routines to directly address the buffer used for data transfer.

Two utility procedures are made available to device drivers which support terminals. One of these procedures manages a ring buffer to allow type-ahead in the absence of an I/O request from user process. A second utility procedure performs terminal-specific output functions, such as output of padding (ASCII NUL) or expansion of ASCII Horizontal TAB characters. Selection of these two options is made possible by an I/O system primitive for setting device characteristics.

A second class of devices which are supported by the system transfer data on a direct memory access basis and require no processor intervention during the data transfer. The virtual storage structure of the system forces the I/O system to perform a mapping of a user process' I/O buffer into its location in physical storage before calling the device driver which initiates the transfer. (I/O devices which directly access memory do not utilize the processor's memory mapping hardware.) Additionally, the system must determine whether a buffer which is specified in an I/O request crosses page boundaries, and take special action if the associated physical pages are non-contiguous. When this is the case, the I/O system carries out the operation in a piecemeal fashion, initiating separate data transfers for the portions of the buffer residing in each individual page. User processes may avoid this inefficiency by appropriate allocation of buffer space.

A third class of devices provides a mechanism for inter-process communication in a fashion which appears identical to data transfer to a physical I/O device. A set of pseudo-devices, called "Inter-Process Ports" (IPP's) may be used for data transfer between processes. User processes may take advantage of this facility in order to allow flexible assignment of their Input/Output streams; specifically, a process may accept input from either a physically-connected terminal or a remote process on a network. The utilization of Inter-Process Ports for network communication will be described later.

An Inter-Process Port is effectively a mailbox[12] which may be read or written by a pair of processes. A separate read and write request queue is maintained for each Inter-Process Port. Whenever the I/O system receives a matching pair (read, write) of requests, data is transferred from writer to reader. The writer and reader processes are signalled if their respective requests are satisfied. It is possible for the sender to issue an "end-of-stream" indication, which unconditionally satisfies the request of a receiver which is reading in stream mode; the receiver is signalled as usual with the number of bytes actually transferred. Inter-Process Ports may be assigned to a specific pair of processes.

Timer primitives

Timer primitives enable a process to set a number of interval timers and to receive an event message when a timer expires. Additionally, the process may stop a running timer by setting its interval to 0 or may get the current time remaining before a timer expires.

The Kernel maintains a 32-bit Time-of-Day, which is kept in 40-microsecond ticks. Kernel primitives allow user processes to get (or set) the Time-of-Day value. Conversion routines exist outside of the Kernel for obtaining the Time-of-Day as a character string.

THE ELF EXEC

The EXEC is utilized in ELF systems which require a flexible user programming environment. The EXEC interprets user commands and provides a framework for user program support. The command language provides functions such as user identification, display of system status, and initiation of user processes. Design of the ELF command language is patterned after the executive language of the TENEX operating system because of the user-oriented characteristics of that language.[4]

The EXEC support structure provides a set of primitives which are called by user processes below it and includes a terminal control mechanism for interrupting those processes. EXEC primitives allow logical data paths to be established for terminal control and for access to a system file structure; they also perform a number of utility functions, such as data conversion (e.g., time-of-day to string).

The EXEC is implemented as a set of re-entrant procedures which utilize Kernel primitives to support an inverted tree structure of processes. A process called the Logger issues I/O requests to a set of terminals or Inter-Process Ports and "listens" for the arrival of an attention character (control-C). When this occurs, the logger creates an EXEC process which receives characters from the device and interprets user commands. Additionally, it allocates and formats a set of control tables which are used to maintain resources allocated to the newly-created "Job." A Job is identified by a branch-name which is assigned to the EXEC process and becomes associated with all processes in the inverted tree under it. The Job effects a policy for allocation of resources (storage, files, etc.) to each user.

A system primitive exists to enable the logger process to be signalled when a terminal port has been dynamically added to the system. This function allows the system to respond to remote requests for connection from the network and to support a number of virtual terminals. Once a new logger port is established, the logger process issues I/O requests in the same fashion as it would for local terminals; in this case, however, I/O takes place on a pair of Inter-Process Ports.

The EXEC maintains a directory of "sub-systems" which may be dynamically expanded while the system is running. A sub-system is a named collection of procedures which have been loaded into a virtual address space. The EXEC allows the user to initiate a subsystem by typing its name; the EXEC then creates a user process and enables that process to communicate with the controlling terminal by means of EXEC file primitives.

A number of user sub-systems have been written to perform a variety of functions. TELNET, for example, provides the function of terminal access to remote systems on the ARPA network. The TELNET program utilizes file primitives provided by the EXEC to interpret user commands and to establish or terminate connections to remote network Hosts. A cross-network loader, called USERLOADER, allows programs to be loaded into a user virtual address space from a remote file system by means of the file transfer protocol[8] used in the ARPA network.

Generally, a user process is connected to a controlling terminal until the process halts (by freezing itself) or the user interrupts it by typing the EXEC attention character (control-C). I/O to the controlling terminal is re-directed to the EXEC process until the user allows the interrupted sub-system to resume or runs another sub-system. The active tree of user processes is terminated, whenever a user requests to run a sub-system, explicitly issues a "reset" command, or logs out of the system.

Some user processes require the ability to suppress the interrupt facility provided by the EXEC; the user process may specify a "transparent mode" which causes the EXEC to ignore interrupt characters and places this responsibility on the sub-system. This is needed, for example, in the TELNET sub-system, which must be able to transmit the interrupt character to a remote system on the network.

The association between a controlling terminal and a Job may be dissolved by means of a user command or as a result of an error received on a terminal port. The state of the Job and its user processes is saved, and a user may re-attach to it by an EXEC command.

Design of the ELF file system has been aimed at providing a mechanism for terminal control over a set of user processes and the support stream-oriented Input/Output for a variety of device classes. A table-driven mechanism is used to implement stream Input/Output for sequential and file-structured devices. The file structure is compatible with the FILES-11 structure utilized by the DEC RSX-11 operating systems.[13]

The file system provides a primitive for initializing a file path; the file system returns with a Job-unique identifier called a Job File Handle. This identifier may then be used to efficiently call primitives which perform file I/O. The file system supports I/O primitives which read or write relative blocks within a random-access file, and provide a device-independent mechanism for reading or writing a stream of bytes. Stream-oriented primitives exist for byte-input, byte output, string-input, and string-output.

NETWORK COMMUNICATION CONTROL

The Network Control Program (NCP) is an essential component in the ELF system which makes possible process-to-process communication in a network environment. The NCP provides a mechanism for establishing and breaking connections between ELF processes and processes distributed on the ARPA network.

The NCP includes a set of processes which receive messages from the network, interpret messages according to ARPA network standard protocols, format outgoing messages, and control the flow of data on connections by means of the Inter-Process Port facility provided by the ELF Kernel.

A set of network control primitives enables processes within ELF to request the establishment or termination of network connections. When a process calls an NCP primitive to open a connection, the primitive returns the name of an Inter-Process Port which is to be used for data transfer on the connection. When the connection is opened, the process may cause data transfers by calling the normal Kernel I/O primitives using the Port-name which was returned. A process may request that an Inter-Process Port supporting a connection be specifically assigned to the NCP and user processes in order to prevent malevolent processes in the system from performing unauthorized data transfers on the Port.

An important Kernel function which is used by the NCP in the control of data flow on a network connection is that of obtaining the number of bytes requested to be read or written on an Inter-Process Port. This function is necessary to enable the NCP to intelligently determine the amount of data which may be accepted from a remote process. ARPANET protocols utilize a flow control mechanism whereby a sending process must be informed of the buffering capability at the destination.

In addition to control of communication using standard ARPA network protocols, the NCP provides a simple dispatch function for development of experimental protocols. Processes which utilize this function must specify a field which uniquely identifies received messages. Messages are delivered to the user processes (via an Inter-Process Port) in the form in which they arrive from the network.

SYSTEM APPLICATIONS

The ELF system is being used in a variety of applications which require a set of operating system components for network communication. The ELF Kernel provides a base for a variety of software configurations which are tailored according to system requirements. The configuration of processes shown in Figure 4 is typical of ELF systems which provide terminal access to remote systems on the ARPA network. The Kernel, EXEC, and NCP modules support a number of users who access the network by running the TELNET sub-system of the EXEC.

Additional processes may be added to the system for peripheral support. For example, a simple process which uses the ELF NCP to await a remote request for connection may be included in the system. The process accepts a connection, receives a stream of data, and outputs it to a local line printer. A status indication from the NCP signals that a remote process has closed the connection, and the peripheral control process then returns to the "listening" state.

This process provides a simple mechanism for sharing of a peripheral device (in this case, a line printer) among a number of service sites in the network. A daemon process at each service site checks periodically for files to be listed. When they exist, it opens a connection and transmits each file. The ELF NCP queues remote requests for connection while the peripheral process is busy.

A more flexible mechanism for peripheral support is provided by the ARPA network file transfer protocol server process which may be included in the system. The file transfer server responds to remote requests and utilizes facilities provided by the ELF EXEC (file system) to carry out data transfer to a variety of peripherals.

The support of real-time data acquisition functions for speech research has been one of the goals in design of the ELF Kernel. A user process runs as an EXEC sub-system and performs functions of real-time data sampling and file I/O for digitization of speech wave-

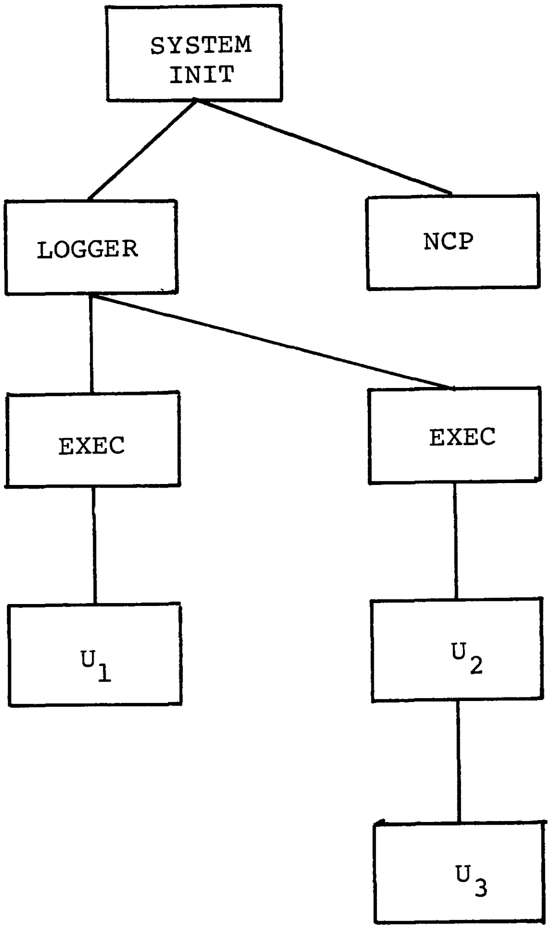

Figure 4—Example process tree

forms. The system may thus be used as a data acquisition station while simultaneously providing a terminal support function for access to remote systems. The sampled signal may be transferred to the remote system by the file transfer protocol process.

The ELF Kernel provides a support base for development of experimental networks and protocols. The packet radio network[14] for example, utilizes the environment provided by the Kernel to support a set of user processes which perform network routing control functions. Additionally, new protocols being tested in the ARPA network utilize the inter-process communication facility provided by the Kernel in the implementation of new network control processes.

DEVELOPMENT AND MAINTENANCE TOOLS

Development and maintenance of the ELF system has made extensive use of software tools provided within the framework of the ARPA network. The ΓENEX operating systems available on the network, for example, have provided a number of services for software development. ELF modules are edited, compiled, and linked together using a set of online subsystems in TENEX. When an ELF system is generated it may be bootstrapped into a target PDP-11 system by transfer of the binary file through the network.

The ELF Kernel, EXEC, and NCP are written in MACRO-11 assembly language. The virtual memory structure provided by the system allows user processes to be written in higher-level languages. Compilers for the BCPL and L1011 Languages are available under TENEX and generate code for the PDP-11. The files produced by these compilers may be transferred to an ELF file structure by means of the file transfer protocol or may be loaded by the ELF USERLOADER sub-system, which was described above.

A number of debugging tools have been developed. A low-level (stand-alone) debugger, called FLEA, was implemented to facilitate checkout of the virtual memory system. FLEA provides the capability of examining or breakpointing any location in physical memory.

Several debuggers which run on a stand-alone PDP-11 have been modified to run in an ELF user address space. Modification was required to make use of ELF I/O primitives for terminal control. Hardware I/O device registers are not available to processes in a user address space.

An additional debugging mechanism involves the interpretation of debug commands received from the network by a system debugging process. This approach minimizes space requirement in a processor being debugged while taking advantage of facilities available on large systems to provide a comfortable user language and a symbolic representation of addresses and instructions. A system debug process* which resides in ELF utilizes the breakpoint signal facility provided by the Kernel and is responsible for debugging of a number of other processes.

ELF system software is distributed as a set of source modules which are accessible in a directory at one of the network TENEX service sites. Users may access the source files by means of the network file transfer protocol. Release-notes and bug-reports (user-feedback) take place through the use of the network message system.

CONCLUSION

The foregoing discussion has presented a structural view of the ELF system as a mechanism for user access to remote resources. A number of design decisions have been made in supporting a range of user applications. At this point we critically examine several of

* Developed at Bolt, Beranek, and Newman, Inc., Cambridge, MA.

these decisions and discuss their relation to the resulting system structure.

The event message scheme which is utilized for process synchronization has proven to be a flexible mechanism which allows processes to wait for multiple events. This capability is required for reliable communication in a network environment: error conditions may arise and "time-outs" are sometimes needed in order to resynchronize a connection sequence. The synchronization mechanism used here is an alternative to the creation of a process for each event; that solution was considered too costly in terms of processor overhead and system table space requirements. Rather, the event message mechanism enables a single process to be multiplexed for several events. Two drawbacks were encountered with the ELF event mechanism, however. First, it is required that any procedure which performs an operation which specifies an event code (e.g., initiation of an I/O request) must receive as a parameter an event code which it may use. In the absence of a statically-allocated set of event codes, an arbitrary system procedure has no knowledge of the set of event codes currently being used by a calling process. A second drawback is the lack of a reliable mechanism for bounding the number of event messages which may be allocated by a signalling process. The strategy of blocking a signalling process when the system's supply of event messages has run out is susceptible to deadlock. For example, the signalling process may be executing an interrupt routine which signals completion of an I/O operation. However, if the process is itself the process being signalled and the supply of event messages runs out the process will deadlock. As a result of these problems, the current system implementation simply returns an error condition to the signalling process, indicating the lack of event message queue space in the system.

The Inter-Process Port mechanism which has been implemented in the system has been valuable in implementing network protocol processes and has provided an effective mechanism for performing local and network I/O in a transparent fashion. There are two disadvantages to that mechanism. First, a Port mechanism requires buffer space in each address space which communicates using the port. Second, processing time is consumed in the copying of data from the sender to the receiver's buffer space. It is believed that these disadvantages are outweighed, however, by the system flexibility introduced by a general inter-process communication mechanism.

The memory management scheme used in ELF has been designed to provide a simple mechanism for allocation of physical storage and to provide a means for sharing of user pages. A problem with the current storage allocation scheme is that of internal fragmentation which results when a number of small user procedures reside in a virtual address space or when a large number of user processes wish to share a small amount of data. A modification of the storage management portion of the Kernel to provide for variable-sized segments is currently under consideration.

The choice of a hierarchical structure of system functions has provided modularity and has facilitated checkout of the system. Its drawback is an occasional overhead introduced in the passing of parameters between levels. Provision of standard memory management functions which facilitate these tasks in hardware would alleviate this problem.

SUMMARY

This paper has presented a description of the ELF Operating system which provides a set of user access facilities for the ARPA computer network. We have attempted to describe the system from a structural point of view and point out operating system functions which are necessary in a network environment.

ACKNOWLEDGMENTS

In addition to the work done by the authors, significant contributions to the design and implementation of the system were made by Mr. Jon Miller, who was responsible for the I/O and Storage Management portions of the Kernel, and Mr. Jim McClurg, who participated in implementation of the file system and maintained system documentation. Contributions were also made by V. Strazisar and E. Mader at Bolt, Beranek, and Newman, Inc., and by Mr. P. Raveling of University of Southern California Information Sciences Institute.

Elements of a planning and modeling system

by THOMAS H. NAYLOR
Duke University and Social Systems, Inc.
Chapel Hill, North Carolina

ABSTRACT

Today there are nearly two thousand corporations in North America and Europe either using, developing, or experimenting with some form of corporate planning model. With the emergence of this new and rather substantial interest in the methodology of corporate planning modeling, there appears to be a definite need for a conceptual framework which can be used to design and implement computer based planning and modeling systems.

In this paper we describe a collection of elements which we believe to be of critical importance in designing a corporate planning model. Our objective is to develop a set of criteria for not only designing a planning and modeling system, but a set of criteria which can also be used to facilitate the evaluation and comparison of alternative planning and modeling systems.

There are nearly 50 planning and modeling software packages on the market today. These include systems such as BUDPLAN, COMOS, and SIMPLAN. This paper attempts to provide the reader with a convenient check-list of possible features to consider in either designing one's own system or selecting an appropriate software package.

INTRODUCTION

A recent survey by Naylor and Schauland confirms the fact that nearly 2,000 corporations in North America and Europe are either using, developing, or experimenting with some form of corporate planning model. For the most part, these models are "what if" simulation models capable of generating alternative futures and scenarios depending on the policy assumptions and external assumptions made by corporate management. Our survey indicated that less than 4 percent of the models in a sample of 346 companies were optimization models. The rest were simulation models.

We believe there are eight basic elements which one must consider in designing a planning and modeling system:

1. Planning System
2. Management Information System
3. Modeling System
4. Forecasting System
5. Econometric Modeling
6. User Orientation of the System
7. System Availability
8. Software System.

PLANNING SYSTEM

The point of departure for any corporate planning model is the planning system itself. That is, the design of the planning system for the organization should be set in place before any consideration is given to the modeling system.

As the most general case let us consider a large, decentralized company consisting of multiple divisions, groups, products, or strategic business units. For simplicity, we shall refer to any such sub-system of an integrated company as a *business unit*. Each business unit is assumed to be autonomous and is responsible for its own marketing and production activities. Although cash management and overall corporate financial planning are centralized at the corporate level, each business unit is responsible for its own income statement.

At the beginning of the planning cycle, global goals and objectives for the company are specified by top management and interpreted to the business units by the corporate planning department. These corporate goals may take the form of specific target objectives for the company as a whole or for individual business units. Typical target variables may include return on investment (ROI), market share, sales growth, and cash flow, as well as environmental, social, and political objectives.

The corporate planning department designs the report formats to be employed by the business units in formulating their business plans. Standardized reporting at the business unit level greatly facilitates the consolidation of plans across all business units. However, individual business units are permitted to make their own assumptions concerning marketing and production provided they are explicit about the external assumptions and policy assumptions underlying their business plans. Financial plans at the business unit level follow logically from given assumptions about revenues and costs.

Plans from the business units are transmitted to the corporate planning department for consolidation, review, and evaluation. In the initial stages of the planning process, the business plans will be returned to the business units for modification and reformulation in light of corporate goals. This iterative process will be replicated until all of the business plans have been approved and consolidated into the company's overall corporate plan.

In the following section we shall describe how business planning models can be integrated into the planning process. The integration of planning models into the planning process is perhaps the single most difficult step in the entire process of corporate modeling. Relatively few companies have successfully integrated corporate planning modeling into the planning process. Two notable exceptions are the Wells Fargo Bank and the Central National Bank of Cleveland.

Business planning models

Figure 1 contains a flow chart of a consolidated corporate planning model which is driven by a series of business planning models for the individual businesses of the company. These models may either be used on a stand alone basis at the business unit level or consolidated and used by the corporate planning department, senior financial officers, or the chief executive officer. Each business unit model consists of a front-end financial model driven by a marketing model and a production model.

The objectives of the business unit models are to generate alternative scenarios and business plans based on varying assumptions about business unit policies and assumptions about the external environment of the businesses.

Financial planning models

Each business planning model produces as output data a proforma income statement for the business unit. In cases where the business unit is actually a subsidiary of the parent company, then proforma balance sheets and sources-and-uses of funds statements may be produced as well. Basically, these business financial models can be used to simulate the effects on net profit of alternative business strategies for a given business unit. The validity of the results generated by a business unit financial model will be no better or worse than the assumptions underlying the revenue and production cost projections which feed the model.

Marketing planning models

Marketing planning models provide the revenue projections which drive the business planning models. Two alternatives are available—forecasting models and econometric marketing models. Forecasting models

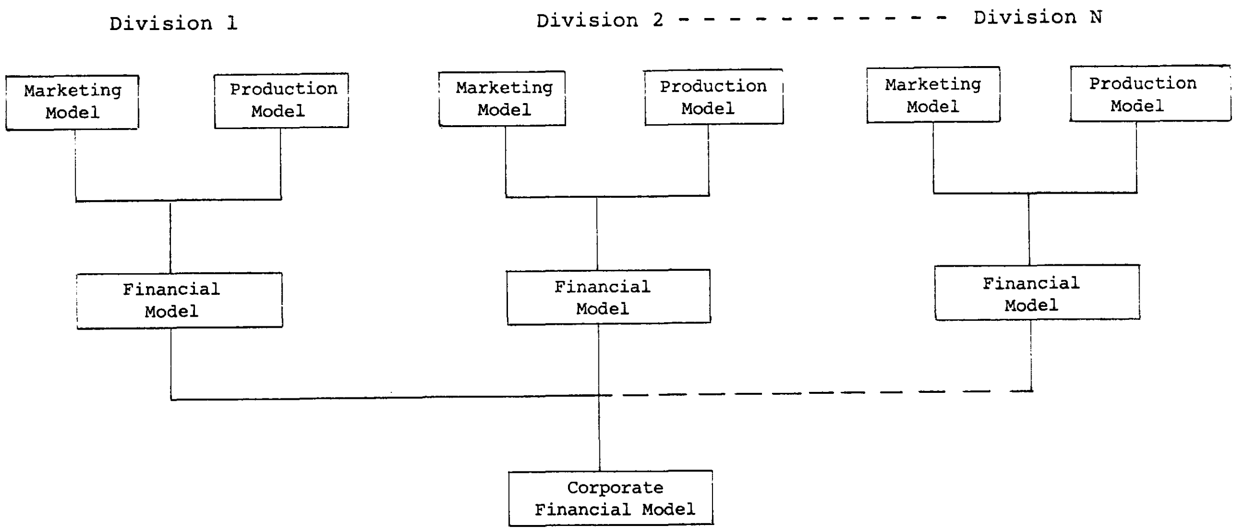

Figure 1—A Conceptual Framework for Corporate Models

are naive, mechanistic, time-series techniques which attempt to forecast next month's sales in terms of last month's sales, sales the month before that, and the month before that. Forecasting models are void of explanatory power and cannot be used to simulate the effects of alternative marketing strategies or alternative assumptions about the national economy on sales or market share. Econometric models, on the other hand, can be used to improve one's understanding of the "market" and to simulate the effect on sales volume, sales revenue, and market share of alternative pricing, advertising, and competitive strategies as well as alternative assumptions about the national or regional economy.

Production planning models

Given a sales forecast for a particular business unit, how much will it cost to produce at a level which will satisfy the demand forecast? That is the *raison d'etre* for production planning models. A number of companies including Monsanto and Inland Steel use a type of activity analysis approach to production planning modeling which generates the cost-of-goods sold associated with a given demand forecast. A reasonable extension of this approach is for the production model to generate the minimum cost production plan associated with a given level of demand for the products of the business unit. This latter alternative represents a logical interface between mathematical programming and other optimization techniques and corporate simulation models.

Consolidated corporate planning models

As we have previously indicated, the individual business planning models may either be used as planning tools for the separate business units, or consolidated at the corporate level to form consolidated corporate plans. The corporate planning department should have the option to perform "what if" experiments with any of the business unit models on either a stand alone basis or as part of a totally integrated planning and modeling system.

The output reports of a consolidated corporate planning model typically include proforma income statements, balance sheets, and sources-and-uses of funds statements. Our survey indicated that of those firms which have some type of corporate planning model the following applications are the most prevalent: (1) cash flow analysis, (2) financial forecasting, (3) profit planning, (4) budgeting, (5) investment analysis, and (6) merger-acquisition analysis.

In summary, a corporate planning and modeling system should have the ability to integrate finance, marketing, and production at the business unit level and the ability to run the business unit models separately or as part of a consolidated corporate financial planning model. Whether the company engages in "top down" or "bottom up" planning is less important than whether or not the planning modeling system can be easily adapted to the planning system. Regardless of the type of planning system, two features are critical—(1) the ease with which financial, marketing, and production models can be integrated and (2) the ease with which financial consolidation can be achieved.

MANAGEMENT INFORMATION SYSTEM

Given a planning system, the next important element in the development of a corporate planning modeling system is the management information system. We shall define the term management information system to include the following elements: (1) database, (2) database management system, (3) security system, (4) report generator, and (5) graphics.

Database

A decision to develop a corporate planning model is tantamount to a serious commitment to the maintenance of comprehensive internal and external databases. Our database requirements become quite explicit once we settle on the design for a corporate planning model.

Internal data

To develop an annual financial planning model we need at least three or four years of historical financial data. We require even more data if the model is a monthly or quarterly model. Econometric marketing models should have 25 to 30 observations of historical data. While most firms have little or no difficulty meeting the data requirements for financial models, data problems are much more severe in the case of marketing and production models.

External data

Most econometric marketing models attempt to link sales volumes and sales revenues to the national or regional economy in which a particular product is sold. A number of service bureaus offer national historical macroeconomic data and econometric forecasts to their clients. These services tend to be quite expensive and the econometric forecasts offered by the bureaus have not been noted for their accuracy in recent years.

An inexpensive alternative to the use of an econometric forecasting service is to subscribe to the historical database of the National Bureau of Economic Research (NBER). The fee for the NBER database is quite nominal and includes over 2,200 economic time-series. In other words, use the NBER data base to specify, estimate, and validate your econometric models. Then either make your own assumptions about the economy of the United States or subscribe only to the quarterly forecasts of one of the aforementioned econometric service bureaus. It is possible to purchase the forecasts for considerably less than a "full service" contract from one of these bureaus. The NBER database is available through most timesharing bureaus and can also be installed on the user's in-house computer.

Database management system

Not only should a planning and modeling system have databases, but it should also have a flexible, easy-to-use database management system for reading data into the system, storing it, and making it readily available for modeling and report generator. At last three different approaches to database management have emerged among the numerous planning and modeling software systems which are currently available—(1) matrix, (2) row-column, and (3) record-file.

Matrix

PSG II, a FORTRAN based planning system as well as several APL based planning and modeling systems use matrices to read data into the system. Both database management and modeling functions are carried out using matrix manipulations. If the user is a scientific programmer, matrix manipulations should cause no problems. However, many corporate planners and financial analysts are neither mathematicians nor scientific programmers and may find matrix manipulations difficult, if not impossible to use.

Row-column

Other planning and modeling systems such as FORESIGHT make use of row numbers and column numbers to create databases, formulate models, and generate reports. While the row-column number approach may have some appeal to accountants who are accustomed to working with financial spread sheets, the user must keep track of the row and column numbers. Furthermore, econometric and production data do not necessarily lend themselves to this restricted notation.

Record-file

Other planning and modeling systems like SIMPLAN make use of records as the basic unit of data. A *record* is a time series variable such as SALES, COST, or PROFIT. A record has a name, an abbreviation, a value, units, and a security level which determines who has access to which SIMPLAN records. A *file* is a collection of SIMPLAN records. Each business unit may have one or more SIMPLAN files. For example, for a given business one file may contain actual historical data. Another file may contain budgeted, projected, or simulated series. Variance reports and validation runs are particularly easy to implement with the multiple file concept.

Security system

There should also be some means of controlling who has access to which files, records, models, and reports within the planning and modeling system. Division managers should be able to access their own databases, models, and reports, but not those of other divisions or the entire corporation. Corporate management should, on the other hand, be able to access the corporate database as well as all division databases, models, and reports. A built-in security system makes all of this possible.

Report generator

The front-end of any planning system is a set of financial reports. Therefore, it follows that a report generator should be an integral part of any planning and modeling system. Basically, management should be able to have any type of report format it desires. That is, the report generator should not impose any restrictions on the type of report which is produced by the system.

The report generator should be flexible and easy-to-use. Some report generators are so easy-to-use that typists with no previous programming experience can be taught to produce financial reports with little or no effort.

Of the 50 planning and modeling software packages available today, over two-thirds of them are primarily report generators. That is, they can produce financial reports and do financial consolidations, but have very limited database management, modeling, and econometric features. PROPHIT II, FAL, FORESIGHT, and INFOTAB are examples of financial report generators. Although financial report generation and financial consolidations are important elements in a planning and modeling system, there are other important elements to consider. Unfortunately, a number of users of systems which are primarily report generators have found themselves locked into expensive outside timesharing charges only to realize, when it is too late, that they need additional database management, modeling, econometric, and forecasting features which are not available in their financial report generator. Although simple financial modeling and report generation are ideal starting points for those who are just beginning to develop a planning and modeling system, beware of dead-end systems which can only do report generation and are not available for installation on your in-house computer.

In summary, in selecting a report generator, make sure that the planning and modeling system of which it is a part has the flexibility and features which you will need in the future as well as the present.

Graphics

An increasing number of planning and modeling software packages now offer graphics as an alternative way of displaying output data and corporate plans. The graphical display of sales, cost, and profit trends can be an effective way to present planning data to top management.

MODELING SYSTEM

Given the discrete nature of business planning data, virtually all corporate planning models take the form of finite difference equations. In this section we shall describe five modeling features which the user may want to include in a planning modeling system: (1) recursive models, (2) simultaneous models, (3) logical models, (4) risk analysis, and (5) optimization.

Recursive modeling

Most of the financial planning models which have been developed to date are recursive or causally ordered models. That is by placing the equations of the model in the proper order it is possible to solve each equation one at a time by substituting the solution values of previous equations into the right-hand side of each equation. Recursive models have the computational advantage that you do not have to resort to matrix inversion or some other simultaneous equation technique to solve the system of equations. Below is an example of a recursive financial model.

```
1  SALES    =A-B*PRICE
2  REVENUE  =PRICE * SALES
3  CGS      =.60 * REVENUE
4  PBT      =REVENUE-CGS
5  TAX      =.50 * PBT
6  NPR      =PBT-TAX
```

In this example, the selling PRICE is given. A and B are parameters and

SALES	=Sales volume (units)
REVENUE	=Sales revenue
CGS	=Cost of goods sold
PBT	=Profit before taxes
TAX	=Taxes
NPR	=Net profit

But in many financial models it is impossible to express the logic of the model as a series of recursive, causally ordered equations. It is for this reason that a corporate modeling system should include the capability to solve simultaneous equation models as well as recursive models.

Simultaneous models

Consider the following five-equation financial model.

```
1  INT     =.12 * Debt
2  PROFIT  =REVENUE-CGS-INT-TAX
3  DEBT    =DEBT(-1)+NDEBT
4  CASH    =CASH(-1)+PROFIT+NDEBT
5  NDEBT   =MBAL-CASH
```

Profit (PROFIT) in Equation 2 is defined as sales revenue (REVENUE) less cost of goods sold (CGS), interest (INT), and taxes (TAX). But INT depends on total indebtedness (DEBT) in Equation 1. From the balance sheet total debt in Equation 3 for this period is equal to last period's debt DEBT(−1) plus new debt (NDEBT). New debt is defined in Equation 5 as the difference between the cash balance (CASH) and the firm's minimum required cash balance (MBAL). CASH in Equation 4 is the sum of last period's CASH, PROFIT, and NDEBT.

Although this model is quite simple it is, nevertheless, a simultaneous equation model. It is impossible to solve the model recursively merely by placing the equations in the correct order. Solution of this model requires the use of a technique capable of solving simultaneous equations. This model may either be solved through matrix inversion techniques or some other generalized technique such as the Gauss-Seidel method which is suitable for both linear and nonlinear simultaneous equation models.

As you can see from our example model, it is indeed quite likely that we will encounter simultaneity even in quite simple financial models. Very few of the financial modeling software pakages have the ability to solve simultaneous systems of equations. CUFFS, SIMPLAN, and XSIM are exceptions to this rule. SIMPLAN and XSIM can handle linear and nonlinear simultaneous equation models. CUFFS can solve linear models.

Simultaneous equation problems can also arise in econometric marketing models where two or more products are either complements or substitutes.

Many banks have developed a special type of financial planning model known as an asset-liability model. Most of these models have been formulated as recursive models. Yet logically this is totally absurd, for the very nature of a bank's assets and liabilities is a simultaneous jointly determined structure. For example, demand deposits and time deposits are substitutes and both are likely to be correlated with various loan demand equations. Loan demand depends on interest rates and interest rates depend on the supply and demand for loans. Consumer loans and mortgage loans may be substitutes for one another. To attempt to model the asset-liability structure of a bank with a recursive model makes little or no sense. It is not surprising to find that a number of banks have encountered serious difficulties in attempting to validate recursive, bank planning models. The financial structure of a bank is simply not recursive.

Logical models

The ability to check whether or not cash balances or inventory levels have dropped below some predetermined minimum level is another important element of a planning modeling system. Logical commands such as an IF statement or a GO TO command are desirable features for a planning modeling system.

Risk analysis

A strong case can be made for treating some of the external variables in a corporate planning model as random or probabilistic variables with given hypothetical or empirical probability distributions. This type of analysis is known as *risk analysis.* Risk analysis is useful in testing the sensitivity of the planning model to random shocks and perturbations, constructing confidence intervals, and testing hypotheses. But our survey of 346 corporations indicates that of those firms which have some form of corporate planning model, only 6 percent make use of risk analysis.

There are two major reasons why risk analysis has been used so seldom with planning models. First, use of risk analysis with corporate planning models is prohibitively expensive. Plan on multiplying your computer bill for the deterministic version of your model by a factor of 100 if you use risk analysis. Second, risk analysis is difficult to explain and interpret to management.

Some analysts use a type of pseudo-risk analysis in which they experiment with "optimistic," "pessimistic," "most likely" values of external variables rather than treating them as random variables.

Optimization

As we have previously indicated, only 4 percent of the users of corporate planning models identified in our survey were found to be using their models as optimization models. Those firms which do not use optimization techniques in conjunction with corporate planning models tend to use them for production planning rather than as global optimization models for an entire business or the corporation as a whole.

Although optimization models are widely used in certain process industries such as oil refineries, rarely are these production scheduling models integrated into a corporate planning model. Virtually every major oil refinery in the world uses mathematical programming to schedule its operations. At this point in time we are not aware of a single oil company which has a linear programming model linked to a corporate planning model.

The difficulty with using optimization techniques to develop optimal plans for a corporation as a whole is a problem of problem definition. Although top management is indeed interested in profits, ROI, discounted cash flow or some equivalent measure of performance, these are by no means the only measures of effectiveness which management uses to evaluate corporate plans. Output of corporate planning models is a vector not a single variable. If the company wants to survive, management must necessarily monitor a whole host of output variables—profit, ROI, market share, sales growth, cash flow, as well as all of the line items of the income statement and balance sheet.

Faced with a multiple output planning problem, optimization techniques which optimize with respect to a single output variable are of limited use to corporate planners. The use of *goal programming* and *utility theory* have been suggested as means of quantifying trade-offs among conflicting corporate objectives. The track records of these two techniques as corporate planning tools are not impressive.

Although the energy crisis, shortages of a variety of production inputs, and inflation may cause more firms to utilize optimization techniques for production planning modeling, we do not foresee significant usage of these techniques as global optimization techniques for overall corporate planning. However, we do expect them to be used more often as production planning tools at the business unit level and integrated into business financial models.

Very few of the existing planning and modeling languages have mathematical programming routines incorporated into their structures. COMOS, the planning and modeling system developed by CIBA-GEIGY, does have this feature. Some planning and modeling systems have the ability to interface and exchange files with mathematical programming packages.

FORECASTING SYSTEM

The ability to generate short term forecasts not only for market planning models but for any external variable which appears to have a reasonably stable relationship with respect to time is another important element to be considered for inclusion in a planning modeling system. A variety of short term, "naive," forecasting tools are available ranging from simple time trends to the Box-Jenkins technique in terms of degree of complexity. Although short-term forecasting models have a definite role to play in corporate modeling, they have little or no explanatory power and cannot be used for "what if" analysis.

Time trends

Probably the most straightforward forecasting models are simple linear, quadratic, exponential, or logarithmic time trends which express sales volume, for example, as a function of time only. The parameters are estimated by ordinary least squares techniques.

Exponential smoothing

Exponential smoothing techniques consist of a set of weighting schemes which assign greater weight to more recent historical observations than those from the more distant past. Again the rationale is the same. To forecast the future all one needs to know is the correct relationship between past sales and future sales. The problem of exponential smoothing is one of selecting the approximate weighting scheme.

Adaptive forecasting

Adaptive forecasting models are a collection of techniques which have the ability to "self correct" if the forecast is not tracking the actual behavior of the system. Adaptive forecasting techniques are much easier to use than Box-Jenkins techniques and have been known to perform equally well.

Box-Jenkins

Box-Jenkins techniques are the most powerful, most sophisticated, and most difficult to use forecasting techniques available. They are not techniques for amateurs. In fact, the user will probably need a mathematical statistician to hold his hand while using these complex procedures. Through a set of "transfer functions" it is possible to link Box-Jenkins forecasts to a set of external leading indicators.

ECONOMETRIC MODELING SYSTEM

If the user wants to do computer simulation experiments simulating the effects on sales volume or market share of alternative pricing, advertising, and competitive strategies, then econometric models are the appropriate analytical tools. Econometric models can also be used to link market forecasts to the national and regional economies. Finally, our understanding of the market behavior of specific products or groups of products can be considerably enhanced through the use of econometric marketing models. But the forecasting accuracy of any econometric marketing model is no better than the accuracy of the policy assumptions and assumptions about the firm's external environment which underlie the model.

Methodology

Econometric modeling involves a four-step methodology which will be summarized below. These steps include: (1) model specification, (2) parameter estimation, (3) validation, and (4) policy simulation. Given the present state of development of computer software, it is now possible to implement all four of these steps within the planning modeling system without having to go out of the system to FORTRAN, PL/1, or some other type of subroutines. SIMPLAN and XSIM are among the very few modeling systems which have a fully integrated econometric modeling capability.

Specification

Unfortunately, most econometrics textbooks are concerned only with the question of "Given an econometric model, how do we estimate the parameters of the model?" In other words, the entire question of model specification has been assumed away by most textbooks and university courses on econometrics.

The specification of econometric marketing models requires: (1) considerable knowledge of the market of the product or group of products being modeled, (2) familiarity with econometric and statistical methods, and (3) some knowledge of microeconomics and the theory of markets.

If multiple product econometric models are to be developed, we recommend the use of a well designed questionnaire to be used by analysts in extracting relevant market information from product managers. Such a questionnaire can greatly reduce the amount of interaction time between analysts and product managers.

Estimation

Single-equation econometric models can be estimated using ordinary least-squares (OLS) regression techniques. Simultaneous-equation models require the use of techniques like two-stage least-squares (TSLS) or other simultaneous-equation estimators. The application of OLS to simultaneous-equation models may yield biased, inconsistent estimates. Most of the planning and modeling software packages include OLS, but very few of them offer TSLS or other simultaneous equation estimators.

Validation

The ultimate test of the validity of an econometric model is how well it forecasts the actual behavior of the system it was designed to emulate. This implies solving the model each period for the output variables in terms of given policy variables and external variables as well as lagged values of the output variables generated by the model in preceding time periods. In other words, the model is viewed as a closed loop dynamic system which is driven by a set of starting values for the lagged output variables and given values for the policy and external variables.

Since econometric models may either be linear or nonlinear and either recursive or simultaneous, some technique like the Gauss-Seidel method is needed to solve the simultaneous equation models. Ideally, simple one-word commands like SOLVE and VALIDATE can be used to solve and validate econometric models. It is also desirable to produce a comparison of simulated and actual values and perhaps compute mean percent absolute errors for each output variable.

Simulation

Finally, once we have specified, estimated, and validated an econometric model which we feel we can live with, we are then ready to conduct policy simulations with the model. We simply change the policy variables and external variables and solve for the output variables. Again we need a technique like the Gauss-Seidel method to solve the simultaneous equations.

Integrated models

Although estimation, validation, and policy simulation are, in fact, three separate computer programs, it is possible to integrate each of these steps into a single system so that the user can move easily from one step to another. Commands like ESTIMATE and TSLS can be used to estimate the parameters with ordinary least-squares and two-stage least-square respectively. In addition, a set of test statistics for each equation will also be produced—R,^{2} t-statistic, F-statistic, standard errors, Durbin-Watson statistics, etc. VALIDATE and SOLVE commands generate the time paths of the output variables for validation purposes and policy simulation.

Some systems also contain a SAVE command which enables the user to save the structural specification and parameter estimates of an econometric marketing model and pass them on to a financial model without ever leaving the system. With this feature, it is quite easy to integrate financial, marketing, and production models. No longer is it necessary to develop econometric models on one system and then re-code them for use on a different system if one wants to use the econometric results for planning. Econometric modeling as well as forecasting modeling can now be fully integrated into the planning modeling system.

National and regional economic models

It is also possible to link national econometric models and economic databases directly to a planning and modeling system. For example, Monsanto and Dresser Industries each have the Wharton Econometric Forecasting Model installed on their in-house computer and linked to their business planning models. Hundreds of firms use modeling systems which are linked to the NBER economic database on several timesharing service bureaus.

USER ORIENTATION OF THE SYSTEM

Up to this point we have described a number of basic elements which we believe to be worthy of serious consideration in the design of a planning and modeling system. Various subsets of each of these elements are available in the form of special purpose computer software packages. For example, RAMIS, NOMAD, TOTAL, and INS are all excellent database management systems. FAL, INFOTAB, PROPHIT II, PSG II, and FORESIGHT are all financial report generators. ESP, TSP, ECON, and SPX are econometric and statistical estimation packages. Many of these software packages are quite well suited for special purpose functional applications.

But if our objective is comprehensive corporate planning and modeling then we are likely to require (1) a database management system, (2) a security system, (3) a report generator, (4) a simulation modeling system, (5) a forecasting system, and (6) an econometric modeling system. And, furthermore, it would be extremely convenient to have all of these features linked together as subsystems of a truly integrated planning and modeling system.

Ease of use

It is one thing to advocate an integrated planning and modeling system consisting of the six subsystems described in the preceding paragraph, but what if the resulting system is an extremely cumbersome, difficult-to-use system which requires the user to be a senior programmer or computer scientist? Fortunately, recent breakthroughs in computer science and corporate modeling techniques have made it possible to design and implement an easy-to-use planning and modeling system which includes all six of the subsystems described in this paper. More will be said concerning the ease of use of planning modeling systems, when we discuss computer software systems.

User specified subroutines

Although we have advocated a planning and modeling system which contains a substantial number of powerful built-in functions and subroutines, we recognize the impossibility of building a system which is all things to all people. There will always be a user who wants some special subroutine to satisfy his own unique needs. With this thought in mind, an integrated planning and modeling system should be sufficiently open ended to permit the user to write his own subroutines in, for example, FORTRAN or PL/1. With this feature, the user never gets locked into a particular system.

SYSTEM AVAILABILITY

Corporate planning modeling systems may either be run interactively or in batch either on the user's in-house computer or on an outside service bureau. Although computer service bureaus, particularly time-sharing bureaus, may provide a convenient vehicle for the development and testing of individual business unit planning models, putting an integrated comprehensive total corporate planning model and database up on an outside service bureau is likely to be prohibitively expensive. The disk charges for the corporate databases alone will be enormous. Over the long run, we believe that most of the really serious corporate planning and modeling systems for large companies will be implemented on in-house computers rather than on an outside bureau. However, smaller firms which are equivalent to single business units in our Figure 1 flow chart, will still find service bureaus to be the most cost effective alternative for doing financial planning and modeling.

Interactive

All things being equal, it is difficult to argue against the merits of interactive computing for corporate planning and modeling. The benefits of conversational computing to planning are obvious and well documented in the literature. But interactive computing can be quite expensive even on in-house computers, if one considers the opportunity cost of alternative uses of computer central processing units. Therefore, we recommend interactive computing during the model debugging stage and when the timeliness of alternative plans and scenarios justifies the premium charges for interactive computing.

Batch

Batch computing is more appropriate for creating large historical databases and doing multi-scenario production runs where the user is not faced with an urgent deadline to make a decision.

SOFTWARE SYSTEM

What about the task of programming a corporate planning and modeling system? Basically, two alternatives are available. The system can either be programmed in a general purpose scientific language like FORTRAN, PL/1, or APL or it can be coded in a planning and modeling language like BUDPLAN, COMOS, or SIMPLAN.

There are at least two major benefits associated with the use of one of the scientific programming languages. First, they are extremely flexible. That is, every feature which we have proposed for a planning and modeling system could be coded in FORTRAN, PL/1, or APL. Indeed, our survey showed that 50 percent of the corporate models in our sample had been written in FORTRAN. Second, these languages are quite well-known, particularly FORTRAN.

But there are some very serious limitations to the use of scientific programming languages for corporate planning models. First, corporate planners and financial analysts may not be familiar with any of these languages since they may not have previous computing experience. Second, database management and report generation are not the main strengths of FORTRAN and APL. (PL/1 admittedly has some features which facilitate file manipulation and report generation.) Third, these languages offer little assistance in either formulating or coding corporate planning models, since they are general purpose scientific languages. Fourth, it is the rule rather than the exception for top management to make frequent changes in their requirements in terms of report formats, policy assumptions, external assumptions, types of consolidations, etc. Mergers and acquisitions occur, new products are introduced, and old products are dropped. These types of changes are not easy to implement with scientific programming languages. A major reason for the demise of most of the large-scale models developed in the 1960's was their lack of flexibility. Without exception, the Sun Oil, Xerox, and *New York Times* models, as well as several others, were all written in FORTRAN. When Sun Oil merged with another oil company, the model was dropped rather than re-programming it in FORTRAN. Fifth, even if the model builders are accomplished programmers, econometric modeling is very difficult with scientific programming languages.

Some have suggested that APL will be the wave of the future for corporate modeling. Although APL is by far the most powerful scientific language available today, it has some unique disadvantages which are likely to render null and void the fantasy of corporate managers sitting at their APL terminals doing corporate planning. First, APL assumes the user is proficient at mathematics including matrix algebra. This assumption simply does not hold up in the real world. Very few managers have ever been exposed to matrix algebra. Second, the special characters and mathematical operators of APL are likely to be foreign to most managers, financial analysts, and corporate planners. In summary, APL is a fantastic language for computer scientists and mathematicians, but its utility as a corporate planning tool is severely limited.

The alternative to scientific programming languages is to use one of the new planning and modeling languages designed specifically to facilitate the formulation and coding of corporate planning models. Among the benefits to be derived from using one of these planning and modeling systems are the following. First, they are easy to use. To do financial modeling with a system like SIMPLAN, the user must be familiar with high school algebra, accounting, and finance. The user need not be familiar with modeling or computer programming. Second, some of these systems provide a conceptual framework for planning and modeling which makes it much easier to develop the model in the first place. Third, with a select few of these systems, it is possible to have all six of the following subsystems integrated within the planning and modeling system: (1) database management, (2) security, (3) report generation, (4) simulation modeling, (5) forecasting, and (6) econometrics. Fourth, many of these planning and modeling systems are quite flexible. Changes in databases, models, and reports are easy to implement. Fifth, even if the model builders are senior programmers, econometrics, forecasting, and risk analysis are much easier to implement with one of these systems than with a scientific language.

Of course, the advantages of these planning and modeling software systems must be weighed against their costs. First, these systems are not available free of charge to the user. That is, the user must pay a fee for the use of one of these planning and modeling systems. A limited number of these systems can be licensed for use on in-house computers. These include BUDPLAN, FORESIGHT, FP-70, PSG II, and SIMPLAN. Nearly all of these systems are available on a surcharge basis on various timesharing service bureaus. Second, since the computer is doing the work of many programmers, the computer running costs will definitely be higher than say similar models programmed in FORTRAN, but the human costs should be considerably less.

SUMMARY AND CONCLUSIONS

With nearly 2,000 companies now experimenting with some form of planning model, it is not surprising to observe that many of these companies began using a particular modeling system without giving much thought to the long-run implications of the system which was selected. It is not uncommon to find one division of a company using FAL, another using PROPHIT II, and a third using a FORTRAN model running on yet a different service bureau's computer. At the same time, the corporation maintains a corporate database as well as databases for each division on the in-house computer. Corporate planning may also subscribe to one or more outside econometric forecasting services.

In other words, it is not unusual to find large companies subscribing to as many as six different modeling services with exact duplicates of the corporate database running on the in-house computer as well as on outside service bureaus.

With a little thought and careful planning, it is possible to design an integrated planning and modeling system which will satisfy corporate management as well as the management of all of the business units. Financial, marketing, and production planning models can all be developed within one system which is linked to a national econometric database. And, finally, the system can be implemented on the company's in-house computer thus eliminating outside timesharing charges and the costly duplication of databases.

In summary, time spent on the design of a company's planning and modeling system may be time well-spent.

Analysis of "natural" language discourse*

by SALLY YEATES SEDELOW
The National Science Foundation
Washington, D.C.
and
The University of Kansas at Lawrence

ABSTRACT

Referential linkage in extended language strings (multiple-sentence, paragraph, etc.) is of great interest to computer scientists, linguists, and literary scholars concerned with the analysis of discourse. In all three disciplines, semantic relationships are central to approaches to inter-sentential, inter-paragraph, and inter-supraparagraph linkings. This paper compares and contrasts some of the directions taken in current research and explores the possible utility of a general-purpose thesaurus for the construction of semantic frames of reference. The utility of such a thesaurus for measuring semantic distance between terms and thus establishing possible linkages is suggested by an experiment concerning word prefixation.

Discourse analysis is now being undertaken by research scientists in a number of disciplines. Its meaning varies from field to field and even from scientist to scientist; traditionally, it has implied the structural analysis of a relatively large number of consecutive natural language sentences, paragraphs, chapters, or larger units. (It is not restricted to the spoken word, although that is one meaning of discourse.)

As a former professor of English literature with a major interest in the analysis of language-strings of the length of *Hamlet*, or *Paradise Lost*, I have watched the growing interest in discourse of my newer colleagues in computer science and in linguistics with both genuine excitement and, it must be confessed, a frequent feeling of *déjá vu*. Thus, extended debate on the subject of "frames" at a recent workshop on theoretical issues in natural language processing sounded very like discussions over the years by literary scholars and students on topics such as "frame of reference" and "point of view." I feel that my new colleagues are, in a sense, just beginning to learn to talk but, on the other hand, perhaps in time their talk will be couched in more precisely used terms than those employed in analogous literary conversations. I certainly hope so, since such precision was for me a prime motivation in having become associated with computer scientists and linguists.

Although discourse analysis has been a primary concern of literary scholars for many years, for both linguists and computer scientists it does represent an exciting new concern. The reasons for computer science coming to this study rather late are quite obvious, but that linguists should be so slow to arrive on the scene may seem to some rather surprising. For the sake of clarification, it might be noted that for a number of decades literature and linguistics (at least as linguistics is practiced in this country) have been very much separated from each other. Linguistics departments have sometimes provided, as a service, courses on the English language, but the heart of the discipline has been elsewhere. The "elsewhere" has been a world of micro-events, such as the basic units of sound, or the basic units of grammatical structure, which were long considered to be solely syntactic. Given this concern with microunits, the outer bounds considered necessary for adequate study of such units were provided by the sentence. As I have already noted, literary scholars find it necessary and desirable to concern themselves with texts of lengths greater than a sentence; thus, the work of linguists has not been of overwhelming interest to literary scholars, and vice versa. Further, there has been relatively little of the interdisciplinary dialogue which might have pushed linguists somewhat sooner toward looking at the types of language phenomena of interest to literary scholars.

More recently, linguists have been forced, perhaps partially through their own need for new approaches to the study of language but also because of efforts to use computers for language-dependent tasks—such as machine translation—to try to place their microunits within systems which, in turn, have proved to be parts of ever larger systems. Early efforts to use the computer to provide translations produced generally unsatisfactory results partly because semantic systems had been essentially ignored by linguists. Attempts to apply the computer to other areas entailing heavy

* The views expressed in this paper are those of the author, and do not necessarily reflect any policies of the National Science Foundation.

manipulation of natural language—areas such as information retrieval and computer-assisted instruction—have clearly demonstrated both that semantics must be taken into account and that the length of a sentence does not provide an upper bound for semantic interpretation of a language string. Linguists, of course, have not been ignorant of the existence of semantics and long language strings. In effect, they simply decided to ignore these areas because they looked intractable. Currently, practical necessity and intellectual curiosity are moving linguists into discourse analysis; so that now we have a coincidence of interest among some linguists, some computer scientists, and some literary scholars (not to mention certain psychologists and other social scientists). In order to provide context for the relevance of my own research to this emerging area, I'd like to refer briefly to some forefront thinking about discourse analysis in computer science and linguistics and then show where my own work, which originated in the study of literature, fits.

At the moment, it is probably accurate to divide approaches to discourse analysis into those efforts which are concentrating upon rather short, although still multiple, sequences of sentences and those approaches which are concentrating upon texts which are much longer, even of narrative length.

Those scholars and scientists concerned with "small-scale" discourse analysis want to describe linkages between and among contiguous or near-contiguous sentences, as well as to describe linkages between a single sentence and its context; the context may be provided either by contiguous sentences or by networks of associations built up from earlier experience with reality, however perceived. A simple example of linkage between sentences is pronominal reference: both linguists and computer scientists have been concerned with this aspect of anaphora (literally, the carrying up or back to something earlier) and of cataphora (carrying forward).

Examples of computer-based natural language systems which deal with aspects of reference linkage can now be readily located. They range from examples in Winograd's block world program in which the computer responds to the command "Grasp the pyramid" by saying "I don't understand which pyramid you mean" because the particular pyramid implied by the article "the" was not specified in an earlier sentence,[1] to concerns such as those described by Barbara Deutsch at the Stanford Research Institute in her recent paper on "Establishing Context in Task-Oriented Dialogues."[2] When the SRI computer is told to "Assemble the air-compressor" and to "Begin by attaching the pump to the platform" it starts by inspecting something called focus spaces to determine whether there is more than one air compressor to worry about; it proceeds analogously when "attaching *the* pump to *the* platform."

The SRI grammar, described by Jane Robinson,[3] can also handle elliptical references between sentences, as in the following sequence: "What is the length of the surface displacement of the Lafayette? . . . What is its draft? and "What is the length of the Lafayette? . . . The Ethan Allen?" In this sequence of four sentences we have an example of anaphoric reference through the use of "its" in the second sentence and of elliptical anaphoric reference in the fourth sentence which, in its entirety, would read "What is the length of the Ethan Allen?".

Let me offer one more example of current speculation by a computer scientist about an aspect of small scale discourse analysis; in this case, the concern is with linkages among single sentences and an individual's "store" of earlier verbal and sensory experience. This example is the beginning of a fable, as told by Wallace Chafe, a linguist at Berkeley, and retold by Marvin Minsky:[4]

> *There was once a Wolf who saw a Lamb drinking at a river and wanted an excuse to eat it. For that purpose, even though he himself was upstream, he accused the Lamb of stirring up the water and keeping him from drinking . . .*

Minsky says that to understand this fable one must realize that the wolf is lying. To understand "even though" one must realize that the contamination in question doesn't move upstream. This realization in turn requires us to understand (among other things) the word "upstream," itself. Minsky then devotes several pages to indicating how his framework might help one understand some of these terms as well as the more extended meaning of these two sentences. By frame, Minsky means a

> data-structure for representing a stereotyped situation, like being in a certain kind of living room, or going to a child's birthday party. . . . For visual scene analysis the different frames of a system describe the scene from different viewpoints, and the transformations between one frame and another represent the effects of moving from place to place. For nonvisual kinds of frames, the differences between the frames of a system can represent actions, cause-effect relations or changes in metaphorical viewpoint.[4]

A little later, I want to return to this example to indicate how some of my research can help to get at "frames of reference" which, in turn, will help to delineate discourse structures where the structure depends upon the perception of semantic relationships.

For macro discourse analysis, the most relevant current work in computer science is content analytic and I will recur to it briefly later. When we turn to linguistics, we find a number of linguists—notably Robert Longacre[5,6] and Joseph Grimes[7] and students associated with them—who have become involved in the analysis of macro discourse ranging up to short narratives in length. In *The Thread of Discourse*,[7] Joseph Grimes provides a broad overview of these discourse analytic techniques, a number of which would be useful for discourses of any length. Many of the approaches to discourse analysis described by Grimes depend on too much preliminary background for use in this paper, but a brief description of two of the approaches would seem worthwhile in order to provide some sense of linguists' orientations toward this new area.

One very simple technique is span analysis. An identification span consists of a series of identifications of the same participant in a narrative—a series in which no identification is stronger than the one before it. Strength of identification is defined as a ranking that goes from proper names, to explicit descriptives like "the last speaker at the symposium," to common nouns like "the speaker," to nouns used generically like "the fellow," to pronouns like "him," to reference without identification. When a shift occurs from a weak form of identification to a stronger form, the current span is terminated and a new one begins. The spans can be shown graphically simply by taking a piece of paper, listing vertically from 1 to n the number of clauses, or phrases, and drawing vertical lines to show the length of the spans. Such spans can be used for many other characteristics of discourse such as setting, time, and place, and can reveal patterns which graphically illustrate the differences in style between one work and another, between one author and another, and so on.

I would like to mention one other discourse analytic technique described by Grimes and, in fact developed by his students, Mary Ruth Wise and Ivan Lowe.[8] This approach depends upon the roles taken by participants in a narrative. Here, roles are described by such terms as agent, experiencer, instrument, and other analogous categories drawn from case grammars, which are now of great research interest to both linguists and computer scientists. This approach to discourse analysis studies the shifting of roles among the participants in a discourse. The perception of shift is based upon relative rankings among cases such as agent, experiencer, and so on. In this system, agent is the highest ranking role and a case called essive, which is rather analogous to the existential state, is the lowest ranking.

One type of role shift is a reversal, which involves an exchange of relative ranking between two participants in a narrative. In some simple narratives, reversal is the only shift which occurs. The text tends to start out with one character as agent and the next as, say, goal, then reverses so that the second character is agent and the first has a role of lower rank. A second reversal brings the characters back into the original orientation; in some of the simple folk narratives studied by Grimes and his students, this second reversal signals the beginning of a new paragraph.

Another kind of role shift is described as a switch, in which the second and third participants undergo reversal of rank. In a number of narratives studied by Grimes and his students, the regular progression of events is carried by single operations such as a single reversal or a single switch. Whenever there are composite operations, such as a switch and reversal, or reversal and switch, there is a surprise, an interruption or a point in the narrative where things go wrong.

Grimes tries, with varying degrees of success, to provide a text-analytic operational significance to such categories as cohesion, theme, setting, background, evaluation, and many others, including a range of types of linkages between sentences. Almost all, if not all, the categories for discourse analysis he explores depend upon understanding word meanings, phrasal meanings, clausal meanings, paragraph meanings, and so on. Meaning—semantics—is the key to discourse analysis and therein lies a challenge for any efforts to use the computer for discourse analysis.

My own research on computer approaches to discourse analysis has been partly built upon training as a literary scholar. Thus I have been concerned with texts of extended lengths and I have wanted to find methodologies, procedures, and/or algorithms suitable for use with a broad range of texts. By contrast, for the most part computer scientists concerned with discourse have tended to constrain the universe of discourse with which they deal to a very small segment of reality. The reasons for such constraints are obvious when you consider the complicated problems which must be dealt with in even a very modest universe; but I have chosen not to follow this path because my own preferences and training make it uncongenial and, especially, because as a scientist I strongly prefer general solutions for natural language problems to *ad hoc* solutions.

When I began working with computers* I decided to concentrate upon structures of meaning because those are of major importance to discourse which, as I have stated before, is of central importance to most literary scholars. At that time (thirteen years ago) other people were working on parsers and I planned simply to borrow a parser from someone else when the need arose. It is doubtless a splendid testimonial to man's ingenuity as a user of language that the general-purpose parser I need is still not available, although there has been excellent research on this problem and there are parsers to which I would now like access.

My approach was to develop a set of content analytic programs which I used to look for literary themes. Themes comprise semantically-related words and form

* Much of the research described on the following pages has been supported by the Information Systems Branch, Office of Naval Research.

part of the structure of a discourse. For example, part of the structuring form of *Hamlet* is provided by a network of associations involving disease, madness, and decay, just as part of the structure of *Paradise Lost* involves a semantic network of words associated with variety and variation. I have written and talked about this research elsewhere[9-12] and I will not discuss it further here. But I do want to talk about an outcome of that research—that is, further research, on the nature of thesauri.

Thesauri now come in many forms. In the context of information retrieval, a thesaurus most often consists of a list of terms, sometimes divided into categories, relating to some specialty area. The kind of thesaurus I have in mind is not one of these special-purpose word lists, but rather a general-purpose reference work showing semantic relationships among words in a whole language. Specifically, I have in mind the English-language thesaurus, *Roget's International Thesaurus*.[13] Although no such general reference work is 'perfect,' or even nearly perfect, it does have the strong advantage of validation through time and across a culture. I argue that large corpora such as *Roget's Thesaurus* or the Merriam-Webster's dictionary should be investigated for their potential utility in dealing with semantics for all kinds of computer-based tasks. They also lend themselves to segmental exfoliation when a finer semantic mesh is needed for a specific purpose. Such potential sources of semantic information have been largely ignored by those seeking to use the computer to capture meaning in natural language. Notable exceptions to this rule are John Olney at SDC and his associates who have put *Webster's Collegiate Dictionary*[14] into computer-accessible form; among those using this version of the dictionary are Robert Simmons and Robert Amsler who, in a recent paper[15] state that "from a linguistic point of view . . . the proper source of semantic information is a large corpus of ordinary usage of the language."

One of the reasons these general purpose corpora haven't been more extensively employed is that they are difficult to use. Another is that they are difficult to get into a useable form. Part of my own research effort in recent years has been directed toward putting *Roget's International Thesaurus* into computer-accessible form. The *Thesaurus is* now in computer-accessible form although the editing hasn't been completed.

Editing is a major problem because the *Thesaurus* makes many assumptions concerning the ability of the human reader to fill in elisions, supply context, and otherwise rely on the enormous store of information in the human brain. An example of a frequently occurring type of elision is "jump up or off" in which the jump for "jump off" is omitted. An example of the dependence upon the human reader to fill in or at least understand what a possible extension of items in the *Thesaurus* might be is the frequent use of etc. to indicate the continuation of lists. Examples of such lists are "Pan-American, Pan-Pacific, Pan-Hellenic, etc.", (multiply by 5, etc.)", "hourly, daily, etc." and so on. These and other analogous problems which must be dealt with in order to use the *Thesaurus* in automated systems have been discussed elsewhere.[16,17]

Our reason for putting the *Thesaurus* into computer-accessible form was to use it for content analytic applications. In order to put it to such use, it is desirable to have a clear understanding of the structure of the *Thesaurus*; approaches to the study of the structure have been explored by a graduate student, Robert Bryan, and are described in research reports for this project (available through the Computer Science Department at the University of Kansas).[18,19] A major potential utility of the *Thesaurus* not only for content analysis but for many other efforts to use the computer to understand natural language is as a guide to measures of semantic distance. That is, the number of nodes one must pass through in the *Thesaurus* to get from one word to another, or from one concept to another, can be taken as measures of semantic distance. Again, the graph theoretic approaches outlined by Bryan are intended to facilitate research on this question. It should be borne in mind that since any given term may appear at several different nodes in the graph, semantic space in the *Thesaurus* is much more complex than the organizing tree-structure for the *Thesaurus* content might lead one to suppose.

The viability of the *Thesaurus* as a potential source of information concerning semantic distance was a central issue in an experiment we undertook with reference to prefixation. Our experiment was to see whether the *Thesaurus* might be used for determining when a particular string of alphabetic characters is serving as a prefix. The experiment is described in some detail by Sam Warfel in one of our research reports.[20] As you may know, the *Thesaurus* is organized hierarchically, with the basic text consisting of 1040 semantic categories each with a number and a label, *e.g.*, "854. lack of feelings." Each of these numbered categories is divided syntactically and semantically. For the purposes of this experiment the syntactic categories were ignored, because a preliminary investigation suggested that syntactic categories added no useful information toward the determination of prefixed words. (An obvious reason for this impression is that syntactic category membership is most often indicated by suffixes.)

To clarify the following discussion, it may be worthwhile to describe briefly the general structure of the hierarchy in the *Thesaurus* so that ensuing references to "levels" will be understandable. The 1040 categories are related at a higher level in the *Thesaurus* by the "Synopsis of Categories," which is not part of the basic text but is presented as an outline following the Preface. In this synopsis the *Thesaurus* is divided into eight classes (*e.g.*, Class Six: Intellect). Each class is divided into several labeled sub-classes indicated by Roman numerals (*e.g.*, I. Intellectual Faculties and Properties) and each sub-class is divided into labeled sub-sub-classes designated by capital letters (*e.g.*, L. Conformity to Fact). Each sub-sub-class is divided into several of the 1040 categories (*e.g.*, 515. Truth) which are numbered consecutively throughout the text. Each of the 1040 categories is subdivided into numbered 'paragraphs' of words; for example, there are twenty-two such divisions under 515. Truth, so that there are subcategories 515.1–515.22. These 'paragraphs' are, in turn, subdivided into semi-colon groups; that is, within a paragraph those words most closely related are grouped and delimited by semicolons, *e.g.*,

accuracy, correctness, rightness;
exactness, exactitude;
preciseness, precision;

Thus, in the following discussion of the value of semantic distance measures for determining prefixation, the levels referenced are as follows:

Level 1 *e.g.*, Class Six: Intellect
Level 2. *e.g.*, I. Intellectual Faculties and Properties
Level 3. *e.g.*, L. Conformity to Fact
Level 4. *e.g.*, 515. Truth
Level 5. *e.g.*, 515.3
Level 6. *e.g.*, accuracy, correctness, rightness;

Our assumption was that words occurring either in the same place in the hierarchy or very near each other in the hierarchy are more likely to be related than those further away. Therefore, it seemed possible that words having the same root and differing only by prefix would tend to fall together in the *Thesaurus,* (i.e., to be only short distances apart). In general, our sampling bore out our hypothesis. That is, words such as joy and enjoy (863), rich and enrich (835), guise and disguise (230), courage and encourage (891), occur in the same fourth level categories in the *Thesaurus* hierarchy. On the other hand, words such as *vent* and *prevent* are shown not to belong together because prevent does not occur in either the same category or any of the categories related to categories associated with the unprefixed root *vent.*

To gain a further sense of the utility of the *Thesaurus* for this purpose, we compared the use of the *Thesaurus* with that of our prefix recognizing program (which is operational and which is based on ad hoc decisions on all the words in the *Random House* dictionary).[21] We used the *Thesaurus* for the comparison of thirty-eight word pairs which had been turned up during the course of a computer run of the PREFIX program (22). PREFIX produced ten word pairs which struck me as viable pairings. Had the *Thesaurus* been used to examine those same word pairs, eight of them would have been linked together. The word pairs are shown below, with those bearing the * indicating the pairings also produced by the *Thesaurus*:

integration-disintegration
* able-enable
* courage-encourage
* danger-endanger
* doubted-undoubted
moralize-demoralize
* capacity-incapacitate
* labor-elaboration
* sequence-consequence
* valuate-evaluate

Of the ten pairs on the above list, the grouping of *moralize* and *demoralize* is at least questionable. The *Thesaurus'* judgment here may be preferable to my own when I was earlier looking at the results of the PREFIX run.

The PREFIX program grouped together three word pairs which should not have been grouped. The *Thesaurus* identified none of these words as appropriately paired:

cent-recent pare-prepares tribute-distribution

The PREFIX program produced twenty-five pairings which I judged to be helpful in some contexts (some of them very rare and esoteric) but not in others. Those pairs in the list below which would have been linked by the Thesaurus are again shown with an *:

* compass-encompass
* conceivable-inconceivable
cover-discover
* fend-defend
fluence-influence
* joy-enjoy
* junction-conjunction
ligation-obligation
mode-outmode
* ply-apply
promise-compromise
* refutable-irrefutable
* rich-enrich
* rupture-disrupt
see-foresee
* separable-inseparable
stead-instead
strict-restrict
* thinkable-unthinkable
tinction-distinction
gaged-engaged
ordinate-coordinate
vestigation-investigation
jugate-subjugate

As should be apparent from the examples above, as well as, hopefully, from any sampling others might make of the *Thesaurus,* while the *Thesaurus* is not perfect for this task, nonetheless, it is rather good. Some problems could be taken care of if inconsistencies in the organization of the *Thesaurus* were eliminated. For example, although most negation and reversal relationships are expressed in adjacent categories under the same third level headings, there are exceptions to that organizational principle. Thus, although there is a category at the fourth level in the hierarchy labeled "disintegration" there is no comparable category labeled "integration," despite the fact that there are categories labeled "order" and "disorder" as well as "continuity" and "discontinuity."

The same inconsistency is apparent with *talkativeness* and *untalkativeness* where the third level categories containing the words are quite far removed from each other, unlike other positive-negative category pairs:

(Level 2)	III. Communication of Ideas	
(Level 3)	B. Modes of Communication	M. Uncommunicativeness; Secrecy
	552. Communication	611. Uncommunicativeness
	552.4	611.2
	communicativeness, talkativeness. . . ;	taciturnity, untalkativeness. . . ;

A different problem arises with the pairs *birth-rebirth* and *born-reborn* where the first word in each pair occurs in fourth level categories related to either "beginning" or "physical birth" while the second word in each pair occurs only in fourth level categories related to the religious experience of conversion. Therefore, the words in the pairs are not judged by the program to be prefixed since the metaphoric relationship between the two uses of *birth* is not shown in the *Thesaurus.*

In order to achieve comparability in these measures of semantic distance provided by the *Thesaurus,* organizational inconsistencies in the *Thesaurus* such as revealed by this experiment would need to be coped with either through cross referencing or shifts in the structure of the *Thesaurus.* Metaphorical relationships will be more difficult to capture, although it is the case that the *Thesaurus,* unlike a dictionary, is rather strong on making some metaphorical relationships explicit. This facet of the *Thesaurus* is useful, as we shall see in an experiment with the *Thesaurus* and the few sentences from the fable about the wolf and the lamb cited earlier.

For the sake of convenience, the initial sentences of the fable I cited earlier are repeated:

> *There was once a Wolf who saw a Lamb drinking at a river and wanted an excuse to eat it. For that purpose, even though he himself was upstream, he accused the Lamb of stirring up the water and keeping him from drinking. . .*

The experiment I want to undertake here is first to use the *Thesaurus* to see what kind of contextual "frame" it can provide to facilitate understanding of the fable. When the *Thesaurus* fails, I will suggest the use of a parser or dictionary, either separately or in combination with each other or with the *Thesaurus.* Let me say, prefatorially, that this experiment, as is the case with Minsky's article on frames, ignores many difficulties that would in fact arise were one using the *Thesaurus,* as well as, for that matter, the dictionary and parser to cope with the fable. The goal in this next little exercise is to see whether there is any point in pursuing further the use of the *Thesaurus* for such a task.

Our assumption—a strong one—will be that the computer has no information about any of the words in these sentences and that, in fact, the *Thesaurus* must be used to provide the context.

You will observe that the first sentence of the fable is: "There was once a Wolf who saw a Lamb drinking at a river and wanted an excuse to eat it." A lookup of "river" in *Roget's* will locate "river" under "running water" and it will be linked with "stream" as well as with "drinking water." Thus the notion of river as drinkable emerges. The word "wolf" appears in a listing of animals. "Lamb" does not appear in that list but it is linked to "sheep" which, in turn, appears as an animal. "Sheep" is also linked to "mutton" which is linked in the *Thesaurus* index to "meat" which in turn occurs with "feed" and "dine." Given metaphors' pleasing property of frequently having some relationship to (symbolic) reality, it would probably be useful to find in the *Thesaurus* the use of "wolf" to mean "devour," which in turn occurs in the index under "eat up." Thus, as it happens, the *Thesaurus* associates wolf with eating and on the basis of this association it might be possible for a computer program to assume that the creature who "wanted an excuse to eat it" is the wolf. The lamb is not particularly associated with drinking through any references in the *Thesaurus.* Rather, a syntactic parser might be expected to work out the relationship between the lamb and drinking in the phrase "lamb drinking at a river."

The chief problem in this sentence is the identification of "it." To repeat the sentence: "There was once a wolf who saw a lamb drinking at a river and wanted an excuse to eat it." "It" could refer either to the lamb or to the river. The only route to disambiguation that looks possible to me is at the syntactic level, which might point up a parallelism between the wolf seeing an object—the lamb—and eating it. In both cases, "it" is the object of an action by the wolf and possibly through this parallelism "it" might be identified with lamb. I find no information in the *Thesaurus* that would enable a program to perform this disambiguation. It is possible to deduce from the *Thesaurus* that a lamb can be eaten if you follow a somewhat circuitous path which, under the listing of animals, provides the word "flesh" in connection with "horse flesh" and under "eating" provides the word "flesh eater." You will remember that "sheep" appeared under "animals" and that the word "lamb" was linked with "sheep." Unfortunately, there is no information in the *Thesaurus* which would suggest that a river cannot be eaten.

To the contrary, the words "drinking" and "drink" occur under the general heading of "eating," so one might conclude that the "lamb," for example, could just as well be said to be eating a river as to be drinking it. The preposition "at" in the phrase "lamb drinking at the river" might be helpful here, but it is difficult for me to see how it could solve this problem.

With reference to the word "excuse" in this sentence: the wolf "wanted an excuse to eat it"—the *Thesaurus* lists "excuse" along with "guise," "mark," "pretext" and "false pretence" and it also links "false pretender" with the expression "wolf in sheep's clothing." Syntactic analysis might be necessary to establish that it is the wolf, not the sheep, which is linked to "false pretender" in that group but, given such analysis, "excuse" is linked to "wolf."

The portion of the second sentence we have is: "For that purpose, even though he, himself, was upstream, he accused the lamb of stirring up the water and keeping him from drinking. . . ." Syntactic analysis should establish that "he, himself" is the subject of the second sentence and rules governing anaphoric reference would identify the subject, "he, himself," with the subject, "wolf," of the first sentence.

The meaning of "upstream" and its connotations for this little narrative are quite difficult to get at. As noted earlier, the *Thesaurus* is structured so that, frequently, categories having opposite meanings are juxtaposed. For example, Ascent, which contains the word "upstream" is next to Descent, which contains the word, "downstream." It would be possible to get from one category to the other by searching on the word "stream." If one looked up "upstream" in *Webster's Seventh Collegiate Dictionary,* the definition "at or toward the source of a stream" turns out not to be terribly helpful. On the other hand the definition of "downstream" is "in the direction of the flow of the stream" and flow is associated with movement both in the dictionary and in *Roget's Thesaurus.* The index of the *Thesaurus* provides many clues that "move" and "motion" entail a change of position; for example, one finds the phrases "move back" and "move forward." The dictionary, as you remember, associates movement or flow with directionality and "downstream" is shown by the thesaurus structure to be the opposite of "upstream." Further, the "even though" in this sentence implies some condition—opposite or contrary to—not consonant with one's "frame" involving "upstream."

At this point, the computer-based information processing programs might be in a position to try to produce some version of the representation suggested by Minsky in his discussion of this small segment of discourse. It might be desirable to represent the relative positions of the wolf and the lamb vis-à-vis the direction of flow of the river; and it may, indeed, be necessary to build into the computer program some sort of "primitive sense perception" to show that disturbing the water at the lamb's location doesn't affect the water at the wolf's location. This kind of "sense-perceived" knowledge, which forms the basis for much exploratory work in computer science, does not depend, initially, upon word associations but rather upon visual experience. (It may even depend also on a stored analytical model of physical processes.) Much knowledge, of course, has an *ultimate* dependence upon visual experience but this particular perception is difficult to track down to its final meaning through either thesaural associations or dictionary definitions. Given some such primitive representation of the factual situation it would then be desirable to try to contrast the verbal statement after "accuse" with the realistic representation produced by the "even though."

One can see how it might be possible to combine a parser, a thesaurus, and a dictionary, as well as, perhaps, sensory primitives to conclude that the wolf intends to pick a fight with a lamb, but I am not certain that it will be clear whether the wolf wants to eat the lamb or the river—although the suggested syntactic clues might provide some probability that the wolf would like to eat the lamb. If the syntactic information doesn't provide a satisfactory resolution, then one envisions having to provide some primitive sense perception based on the size of a river relative to that of a wolf or on what animals, perhaps even wolves, have been seen to eat, or some combination of those perceptions. The role of *Roget's* and the dictionary, obviously, would be to try to reduce markedly the number of such perceptions one would have to build into a system and to capture, instead, many such perceptions through patterns of word association which presumably reflect one's sense perceptions (and [implicit] reality models).

It is certainly clear to me, as I'm sure you will be able to guess, that an effort to get down to cases and actually program a computer to make its way through a thesaurus and dictionary, draw the appropriate inferences, and combine those inferences with syntactic and sensory information is going to be exceedingly complicated. But it needs repeated, strong emphasis that we require general, not ad hoc, solutions to these problems. I argue that one should be exploring the possible utility of these general-purpose reference works with an eye toward revising and adapting them to the needs of specific discourse analyses for the very pragmatic reason that no one seems to have the patience to construct from scratch a thesaurus or dictionary that deals with a very large segment of "reality" and, at the same time, is specifically designed for a set of "language understanding" computer programs. Further, there is at present no consensus as to what theories or procedures the computer programs should embody; therefore, there is no consensus as to how words and their semantic relationships should be represented. It is also the case that general-purpose reference works have some claim to cultural validation; such is not the case for ad hoc thesauri or dictionaries for special-purpose programs.

In summary, one can surmise, I think, how one might build upon some of the types of analyses I have suggested to use the computer to analyze discourse. For small scale, or micro discourse, syntactic parsers will be valuable, as will dictionaries and thesauri for their guides to meaning. Representation of at least visual perception "primitives" probably cannot be circumvented. I've said nothing about sound patterns, but research directed toward enabling the computer to move from the written word to spoken "output" as well as to enable the computer to understand speech is currently in progress and such research clearly has relevance for the study of patterns of sound in discourse. For macro discourse, all the procedures relevant for small-scale discourse are germane. In addition, the kinds of thematic analyses made possible by my programs are relevant for extended discourse. It is then possible to make visible patterns of thematic occurrence within a text by graphically portraying the themes at the locations in which they occur. John B. Smith of Penn State, once a student of mine, used some of my programs and some of his own to portray occurrence patterns of images in Joyce's *Portrait of the Artist*—and discovered that those moments Joyce had described as epiphanal were graphically obvious because of the coincidence of major imagery patterns at those points in the *Portrait*. Spans of setting, of identification, and of other categories to which I have alluded will eventually be amenable to computer analysis if we are able to deal with the many thorny issues related to perception of meaning that I have illustrated through examples in this paper.

The importance of computer-based discourse analysis for the many natural language applications in computer-based systems cannot be overemphasized. The long-awaited breakthroughs in information retrieval and in other application areas, such as computer-assisted instruction, which are dependent upon information retrieval (broadly defined) must await an increased algorithmic and computational capability for the analysis and generation of extended discourse. It behooves us to explore every possible avenue to full or partial solution of the many complex problems which must be solved in order to achieve computer-based discourse analysis. The implications are immense—both for the development of the non-numeric aspects of computer science and for the next major stage in the application of computers to the solution of human problems and to aiding with society's work-a-day tasks.

Computer animated film systems—A rat's nest of trade-offs

by BRUCE CORNWELL*
Consultant
Brooklyn, New York

and

KATHARINE CORNWELL*
Peat, Marwick, Mitchell & Co.
New York, New York

ABSTRACT

Selected examples of computer animated film production systems are analyzed in regard to usefulness for student projects, commercial film production and graphic research. No system seems ideal for all of these purposes and the most sophisticated systems inhibit a "collaborative" relationship with the computer, especially regarding images that relate to mathematics, science, or aesthetic spin-offs from these fields. A minimal system of batch mode computing with microfilm output is described.

The two most beautiful aspects of the computer as used in batch mode processing is that most any system is infinitely expandable from the standpoint of hardware, and it has unlimited flexibility in view of the vast range of languages that can be utilized. It is almost astounding that one can gradually expand a computer from scratch, without having to make far-reaching decisions, other than the jump from a hand-held programmable calculator to a system with peripherals, or the jump to a larger word size if one starts out with a mini computer. In contrast to this possible oversimplification, the building of a general purpose system for the production of computer animated films is practically an insoluble problem. Not only is there no ideal *final* system, but the route toward the building of a high-capacity or high-versatility system presents an obstacle course of decisions. These decisions are simplified if the system is dedicated to a single purpose, such as films for use as engineering simulation studies produced by an engineering concern with an in-house facility.

Aside from such specialized applications, there are two questions that might be explored: (1) What is a minimum, workable computer animated film system, and (2) What are the trade-offs as one expands upward? These questions are especially relevant when considering the possibility of a facility for production of computer animated films within an educational environment.

There are several insights that can be gained from an examination of the problems encountered in the selection of equipment, materials and facilities for conventional motion picture production. To begin, there is no such thing as a *general purpose* film production facility, or motion picture camera. Equally sophisticated film producers may require totally different equipment, as when shooting on a wildlife refuge, or on a sound stage. The term, *trade-off,* in the motion picture field is not a matter of differences of degree—like 10 to 25 percent in cost, portability, speed—it can mean equipment being totally incompatible for diverse tasks. Trade-off with equipment for computer animated films can be almost as drastic.

If the proposed facility is predicated toward ease of film production, eventually the filmmaking process can become child's play, and the end result may be trivial. For instance, Fortran can be used to construct an endless variety of mathematical functions as graphs. And these can be subjected to motion that is also mathematical. But, if Fortran is bypassed by the filmmaker for the option of a graphic display with light pen, the whole universe of mathematical graphics is essentially discarded. When a computer is used to execute elaborate mathematical functions—or even simple ones—this user often feels the presence of the computer as an unseen collaborator. On the other hand, freehand graphics is reputable. It was invented millenniums before mathematics. However, with the availability of interactive graphics, it is practically impossible to direct students *not* to use a tool that instantly generates dynamic results in preference to doing something the hard way. A parallel to this is a problem of students who are starting to shoot live films. Although the zoom lens is simpler and more versatile than a turret with three fixed focal length lenses, it is most difficult to

* Free lance computer animated film producers.

convince the students not to zoom in and out *ad nauseam.*

There is no absolute minimum configuration for a computer animated film system, and the minimum end of the spectrum is in almost the same state of flux as the maximum configuration end of the spectrum. However, for purposes of this discussion we would like to present for consideration a system that we have used for over ten years of experimenting, teaching, and contract production of computer films in a variety of areas. Probably it should not be called a system since there is no dedicated hardware, Figure 1. The only dedicated item is four boxes of punched cards that comprise a standard graphics software package. We are presently working with a modified version of the Integrated Graphics Software developed by the Rand Corporation. Our version is for the Stromberg Datagraphix 4060 plotter. All of the computing is done batch mode on any of several IBM-360-370 installations. The plotting has been done off-line on a number of microfilm plotters, including Datagraphix, Gould, Seaco, and most frequently the Information International Inc. FR-80. Since most microfilm plotters have the ability to emulate their competitors, there has been little need for changes in software (those subroutines that convert our vector descriptions into commands that drive the microfilm plotter).

In order to assess this minimum system within the total range of computer animated films, its throughput potential should be compared with that of several other configurations. As in discussion of live film production, it is most simple to classify a mode of film production by the end product rather than by the equipment needed to achieve that result.

The minimum system described above is reasonably effective for the production of *dynamic line images.* This would include films that demonstrate scientific as well as mathematical principles since some areas of science, particularly physics, lend themselves to mathematically controlled graphics.[1] For some obscure reason, it is practically impossible to present a dynamic mathematical structure that does not display aesthetic attributes to even the non-mathematician, especially if a music track is synchronized with the images. Probably the most significant example of this effect is in the work of John Whitney.[2] This type of film is described by curve (1) of Figure 2. It requires a great amount of planning and usually rather elaborate programs to drive the plotting software. However, the end result can be accomplished with a minimum of hardware as shown by the descent of the curve. (It should be noted that Whitney has used an interactive graphic terminal to simplify input to his driving program. This saves time.) Finally, it will be noted that this type of film requires the most time for throughput. This is not entirely discouraging in the long view. If the film is to display a unique time-motion structure, the conception, design, the writing of a driving program along with a few new subroutines that are invariably required, and the debugging of these programs—all these added together make the throughput ability of the hardware less than crucial. When this system is used for classes in computer animated film which we teach at the New School, some students choose to spend far more time at the blackboard than the computer center.[3]

A second type of film is emerging in the area of computer animated cartograms and statistical graphs.[4] This is graphed as (2) in Figure 2. Typically, this type of film displays very complex information and requires massive input data to accomplish its purpose. Once a program is operational, there is little need for the programmer to interact with the system, since the primary purpose of the film is to reveal what the data has to show. This curve (2) would also apply equally well to films that simulate traffic flow through a system of paths with symbols that represent people or vehicles.[5]

An emerging category of films could be called *simulated cinematography,* (3). The major initial thrust in this direction was made at the University of Utah

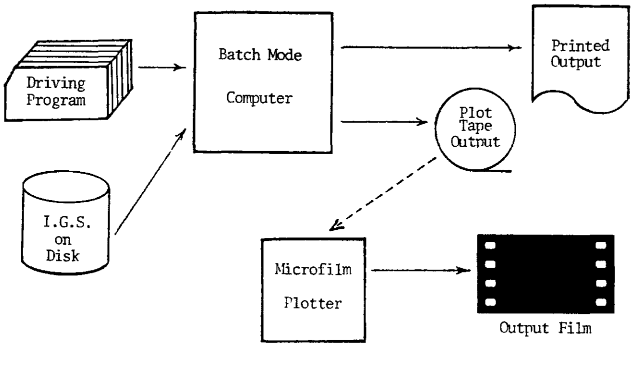

Figure 1—Flow diagram of minimum computer animated film system

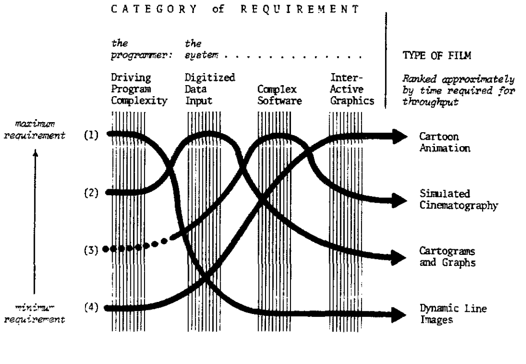

Figure 2—Comparison of computing needs required by selected types of animation

where the scheme was developed for representing curved surfaces with a continuously shaded image that would take into account the location of the light source and the reflective characteristics of the surface.[6] Or, in other words, photographs without a camera pointed at an object. The computing required to display a full frame of shaded image is vastly greater than required for line structures of considerable complexity. This is a major inhibiting factor if the object of producing motion pictures is to study the motion rather than the object in motion. Also the output film must be generated on a display that has beam intensity controllable by very small increments, unlike any of the microfilm plotters. However, considerable effort and ingenuity is being directed toward making these techniques of simulated cinematography a viable avenue of film production, especially in view of accomplishments at the University of Ohio.[7]

A fourth type of film, curve (4), is the computer animated cartoon. Probably the foremost example of this type would be the output of Computer Image Corporation.[8] This also involves a much more complex system than dynamic line images and the characteristic curve is almost a reciprocal of the *dynamic line images* curve (1). Although the computer slavishly follows the animator's guidance, it would be more fitting to consider the computer as an entire animation studio production staff, rather than a slave. This is a very sophisticated use of the computer as both a time-saving and labor-saving device. One of the main fascinations of experimenting with dynamic line images is that the aesthetic effect of the film created is often surprising. Conversely, the virtue of a cartoon animation system is its ability to deliver exactly what the designer requests.

One major omission from the graph is computer generated films that display a walk-through of three-dimensional space (usually architectural) in full color. Its characteristic curve would be a straight line through the maximum requirement in each category. Since there are only a few such systems in existence, it is hardly an optional route for building a computer animation facility from available resources. But even this area is in a state of flux with simplifications of hardware.[9]

It can be observed that the more efficient a system is at performing a given graphic task, the less feasible or encouraging it is to use that system for a diversity of generalized tasks. For instance, it would be almost ridiculous to use a system capable of cartoon animation or simulated cinematography to drive simple geometric symbols of vehicles in a traffic engineering simulation. Computer animation systems might be separated by purpose into two categories. Is the system intended to simulate other clearly established processes of motion picture production (including animation)? Or, is the system intended to offer the most direct means of producing motion graphs that describe, or are driven by, numerical processes? Or, restated, the choice is graphics that emulate graphics, or graphics that synthesize numerics.

If this comparison of various systems justifies consideration of the *minimum system* as a starting point, there are several items concerning its application that could be clarified.

Fortran seems the most commonly used language since the majority of graphic software packages are compatible with Fortran. Simscript is another very useful language, especially for engineering simulations, and it can be used to drive the graphic software, although not as simply as Fortran.

Graphic debugging can be accomplished on a line printer by a fairly simple set of subroutines, about 100 statements, which emulate the plotting software and produce strings of asterisks. Batch mode turn around can slow the throughput until the user discovers that working on several portions of a project simultaneously can leave little idle time. Another point on debugging that can effect considerable cost savings involves a modification in the graphic software. All of the subroutines that are accessed by our driving program are subject to being turned off or on by one call from the main program. This enables us to run through a lengthy sequence but plot on film only a few selected frames. This does consume extra computing time, but that cost is small in comparison with costs of debugging by means of a long plotting run.

The final component to consider is the microfilm plotter. Even if one has funds available to purchase or lease a plotter, it could be viewed as a serious misuse of funds if there were not enough footage of film output to keep the machine going at least two hours a day (figure about 100 16mm feet/hour) Furthermore, an in-house plotter demands a motion picture film processing machine, such as a Kodak Prostar, but if the film output is to be used as a master for making extra prints, or color prints, the film from the plotter should be reversal processed and that is not simple on a Prostar. And finally, unless one has a resident engineer provided by the manufacturer of the plotter, the system may be down at times less than convenient.

The alternative is to use a commercial microfilm plotting facility. Although we are located in New York City, it has proven most convenient and economical to work with a company in Los Angeles. They are located within a mile of the airport, and operate 24 hours a day, seven days a week. Our cost for this service is about 10¢ per 35mm frame. However, we often plot four separate 16mm images within the 35mm frame which reduces the cost to .025 per 16mm frame.

In conclusion, computer animated film production has one pitfall that also afflicts many would-be conventional film producers: It is quite easy to fall in love with beautiful, sophisticated and versatile equipment without first determining the objective of the undertaking toward furthering film as a communication medium. If there is any doubt about this objective, it is far safer to start small.

Speakeasy—A window into a computer*

by STAN COHEN
Argonne National Laboratory
Argonne, Illinois

ABSTRACT

Speakeasy is a system that enables a user to harness the power of a computer as a tool for problem solving. This paper describes the structure of that system and demonstrates some of its capabilities. The examples show some of the power that results when relatively straightforward graphical facilities are added to this general purpose system.

INTRODUCTION

A modern computer complex is an extremely fast information processor with a vast amount of stored information available to it. Machines and their associated software are becoming ever faster, ever larger and ever more complex. This growth in capability brings with it increasing responsibility to provide the normal user with adequate access to available information. Unfortunately a sense of isolation from advances in computer science is common in many disciplines and results in the people most in need of the capabilities provided by a computer being forced to rely on secondary sources for solutions to their problems or to ignore advances entirely and to program using first generation computer techniques.

One answer to this problem of information exchange can be found within the structure of the computer itself. A generalized modular system that is designed to access and operate with libraries of stored information can make advanced algorithms and general information available to users in a sensible way. Properly structured, such a system acts as an interface between user and the computer, matching the user's needs to capabilities available to him. Inadequacies in such a system are answered by adding new capabilities to satisfy existing needs. A system designed for growth provides the environment to answer the needs of users; it can at the same time provide researchers in computational science with an audience for their work.

This paper describes a system of this type that has been in use and under development for over a decade. Originally designed as a tool for research scientists, the generalized and easily used structure of this processor has now led to its acceptance by a large and varied user community. Although Speakeasy[1-4] has been in existence for many years, it is the widespread availability of time-sharing systems such a TSO and VM/CMS that accounts for the recent rapid growth in acceptance. The Speakeasy processor is currently available for use on IBM 360 or 370 computers operating under OS, TSO, VM/CMS or MTS. It has been translated for use on FACOM-230 and PDP-10 computers. Translations to several other computer systems are now being carried out.

There is an active user group involving some 70 different installations and over a thousand users. The user communities already include physical scientists, engineers, econometricians, government agencies and universities. The growth in the capabilities of Speakeasy in recent years is partially in response to the diverse nature of its user group and partially due to contributions from it.

This paper is intended as a general description of the Speakeasy system. It is divided into two major sections. The first describes the structure of the system. The general form of this system should be of interest to a computer scientist since it is here that the extensibility and growth capabilities reside. The second section is a sampling of the capabilities found in actual operational versions of the system. The features illustrated are only a few of those that make this system valuable to its users. They show that a truly user oriented system can at the same time be a powerful one.

THE OVERALL DESCRIPTION

The structure of the Speakeasy system is illustrated in Figure 1. The system consists of a language processor that interprets the requests of the user and breaks them down into basic syntactical components. The language structure is a straightforward one modeled on conventional mathematics. A scratch-pad storage facility available to the processor enables it to maintain transient information for the duration of the

* Work performed under the auspices of the U.S. Energy Research and Development Administration.

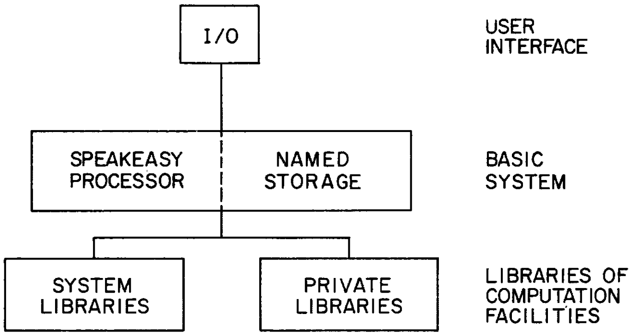

Figure 1—A schematic view of the Speakeasy system. The bulk of the computational facilities are contained in the modules that make up the libraries attached to the system

particular application. The processor and this scratch pad provide the mechanism for a user to define and address structured objects that represent transient information in the tasks being assigned to the system.

Libraries of pre-compiled routines are attached to the processor to provide the system with its working vocabulary. When a specific operator is requested of the system, all of the libraries attached to the system are searched. If the requested operator is found, it is dynamically linked to the system so that it may perform its function. In most cases such operations involve operands previously defined and saved in the transient scratch-pad area. New results are also saved there and are therefore available for later use by other operations.

This operator-operand formulation with a wide variety of operators on structured objects is the heart of the Speakeasy system. The ability to define structured objects such as arrays, vectors and matrices makes it meaningful to develop a large set of operators tailored to specific data structures. The use of attached libraries makes it possible to provide an ever increasing set of such operators without creating a system of immense size and complexity.

The modularity of this system, the use of libraries and the simplicity of its control language combine to provide a powerful system that is easily used and capable of sustained growth.

Design of the language

The Speakeasy system can be viewed as a repository. The communication language for the system (also called Speakeasy) is intended to make this repository usable. In designing the language and its syntactical rules the foremost considerations were naturalness, ease of use and tolerance for trivial mistakes. The basic specification for the language is a simple one. If a request by a user is unambiguous and looks correct to him then it should be accepted by the system.

This design philosophy is somewhat different from that of normal computer languages that provides features to enable the user to exploit the capabilities of the machinery itself. Such languages are specified so that a large number of decisions that relate only indirectly to the calculation must be made by the programmer. To give just a few examples, fixed point versus floating numbers, dimension statements for quantities that occur only as intermediate results, and input and output formats are concepts only indirectly related to the statement of the problem itself. Frequently such relatively trivial specifications constitute the bulk of a program; the parts related to the calculation are but a small part of the material written by the user. It is the volume of this extraneous information that accounts for many of the errors encountered in conventional programming.

In Speakeasy most of such decisions are considered to be part of the internal functions of the system. The user formulates his problem in a brief and natural manner, the system translates this formulation into an executable form, relieving the user of as many trivial decisions as possible. In fact, the Speakeasy language specifications bear little relationship to the structure of a computer and only very indirectly reflect the form of calculation as executed in the computer.

The Speakeasy language is designed to operate with structured objects. Scalars, arrays of numbers, mathematical vectors and true matrices are among the many classes of structured objects that a user may define and use in his calculation. Implicit algebraic rules that are class dependent provide a variety of tools for formulating calculations while operating on defined objects as single entities. Complete matrix algebra is provided in a natural notation. This combined with the array processing capabilities, enables one to write a directive program that does not involve the loops and branches that make up most of the computational steps in conventional programs.

The availability of structured objects means that an operator-operand language with great richness can be developed (one of the limitations of usual languages is that the scalar structure of the languages limit functional values to scalars). Each of the operators in Speakeasy is designed as a self-contained module whose operations are dependent upon the structure of its operands. In this way all of the decisions normally necessary in invoking routines in conventional programming techniques are internally contained in the operators of the system. Each operator is clearly definable in terms of what it does and contains many checks to see that it is being properly applied. By placing decision processes such as these within the system the user is relieved of most of the mundane parts of programming. The user can therefore concentrate his effort on formulating the overall logic of his problem and still be assured that the large number of trivial decisions are being properly made.

The overall language designed around an operator-operand concept combined with conventional algebraic tools is powerful, easily learned and easily used. It is logically complete and is extensible in both the types of structure supported and the operators available for manipulating objects.

The transient scratch-pad—named storage

A special dynamic storage scheme is an important component of the Speakeasy system. This storage facility provides the mechanism for defining and retrieving the structured objects discussed previously. In this scheme each defined object has associated with it a complete description of its structure along with particular values for its elements. Most importantly, the object and its descriptive information can be referenced by name. The name is all that is needed to locate any defined object, to determine everything about its structure and to use it in a calculation.

Named Storage[5] was developed for use with calculations in nuclear physics.[1] It is this storage technique that led to the development of Speakeasy. Individual modules of the Speakeasy system (the operators available to the language processor) are designed to operate on objects defined in Named Storage and to produce new objects there. The extreme modularity of the Speakeasy system is a consequence of this rather straightforward storage scheme.

Each defined object in Named Storage has descriptive information appended to it which designates its class, the type of data in its elements and its dimensionality. The allowed ranges for these designators has been made large so that new data types, new classes, etc. can be supported in later developments. Since no computational capabilities are contained in the storage package it is possible to extend the capabilities of Speakeasy entirely through additions to the operators attached to the system.

The libraries—linkules

In most computer systems each new addition brings with it increases in complexity, more overhead and a larger processor. Even with a very modular system this remains the case. The benefit of each addition must be weighed against the consequence that it will have on the overall system performance. It is therefore unlikely that a feature of great benefit to only a few users will ever be adopted if it degrades the system's use for others.

The library orientation of the Speakeasy system solves this problem in a particularly interesting way. The use of attached libraries containing operators such as those described earlier provides a system with easily expandable capability in a way that neither constrains the growth nor increases the basic structure of the system. Operators that are dynamically attached to the processor, called linkules,[3] provide the means for adding any desired capability for those who need it, without others even being aware of its existence. Private libraries of linkules can be used to give each user community a processor tailored to its own needs.

The freedom provided by a library oriented system is obvious. Growth by the accumulation of new information is automatic. Maintenance is particularly easy since replacement, modification and additions are made on members of libraries and not on the processor itself.

Each new operator added to the system brings with it capabilities that are enhanced by the presence of other operators in the system. A system such as Speakeasy thus reaches a critical stage where the interrelationship between the operators begins to make itself felt. After this threshold is reached the growth of the capabilities of the system are often based on finding new ways to interconnect existing facilities. Speakeasy has passed that threshold and it is no longer possible to clearly define the limits of the capabilities of the existing system.

The user interface

The user's first introduction to a system such as Speakeasy can be through a variety of devices. It is important that a system such as Speakeasy functions equally well for each type of device and that it be able to exploit the particular capabilities of each. In this system this is accomplished by isolating all input and output to specific components of the system, designing interfaces to classes of devices, and providing other general facilities that can be selectively made available to users of specific devices on demand.

This ability to interface correctly to every type of terminal in a time sharing environment is of particular psychological importance since the intent is to make this system appear natural to the casual user. If the introductory session with the processor is spent describing how a particular device is used or why a multitude of peculiar keys are used then it is unlikely that the user will ever be convinced of the naturalness of the language.

The currently operational versions of Speakeasy can be used with card readers, printers, plotters, ASCII terminals, IBM 2741's, Tektronix 4000 series graphics terminals, or any combinations of these devices. In each case the adaptation is one in which the device is natural to use and one where all of its hardware capabilities can be exploited.

EXAMPLES OF SPEAKEASY

Speakeasy is best demonstrated in a time sharing environment, for it is there that the ease of use and natural form of the language becomes most obvious. Complete novices can begin to carry out calculations with only a few minutes instruction. Built in documentation and teaching aids enable such users to learn about the wide variety of capabilities within the system and to soon begin to utilize the system as a tool in their daily work. As their demands grow they find within the system a wide variety of facilities that can be merged together into an extremely powerful tool.

It is obviously not possible in this short paper to convey the feeling associated with an interactive system. Neither is it possible to demonstrate more than a few of the capabilities of this large system. No attempt is made, for instance, to illustrate the use of stored programs or of the editor that is available to construct such programs. Neither is there any discussion of the means of storing and retrieving information. The examples given here must therefore be viewed as a demonstration of only a few of the available features and perhaps as a tantalizing taste of what can be found within the system.

Examples of the arithmetic capabilities

The bulk of the computational capabilities in this system are related to numerics. Many of these facilities were provided by simply designing interfaces to existing Fortran coded mathematical subroutines and functions. Every attempt is made to find the best available technique and to provide as sensible and as general a facility for the users as is possible. It is in this way that the novice computer user is able to make use of advanced computational techniques.*

The system contains the basic operations of numerical calculus, statistics, matrix algebra and most of the usual special functions. Many of the operations are available for both real and complex numbers.

Figure 2 shows the processor being used as a desk calculator. The two characters :_ are the prompt symbols for the manual mode of Speakeasy. The user's request is typed on this remainder of the line. A carriage return indicates that the request is complete and that processing should take place. If the request elicits a response it is almost immediate and it is followed by a new prompt. A special implied print convention echoes simple input requests and prints the result. This result is also given the name ANSWER so that it may be used in later calculations. Users may define variables by straightforward assignment statements such as those illustrated. Standard mathematics notation is clearly demonstrated by the use of absolute value signs and factorials, and by the normal hierarchy for the evaluation of involved expressions.

Figure 2—A sample of the use of Speakeasy in the manual or desk calculator mode of operation. Note the natural form of the directive language

Figure 3 illustrates the definition and use of arrays of numbers. It is of course not possible to show more than a few of the available capabilities. The compactness and the direct form of the language should be apparent. The rather natural and readable form of output should also be noted. It should be realized that this output form is the default form. Further tailoring is of course possible.

Figure 4 shows the means for defining and operating with matrices. The computational power that is hidden within these few statements should be apparent to those familiar with this field of numerical analysis. Some of the available tailoring commands are also illustrated here to demonstrate the flexibility of the system.

In Speakeasy two dimensional arrays and matrices belong to different families. The algebraic rules for operating on such objects are different. In Figure 5 some of the operations shown in the previous figure are repeated using arrays instead of matrices. The differences are apparent.

* For example, EISPACK is a general purpose eigen-analysis package. In Speakeasy the words EIGENVALUE and EIGENVECTOR are used to invoke this package. Decisions relating to the particular choice of path through EISPACK are made by the linkule interface. The novice user is thus provided with a powerful computational package in a simple way.

Documentation

Any computer system must be properly documented in order that it be usable. Documentation for a major system is not an easy task. If approached solely by conventional means it would be even more difficult in a system like Speakeasy that is designed for growth. Any printed documentation would be outdated before it was published. Fortunately, the system itself is capable of providing facilities that not only supply the documentation but do so in a way that is guaranteed to be self-sustained.

A library of documents referred to as the Speakeasy HELP documents is attached to the system. This library is addressed by a linkule in the normal library. Each word, concept or facility available in the system is described in a member of the HELP document library. The library is designed as a tree structure so that a user probing the library in an interactive session is led quickly to the specific concept of interest.

Figures 6-8 illustrate the HELP documents and show how the tree structure provides quick access to information about a specific operation. Each of the over 500 documents in this library is available in a similar way. The intent of these short documents is to inform the user of the operational definition of each word. No attempt is made to explain specifics of the techniques used. A second library containing larger documents is available for that purpose and is equally easily accessed.

A complete teaching facility is also built into the library of the standard system. A series of tutorial sessions provide a novice with step by step instructions on the use of special facilities. One of these sessions is an introduction to Speakeasy graphics. A few pages of this are shown in Figure 9.

Interactive graphics

A graphics display terminal in a time-sharing environment greatly increases the potentials for true interactive computing. This is particularly evident for the exploratory types of computation that are so common in many problem solving and research environments. Because large amounts of information can be rapidly and sensibly displayed it is possible for the user to quickly interpret the effects of various choices.

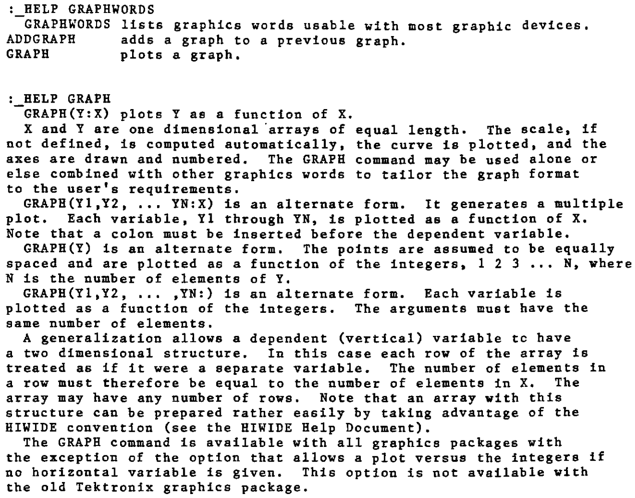
:_HELP
 HELP explains how to use Speakeasy.
QUIT          is the command to leave Speakeasy.
INOUT         lists words dealing with input and output.
MATH          lists mathmatical functions.
PHYSICS       are functions of interest primarily to physicists.
STATISTICS    lists words related to statistics.
OBJECTS       lists words dealing with structured objects.
PROGRAMS      lists words used in writing programs.
DATATYPES     lists words about types of data used in Speakeasy.
MISCELLANEOUS lists other Speakeasy words.
BUGS          gives the known errors and stage of correction.
NEWS          gives recent modifications and new features.
TUTORIAL      tells how to use the Speakeasy tutorial.
VOCABULARY    lists all the words in Speakeasy.
HELP XX       gives an explanation of the word XX.
                XX is any vocabulary word.

:_HELP GRAPHICS
 GRAPHICS are words which deal with graphical output.
CALCWORDS    lists words used to plot on a CALCOMP plotter.
GRAPHWORDS   lists graphics words usable with most graphic devices.
OLDTEK       lists words used with the old Tektronix package.
PRINTGRAPHS  lists words used to plot on a line printer or a
               non-graphics terminal.
TEKWORDS     lists words used to plot on a Tektronix terminal.

 Note: An attempt is being made to, wherever possible, make graphics
words independent of the graphic output device being used to create
the plot. At present only a few meet that goal (type HELP GRAPHWORDS
for the list). In the future, the words listed in the TEKWORDS Help
Document will form the basis of the new graphics vocabulary.

 To obtain a description of a given word XXX, enter
 HELP XXX
```

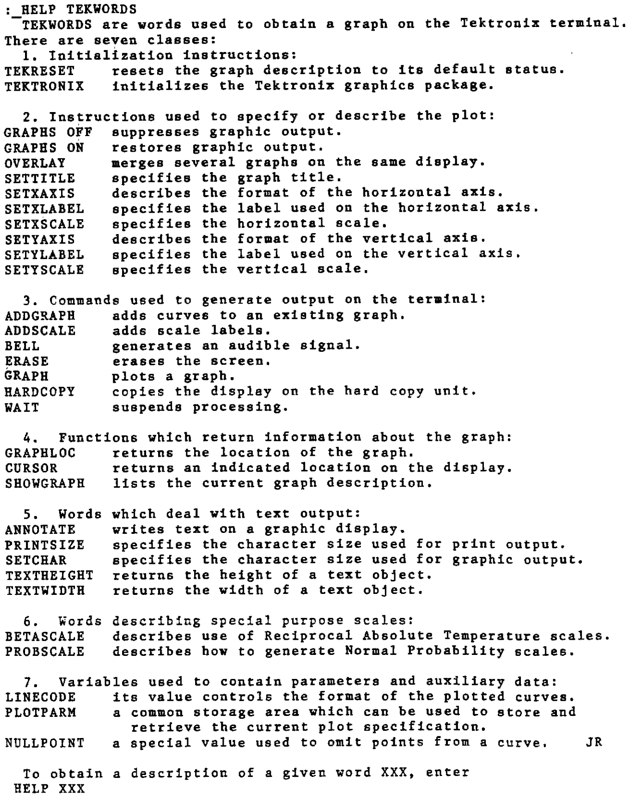
Figure 6—Every word known to the Speakeasy processor is described by a short HELP document. These documents are arranged in a tree structure, part of which is shown here



```
:_HELP GRAPHWORDS
 GRAPHWORDS lists graphics words usable with most graphic devices.
ADDGRAPH     adds a graph to a previous graph.
GRAPH        plots a graph.

:_HELP GRAPH
 GRAPH(Y:X) plots Y as a function of X.
 X and Y are one dimensional arrays of equal length.  The scale, if
not defined, is computed automatically, the curve is plotted, and the
axes are drawn and numbered.  The GRAPH command may be used alone or
else combined with other graphics words to tailor the graph format
to the user's requirements.
 GRAPH(Y1,Y2, ... YN:X) is an alternate form.  It generates a multiple
plot.  Each variable, Y1 through YN, is plotted as a function of X.
Note that a colon must be inserted before the dependent variable.
 GRAPH(Y) is an alternate form.  The points are assumed to be equally
spaced and are plotted as a function of the integers, 1 2 3 ... N, where
N is the number of elements of Y.
 GRAPH(Y1,Y2, ... ,YN:) is an alternate form.  Each variable is
plotted as a function of the integers.  The arguments must have the
same number of elements.
 A generalization allows a dependent (vertical) variable tc have
a two dimensional structure.  In this case each row of the array is
treated as if it were a separate variable.  The number of elements in
a row must therefore be equal to the number of elements in X.  The
array may have any number of rows.  Note that an array with this
structure can be prepared rather easily by taking advantage of the
HIWIDE convention (see the HIWIDE Help Document).
 The GRAPH command is available with all graphics packages with
the exception of the option that allows a plot versus the integers if
no horizontal variable is given.  This option is not available with
the old Tektronix graphics package.
```

Figure 7—A continuation of the tree search shown in Figure 6. These documents are short and supply operational definitions



```
:_HELP TEKWORDS
 TEKWORDS are words used to obtain a graph on the Tektronix terminal.
There are seven classes:
 1. Initialization instructions:
TEKRESET    resets the graph description to its default status.
TEKTRONIX   initializes the Tektronix graphics package.

 2. Instructions used to specify or describe the plot:
GRAPHS OFF  suppresses graphic output.
GRAPHS ON   restores graphic output.
OVERLAY     merges several graphs on the same display.
SETTITLE    specifies the graph title.
SETXAXIS    describes the format of the horizontal axis.
SETXLABEL   specifies the label used on the horizontal axis.
SETXSCALE   specifies the horizontal scale.
SETYAXIS    describes the format of the vertical axis.
SETYLABEL   specifies the label used on the vertical axis.
SETYSCALE   specifies the vertical scale.

 3. Commands used to generate output on the terminal:
ADDGRAPH    adds curves to an existing graph.
ADDSCALE    adds scale labels.
BELL        generates an audible signal.
ERASE       erases the screen.
GRAPH       plots a graph.
HARDCOPY    copies the display on the hard copy unit.
WAIT        suspends processing.

 4. Functions which return information about the graph:
GRAPHLOC    returns the location of the graph.
CURSOR      returns an indicated location on the display.
SHOWGRAPH   lists the current graph description.

 5. Words which deal with text output:
ANNOTATE    writes text on a graphic display.
PRINTSIZE   specifies the character size used for print output.
SETCHAR     specifies the character size used for graphic output.
TEXTHEIGHT  returns the height of a text object.
TEXTWIDTH   returns the width of a text object.

 6. Words describing special purpose scales:
BETASCALE   describes use of Reciprocal Absolute Temperature scales.
PROBSCALE   describes how to generate Normal Probability scales.

 7. Variables used to contain parameters and auxiliary data:
LINECODE    its value controls the format of the plotted curves.
PLOTPARM    a common storage area which can be used to store and
              retrieve the current plot specification.
NULLPOINT   a special value used to omit points from a curve.    JR

TEKTRONI PAGE 1
INTRODUCTION
     A graphics support package is available which allows you
to plot graphs on a Tektronix terminal.  This Tutorial will
introduce you to some of its features.  It will first show you how
to plot a simple graph using only a few Speakeasy statements. Then
It will show you how to add scale labels and a title and how to
change the format of the plotted curves.  It will show you two
methods of making a copy of the display.  Finally it will explain
some of the facilities which allow you to set up your own graph
layout and to create quite elaborate displays.  The Tutorial should
be used while you are logged on to a Tektronix terminal.  If you
are not,  wait until you are.
     Type MORE to start the actual session.

TEKTRONI PAGE 2
PLOTTING A SIMPLE GRAPH
     You must be familiar with only two Speakeasy graphics
statements to begin using Tektronix graphics.  The first,
USE TEKTRONIX, initializes the system and must always be typed
before using any graphics words. GRAPH is then available to
actually plot a graph.  For example, examine the following
series of statements:
     X=GRID(0,10);  Y=SIN(X)
     USE TEKTRONIX
     GRAPH(Y:X)
Try this yourself.  (At your installation,  the USE TEKTRONIX
statement may result in a request for information about the
terminal you are using.)  The GRAPH statement automatically
gives you a complete graph.  Unless you have specified otherwise,
it takes care of the details of planning, scaling, and laying out
your graph.
     Try plotting other functions using the GRAPH command.  When
you are interested in more information, type MORE.

Figure 10—A sample of the output of the contour plotter for non-graphics terminals

He is then in a position to conjecture sensible alternative problems. It is in such situations that the wealth of available facilities combined with the concise and natural directed language of Speakeasy plays its most powerful role. The system provides an environment that matches closely the needs of such a user. He may quickly formulate and carry out alternative calculations and see their results. The flexibility and power of the system becomes most apparent when the results of one calculation lead to ideas that can be tested on the spot by applying new techniques built from tools provided by the system.

The graphical capabilities in Speakeasy are straightforward ones. They are designed to provide the user with the means of displaying computed functions in easily interpreted ways. The discussion here is limited to the facilities currently available for display terminals such as the Tektronix 4012 or 4014. Alternatives exist for other graphical devices and crude graphics are even available on printers and terminals limited to character displays. Figure 10 shows a simple contour plot that can be obtained on such a device. Figure 11 shows a sample of graphical output on a printer.

Perhaps the most dramatic example is illustrated in Figure 12. This example is the result of entering the

_Z=DERIVATIVE(Y:X) ; GRAPH(Y Z:X)
```

Figure 12—A simple graph and the statements that produced it

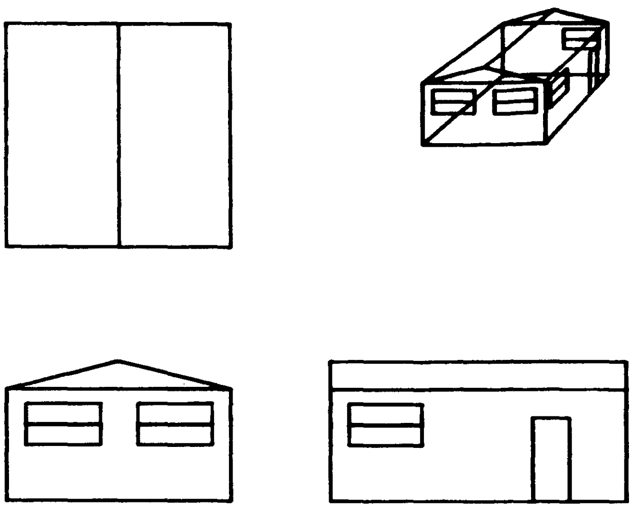

Figure 14—Another use of the three-dimensional package showing its use for a variety of projections of an object

four statements:

X=GRID(0,10)
Y=SIN (X) *EXP (−X/10)
Z=DERIVATIVE (Y:X)
GRAPH (Y,Z : X)

This example makes use of a device-independent graphics package being developed by John H. Reynolds at Comsat Laboratory that is distributed as part of the standard Speakeasy system.

As indicated by this example, automatic scaling and grid generation are provided as a default. A large number of control facilities enable the user to further tailor the graphical output to his specific needs. Figure 13 is a graph that illustrates some of the other features of this package. This graph also shows some of the statistical capabilities of the system. It was contributed by R. A. Stack of The First National Bank of Chicago.

Basic three-dimensional graphics have recently been added to the facilities available[6]. The approach taken has been to define a three-dimensional object by creating a matrix of its vertex coordinates and then describing the edges through a connectivity array involving these verticies. The power of the arithmetic capabili-

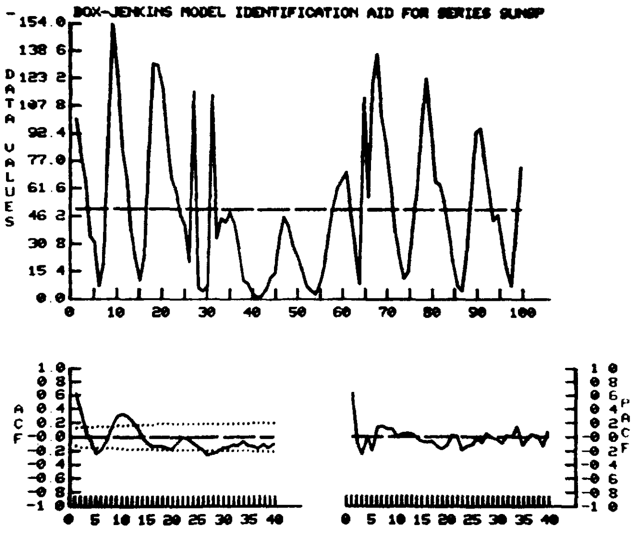

Figure 13—A set of graphs that were produced by a Speakeasy program

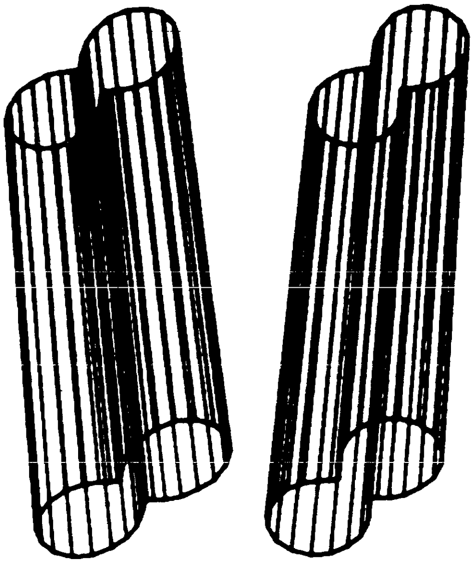

Figure 16.—An example of a steroscopic pairs produced by the three-dimensional graphics package

ties of Speakeasy can be used to manipulate the defined objects. The built-in matrix algebra, in particular, makes it easy to rotate, move or distort objects. Several special linkules were provided to help in the generation of objects made up of several components. The simple command DRAW3D is used to create the visual display. Options for perspective projections are also provided. Figures 14 through 16 show some of the possibilities.

A case study of a young child doing turtle graphics in LOGO*

by CYNTHIA J. SOLOMON
Boston University
Boston, Massachusetts

and

SEYMOUR PAPERT**
Massachusetts Institute of Technology
Cambridge, Massachusetts

ABSTRACT

This paper explores some important issues with regard to using computers in education. It probes into the question of what programming ideas and projects will engage young children. In particular, a seven year old child's involvement in turtle graphics is presented as a case study.

This paper describes and comments on the experience of a young child in the MIT AI-LOGO Lab where she was involved in talking in LOGO to a display turtle and a PDP-11/45 computer. The child, a second grader, spent several hours on a consecutive Saturday and Sunday engaged in interesting debugging sessions. She worked long and hard. Why she could do so and why the experience was so interesting is partially explained by looking at her past experiences. In mid-January, the year before, when she was a first grader, she and I started working together learning about turtles and their world and thus explored turtle graphics. She visited twice a week for a month, staying from ½ to ¾ of an hour. We continued to meet, but less regularly, until the end of April. During that time she learned to talk to the display turtle. She learned the LOGO turtle commands like CLEARSCREEN (CS), FORWARD (FD), RIGHT (RT), LEFT (LT), PENDOWN (PD), PENUP (PU); and she learned to use them to make up her own commands for the turtle.

My goal for her first year had been for her to understand procedures both by using them and constructing them. She was given the following kind of experience. She made the turtle draw something by a series of direct commands. She would then think of a name for the picture (or piece of picture) and teach that word to the computer. To help her in this construction I wrote down the commands as she debugged them. When she "taught" the procedure to the computer she would either read the commands as I had written them or I would read them to her. Then she would try out or "run" the procedure and see if there were any bugs.

The kinds of debugging situations Est encountered varied but I was always ready to intervene in case the situation became unresolvable for her. I presented Est with the same kind of materials and projects as I developed for older children. What I expected to see with a young child was a clearer indication of where bugs in the material and ideas lay, e.g., what ideas are hard to grasp and what ideas can be understood if presented in a crisper manner or imbedded in better situations. From the sessions with Lin, another first grader I had worked with quite extensively, I developed techniques and aids which have helped older children get into turtle work, and subprocedurization, debugging, anthropomorphizing.

Let me back off a bit here and explain what preparations I had made. To aid kids in defining procedures and to exploit the idea of teaching things to the computer I provided a procedure called TEACH. This command was used instead of LOGO's TO for defining procedures. TEACH requested a name for the procedure to be defined and then asked for each instruction of the procedure by saying "STEP 10:" etc. until the child typed "END". Thus line numbers were assigned to each instruction starting at 10 in increments of 10. I also prepared procedures for making squares, circles and pieces of circle. They require inputs, which allow their size to be varied. The child also had the choice of using either RSQUARE or LSQUARE, RCIRCLE or LCIRCLE, RARC or LARC. For example,  could be drawn by RSQUARE or

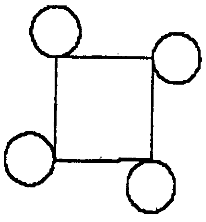
* The research described in this paper was conducted at Massachusetts Institute of Technology in the Artificial Intelligence Laboratory's LOGO GROUP. Under the support of the National Institute of Education Grant No. NIE-G-74-0012, and of the National Science Foundation Grant No. EC-40708X.

** Comments by Dr. Papert.

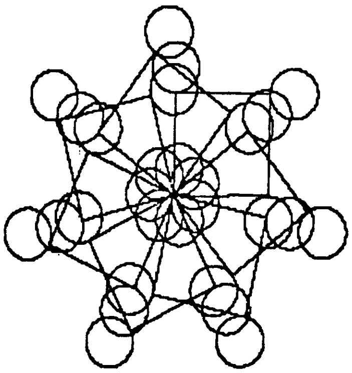
LSQUARE; only the turtle's starting and stopping states indicate which procedure should be used. All of these procedures were treated as primitive commands. Nonetheless, most children will teach the turtle to make a square or circle of fixed size by using FORWARD and RIGHT, thereby understanding the turtle's behavior in the process.

The turtle became more than a drawing device. It was a creature with certain behaviors which are interesting to study and might help us understand ourselves. The turtle lives on a display screen. Its initial state is in the middle of the screen with its nose pointing north or at 0 degrees. We can change its state by telling it to move FORWARD some number of units or turn RIGHT some number of degrees. We have marked the screen with 4 differently colored labels, NORTH, EAST, SOUTH and WEST. So we begin to build up a description of the turtle which is outside of the words provided by the LOGO language. Some of these we use to form a meta-language while others we turn into LOGO commands.

The previous remarks are meant to be background to the core of this paper, which is a picture of Est's two day interaction in the turtle-LOGO world after a break of almost six months. When Est arrived there was an initial bit of awkwardness. Her father was with her and wanted to see what kinds of things she would be doing. The work area was drastically changed. And Est wore a patch on her left eye. Her work from six months ago was in her workspace. I suggested she show her father her flower, a rather spectacular piece of opportunism. She exclaimed, "Oh yes you say CB seven times for this." She did it, her father satisfied at having seen something and reassured that she could see, left. We then abandoned last year's work and proceeded to reinvestigate the turtle's behavior. She remembered turtle commands in their abbreviated form like CS, FD, RT, LT, BK and also TEACH. She had difficulty remembering how to execute commands. That is she forgot to press the CR button and she also forgot to space between words. Last year (in anticipation of the Lebel keyboards) we had marked the CR key DOIT and thus the metaphor of "tell the computer or turtle to DO IT." Unfortunately the key was no longer so marked. But Est developed an interesting way out as a result. This little anecdote will be discussed later.



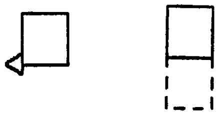
CB



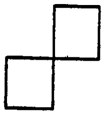
FLOWER

I had not made a firm plan because I wanted to see what she remembered, how she had changed, what the atmosphere was like. I didn't want to burden her with last year's experience. I had wanted to start off fresh and she too wanted that so I cleaned out her workspace. Intellectually we'd build on what she knew but we wouldn't examine last year's work. (Have you ever tried to understand a program you wrote six months ago!) I asked her to make the turtle draw a square or a box. She preferred to think of it as a box. (Last year she had written a procedure called BOX.) I told her in review that RT 90 headed the turtle from NORTH to EAST.

She made a square. Using TEACH (another result of work with Lin) she defined FOX, her box. I helped her by writing down what she did and reading it out to her. But now I wanted to make her independent. I posed the following problem. Make another FOX under the first like this:



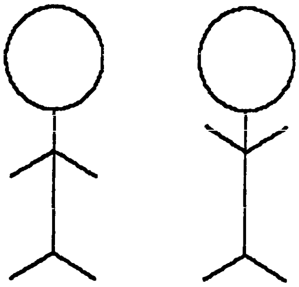
The turtle drew FOX and its stopping state was 90 degrees left of its starting state. This made the problem harder, more distracting. Est kept producing



The turtle's actions upside down!

or this 
but this  was hard. I sat down and talked with her about the turtle's nose when it started and when it stopped. I said "Maybe it would be easier if the turtle ended the same way as it started." So we changed FOX. She did find it easier.

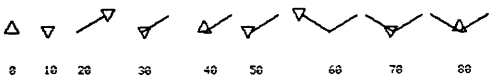
Our next project was a man, a stick figure man. I drew it and said, "What's that?" "A man" she said.



We debugged it together facing the difficulties of this being the same as this , but upside down. I picked this kind of figure rather than one with different arms and legs because it is easier and harder. There are fewer parts making it easier, but the idea of representing arms and legs by the same procedure is a bit jarring the first time. It is, of course, part of exploiting the subprocedure game. Another new idea she encountered was having to relocate the turtle's starting state to accommodate the man's head. We had to back the turtle up 90 units before running the man procedure.

We taught the computer how to draw the LEGS/ARMS. First she taught the computer to EH which caused the turtle to draw this .

```
TO EH
10 RT 60    She knew she could choose another angle
20 FD 100
30 BK 100
40 LT 60    we emphasized the 2 part process
50 LT 60
60 FD 100
70 BK 100
```



```
80 RT 60
END
```

Now Est forgot for a moment that our plan had been to turn EH upside down. When she ran EH she complained it wasn't making legs. This is interesting because it often happens with older kids as well. The idea of rotating objects to make them be different is contrasted here with rotating objects to understand they don't change. But here we look at the object differently. This shape can only be arms, not legs, but rotated like this , it can be arms and legs.

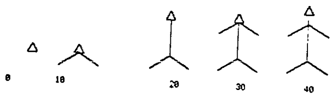
She taught D.

```
TO D
10 RT 180   last year she would have said RT 90 RT
                90
20 EH
30 RT 180
END
```

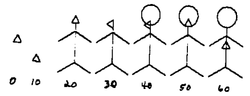
She then put the pieces together and added a neck. This year she chose numbers like 150 and 40. Last year she would have picked 43, 49, etc. or 90.

When it was time to make a head there was very little screen space left. I saw it coming and began suggesting teaching the body parts to the computer. When she ran into the difficulty we were already making plans to deal with it. She taught UH and then before running it she backed the turtle 90 units. (This time she used 90. Was it because BK was not as familiar as FD?) When we made the head there were rotation decisions and then size decisions. She had forgotten the effect of RCIRCLE/LCIRCLE's input, it was the radius not the diameter, but one buggy drawing was a sufficient reminder. Here were her procedures, UH and RUTH. By the way, using D for both arms and legs worked out well and surprised me.

```
TO UH
10 D
20 FD 150
30 D
40 FD 40
END
```



```
TO RUTH
10 BACK 90
20 UH
30 LEFT 90
40 RCIRCLE 50
50 RIGHT 90
60 BACK 100    We took 90 away from 150 and added
  40.
END
```



The way we worked followed last year's pattern:

1. Draw something on paper.

2. Draw "it" on the screen using direct commands, including subprocedures already taught. The quoted it ("it") means that we are opportunistic. If something better turns up as we draw we might change our goal.

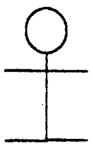
3. Now we teach the computer to do what we just did. (This is the step on which I shall concentrate in the next pages.) So the model for the learner is:

```
10  Do something
20  Teach the computer to do it
```

In more detail we could add:

5 Plan it first
15 Think about how you do it
25 Think about why it didn't quite work . . . debug

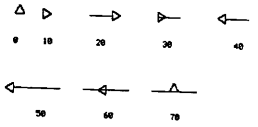
Next I asked Est to make another man without destroying RUTH. We discussed how it differed from RUTH. This one was to be MARIE. Est really wanted to make MARIE and worked hard at it. What she could and what she could not do by herself revealed some interesting patterns I have often seen and talked about but which have not been discussed explicitly. So let's look in detail at her progress.



Marie

Remember RUTH used UH to make the body. UH ran D to make the arms and the legs. To make MARIE we want to replace UH by a new procedure (Est eventually called it S), but first she needed to replace D. She called her new procedure K.

```
TO K
10 RT 90
20 FD 100
30 BK 100
40 RT 180
50 FD 100
60 BK 100
70 RT 90
END
```



Est does not do this directly. Perhaps doing so is too "formal" for her age. Perhaps she was following a pattern I had set up last year. Whatever the reason her way was to "be MARIE herself", i.e., she would give the instructions as direct commands which would later be taught using TEACH. This is how she did everything. But there is more than one way to do this. So back to details.

I left Est entirely on her own. She worked for some X minutes and eventually produced the result she wanted on the screen. This obviously shows a mastery of FD, RT etc. as well as an ability to organize her work. But now comes a difficulty often seen in children this age. She has on the paper in front of her all the commands for MARIE. She knows how to use TEACH and certainly could have typed it all in (this she had done before). But her immediate goal was different. She set herself the sub-goal of "teaching the legs", i.e., of making a subprocedure K, which she would later incorporate into MARIE. But she blocks here. She seems to find it hard to isolate just the instructions she needs for this. Why? Is this a quirk of my teaching or something deep? Seymour says it looks like a "figure ground problem", "structure dependent perception", "reversibility" and like what J. Bamberger sees in children's descriptions of clapping. I don't know, but it feels like a real problem.

I watched from a distance and eventually decided to intervene following a principle of allowing children enough success soon enough to make the fight worth while. It needed hardly any intervention. In cases like this it usually doesn't need much. Often it is sufficient to say: "Ok, let's do it together." But then all I do is read to her what she sees on her paper. Another technique that gets the same result is to write, or have the child write, on a piece of paper just what she has typed to the computer. Why do these subtle things help? Because it is a trivial problem? Maybe. But perhaps also because it is a deep problem related to what psychologists might call attention and what we might call the control process of sub-procedure management. Anyway, it needed very little intervention and she was off on the track and soon Marie worked.

Research issues: understand this phenomenon, get better at observing just what intervention works and why, track the progress of a child over longer periods.

SOME GENERAL OBSERVATIONS

1. Compared with last year Est could work much more independently. (More than half a year is a big piece of her life!)

2. Her work with RCIRCLE and LCIRCLE would have been easier if the inputs were diameter (which "exists") rather than radius (which is about a non-existent point called center). Although later she made a design which was understandable because the input was the radius.

3. She had trouble remembering to ↵ . This she cured by playing this game with the computer: after typing an instruction she would say, firmly and dramatically "DO IT" while hitting the CR key. She knew what "game she was playing". There was no trace of my manipulating her. On the contrary she manipulated herself. We'll see another good example in day 2 of how she is able to set up a deliberate strategy of programming around her own perceived bugs.

I set up the model for DO IT and feel that the way I did it (the rhythm, the degree of "reality" and also playfulness, etc.) made a very big difference as to whether this kind of thing works. On Day 2 she invented similar techniques of her own. So perhaps my suggestion took only because it was a kind of thing she does spontaneously. Big research issue!!

Day 2—Preamble:

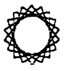
Again I had no detailed plan except the general idea of making an animation in which RUTH and MARIE alternate to give a jumping effect. I had written a new aid to help in snapping pictures called TS whose effect is to save SNAPs. But when I used it with Est I hadn't tried it out and it had a bug! I really got flustered by that. Lesson: don't use undebugged stuff, but if you do don't get flustered.

To warm up I showed Est POLY. She played with inputs. I showed her POLY 50 90. Then I asked her to change the shape. She tried POLY 50 80. She didn't want to call it a star (a 9 pointed star), then she tried POLY 50 40, POLY 50 60. Then she tried POLY 20 30, and POLY 20 20. She remarked that the last two were different sized circles. Finally she tried POLY 20 100 followed by POLY 50 100. She had to struggle with the idea that the 2 figures were the same shape. The first one was very tiny. So she tried POLY 100 100. That she thought could be the same as POLY 50 100, but still the size of the figures did bring into question whether the shape was the same.

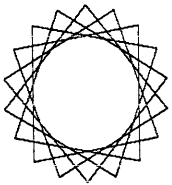
My intention on the day before was to make an animation using RUTH and MARIE. We continued to work on this scheme after I fixed a TS bug. When I discussed what we had to do:

```
DISPLAY :RUTH
WIPECLEAN
DISPLAY :MARIE
WIPECLEAN
```

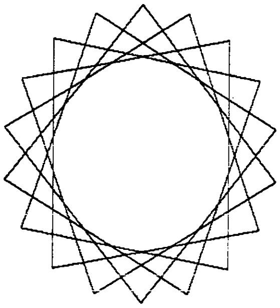
and do these steps over again, I then added we want the computer to wait and suggested that it WAIT 5. The following conversation ensued.



POLY 20 100



POLY 50 100



POLY 100 100

E: Does that mean 5 seconds
C: No
WAIT 60 is a second
E: But if I say 1 that's a second
C: Yes but computers count faster.

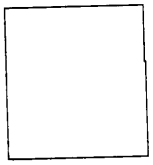
Then Seymour intervened and played a RACE with her. He wrote RACE. It took an input, a starting number and then counted up to 21 by one's. So

RACE→1 2 3 4 5 6 7 8 . . . 21

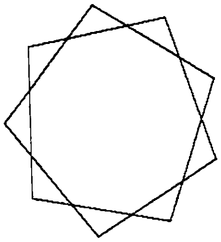
He asked Est to count against the computer. The computer won.

The racing and counting seemed to give another dimension and added more reality to some aspects of the computer:

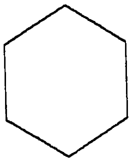
. . . its sequential behavior (After all up to now the results of her programs have been static. So even if



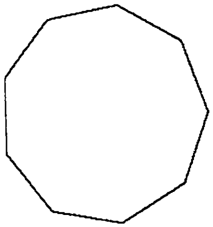
POLY 50 90



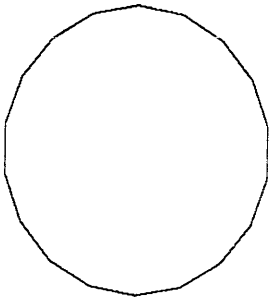
POLY 50 80



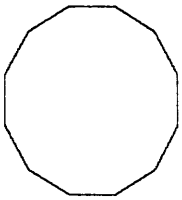
POLY 25 60



POLY 25 40



POLY 20 20



POLY 20 30

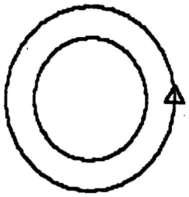
the drawing is sequential, the static may be more real.)

. . . its sense of time

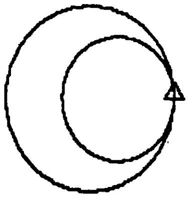
. . . its quickness (even though this isn't in the nano-second range.)

She finished teaching P to the computer. She and I resumed our discussion about recursion. P was to be recursive. We had played the people procedure game (To POW RAISE-ARM LOWER-ARM SAY-POW) last year but she didn't remember. I asked her to be the POW procedure and we worked through it again. Then she made P behave in the same way and ran it. The desired effect was achieved.

I asked her to use LCIRCLE and RCIRCLE to make



she quickly made
out of LCIRCLE 90 and
LCIRCLE 60

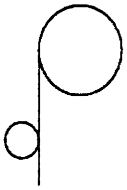


Again an interesting phenomenon (the "start up bug") : she seemed to block until I said "What about moving the turtle?" A trivial piece of advice. Perhaps it really means "stop being complicated, do something simple."

She asked how much to move it. I answered, "Well it walks 90 units to the middle of the big circle and 60 units to the middle of the small so move it 90 take away 60. She did and completed the picture. We then took a break for lunch.

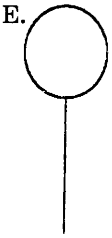
By the way I had tried to accept her first version but she would not give up on the original picture.

After lunch I asked her to make

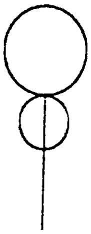


This time using LC or RC (which took diameter as their input).

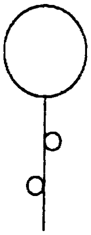
Then I went away. I suspected she had ritualized her experience with the head of RUTH and MARIE. I wanted to see if she could undo it. She worked very hard.



She got



I finally modified the model to

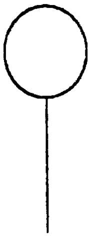


She said no she only wanted 1 leaf. (Esthetics). She did it! She called it DF for dumb flower (again emphatic and dramatic).

In all this I see another interesting phenomenon. Call it making cliches. Are they good or bad? Perhaps necessary. Anyway that's how it seems to go. (Seymour says it now has the blessing of "frame theory" and something cognitive psychologists call "stereotyping". Again I don't know but I'm glad to know that theoretical people are paying attention to the things that seem important. Also, what does Piaget mean by schema?)

Here is a series of events.

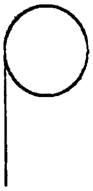
In making the men Est constructed



The obvious first pass at doing this is

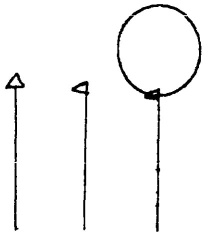
```
FD 50
RCIRCLE 50
```

but this gives

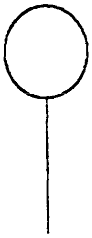


The debugged version is FD 50

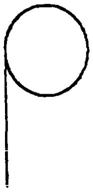
```
LT 90
RCIRCLE 50
```



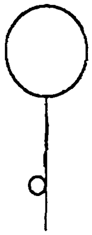
Est worked awhile on this and eventually knew how to make figures like



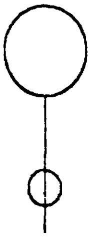
Now the flower model called for



which Est had previously found easier. But now she has trouble. She has "formed a cliche" or "overgeneralized" or whatever. You might say "well she doesn't understand anything. She is echoing mechanically." But it's not so simple. Look at what happened when I suggested putting in a leaf to form:



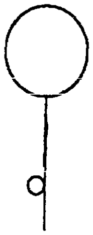
She didn't make



as she would if "LT 90 RCIRCLE" had been completely ritualized. So it's more subtle. Actually Est had developed another cliche. Instead of saying LT 90, she would say RT 90, RT 90, RT 90. In this problem there was payoff. Then she would always turn the turtle right.

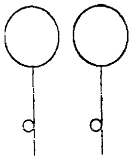
My next suggestion was to make a row of flowers. She did

```
DF
DF
```



but the second DF drew the same flower again. Astonishment! Bug! Again a very "trivial" piece of advice got her going. I pointed to where the next flower could be. No words were necessary (what a lesson for talkative teachers!) . . . she knows how to drive the turtle and she quickly drew a row of flowers.

```
DF
RT 90
FD 50
RT 90
RT 90
RT 90
DF
RT 90
etc.
```



"Fantastic" I said, "and what about one to the left." Serious thinking. It has to go BK 150 she said, "because there are 1 2 3 of them."

Again the research problem: What do these "little" aids mean? What is the learner's problem. This learner sometimes handled this amazingly. Her flower drawer is called DF. Like many children her age she sometimes reverses letters and especially since FD is a LOGO word. So several times her intended DF got the reply:

```
FORWARD NEEDS MORE INPUTS
```

So she wrote a big DF on a piece of paper. Put a circle around it and looked at it ritualistically every time she wanted to draw a flower! (Best model this year of debugging.)

I emphasize: the particular trick for DF was entirely her own idea. If I helped it was by conveying (rather than telling) an attitude to debugging and towards using paper and pencil as a material aid. I had often taken up the pencil in times of difficulty.

Finally another "cliche" which I already mentioned, Est never used LEFT spontaneously. She knew what it did and would oblige if asked to use it. But on her own she would say

RT 90
RT 90
RT 90

rather than

LT 90

There seemed to be no reason to complain or "correct" this perfectly adequate representation! It might be interesting to watch its development. But probably not. One day she will use LT 90 and no one will ever know what happened. Except her, perhaps.

Feature selection for binary data—Medical diagnosis with fuzzy sets*

by JAMES C. BEZDEK
Marquette University
Milwaukee, Wisconsin

ABSTRACT

The notion of fuzzy sets—sets with imprecise boundaries—is a natural cornerstone upon which to build algorithms based on approximate reasoning. Since their inception in 1965 by Zadeh,[1] fuzzy sets have led to first steps towards quantifying data analysis in many fields previously immune to mathematical examination. A fairly exhaustive introduction to the theory and applications of fuzzy sets[2] lists 238 papers dealing with a great variety of recent investigations.

INTRODUCTION

In this paper we discuss the applicability of the fuzzy ISODATA clustering algorithms for (1) dimensionality reduction of binary valued data sets, and (2) computerized medical diagnosis. The first question is often referred to as feature selection; overviews of many popular approaches are available in References 3 and 4. Loosely speaking, one wants to reduce the number of characteristics originally measured to some optimal subset which retains at least as much information about substructure in the data as the original ones. Computerized medical diagnosis is an extremely difficult and ambitious undertaking. Considering the risks involved, enormous improvements need to be made in existing methodologies before the medical community can be asked to rely on the diagnostic suggestions of a computer. However, it is our conviction that the attitude of pessimism displayed in Reference 5 towards this enterprise is largely attributable to the failure of conventional (that is, non-fuzzy) techniques, the results of which must either be accepted at face value or rejected out of hand: we believe that fuzzy sets can be used as a basis for computerized diagnostic *advice* that will provide valuable insight and direction for clinicians with a large data base of previous case histories.

FUZZY CLUSTERING ALGORITHMS

Let R^d denote real, d-dimensional Euclidean space (*feature space*), and let $X=\{x_1,x_2, \ldots , x_n\} \subset R^d$. Each $x_k= (x_{k1},x_{k2}, \ldots , x_{kd}) \in R^d$ is a *feature vector* (subject, patient); each x_{kj} in R is the j^{th} *feature* (characteristic, attribute, symptom) of feature vector x_k; and if every $x_{kj} \in\{0, 1\}$, we call X a binary valued data set. In this instance, we say x_k has attribute j when $x_{kj}=1$, and is lacking it if $x_{kj}=0$. Cluster analysis with respect to X is the problem of finding an integer c, $2\leq c<n$, and c subsets (clusters) of X which partition it into subgroups of points revealing intrinsic substructure in the data. Algorithms to partition X abound; the partitions they find depend on the classification criterion used by the algorithm which defines similarity between pairs of vectors in X.

There are *hard* (i.e., conventional) and fuzzy methods, and each of these main classes can be roughly subdivided into graph-theoretic and objective function techniques. Readers interested in hard algorithms for clustering will find an introduction to the literature in Reference 3; a brief review of fuzzy clustering follows. Clustering with fuzzy sets was first proposed in Reference 6. References 7-10 discuss some of the earliest fuzzy pattern classification schemes. In 1969 Ruspini delineated the first fuzzy clustering method based on objective functions, and foreshadowed the usefulness of information measures (entropy) in the fuzzy sets context. His technique was enlarged and illustrated in References 12-15. Dunn[16] defined the first fuzzy extension of the classical within group sum of squared errors (WGSS) objective functional, and in Reference 17 this approach was generalized to yield the infinite family of algorithms discussed below. Methods of clustering based on fuzzy graphs are still in their infancy; References 18-23 are seminal works in this direction.

CLUSTERING WITH FUZZY ISODATA

A hard c-partition P of X is a collection of c nonempty subsets of X, say $P=\{Y_1,Y_2, \ldots , Y_c\}$, whose

* This research supported by National Science Foundation Grant DCR75-05014.

union is X and whose pairwise intersections are disjoint. To characterize P by a matrix, let $u_i: X \rightarrow \{0, 1\}$ be the characteristic function of Y_i:

$$u_i(x_k) = u_{ik} = \begin{Bmatrix} 1 \text{ in case } x_k \in Y_i \\ 0 \text{ otherwise} \end{Bmatrix}; 1 \leq i \leq c; 1 \leq k \leq n. \tag{1}$$

Denote by V_{cn} the vector space of all real $c \times n$ matrices, let $U \in V_{cn}$, and let u_{ik} be the ik^th entry of U. The set of matrices

$$M_c = \left\{ U \epsilon V_{cn}: u_{ik} \epsilon \{0,1\} \; \forall \; i,k; \sum_{i=1}^{c} u_{ik} = 1 \; \forall \; k; \sum_{k=1}^{n} u_{ik} > 0 \; \forall \; i \right\} \tag{2}$$

is called *hard c-partition space* for X because each partition P of X corresponds uniquely to the matrix in M_c whose rows are the values for the characteristic functions of the subsets in P as shown in Equation (1).

Solutions for all hard clustering algorithms lie in M_c, and this is a fundamental drawback for two reasons: First, each member of the data must be assigned unequivocal membership in one and only one of the c partitioning subsets; however, the substructure in real data rarely—if ever—is so distinct that every member in X is most realistically described as a full member of a single subclass. A fuzzy model can overcome this objection by allowing every individual partial membership in all c subsets, as, for example, one would desire for hybrids when classifying them in parallel with their progenitors. Secondly, M_c is a finite but extremely large set, a complication which often manifests itself in analytical as well as computational intractabilities.

Fuzzy sets provide a natural way to surmount the objections above. We call any *function* u_i that maps X into the closed interval [0,1] a *fuzzy subset* or fuzzy cluster in X. The number $u_i(x_k) = u_{ik}$ is the *grade of membership* of subject x_k in fuzzy set u_i, and fuzzy c-partitions of X are defined by imbedding M_c in

$$M_{fc} = \left\{ U \epsilon V_{cn}: u_{ik} \epsilon [0,1] \; \forall \; i,k; \sum_{i=1}^{c} u_{ik} = 1 \; \forall k; \sum_{k=1}^{n} u_{ik} > 0 \; \forall \; i \right\}. \tag{3}$$

M_{fc} is called *fuzzy c-partition space* associated with X. The requirement that each column in U sum to one stipulates that every vector in X be assigned a *total* membership equal to unity in the partitioning subsets. If M_c is enlarged to include matrices which may have some zero rows, say M_{co}, then M_{fc} is the convex hull of M_{co}.[17] Compactness, convexity, and continuity endow M_{fc} with a pleasant mathematical structure; for example, it has been shown[24] numerically that because M_{fc} is continuous, algorithms defined on it have paths of feasible solutions around undesirable local trap states of algorithms confined to M_c.

Given M_{fc}, how can fuzzy c-partitions of X be found? One way to identify optimal fuzzy clusterings in X is via the family of generalized WGSS error objective functionals defined in Reference 17. On the Cartesian product of M_{fc} with R^{cd}, we define for $m \epsilon [1, \infty)$

$$J_m(U,v) = \sum_{k=1}^{n} \sum_{i=1}^{c} (u_{ik})^m ||x_k - v_i||^2. \tag{4}$$

In (4) $U \epsilon M_{fc}$, $v = (v_1, v_2, \ldots, v_c) \epsilon R^{cd}$, $v_i = (v_{i1}, v_{i2}, \ldots, v_{id}) \epsilon R^d$ for $1 \leq i \leq c$, and $||\cdot||$ is any norm on feature space. J_m is an etxension of the classical minimum variance objective functional J_1 because $J_m = J_1 \; \forall \; m$ whenever $U \epsilon M_c$ is hard. The c vectors $\{v_i\}$ comprising v are presumed to have features prototypical of vectors in X having a high affinity for membership in the respective fuzzy clusters $\{u_i\}$, and so are called *cluster centers* of their respective fuzzy clusters. These vectors will play an important role in the sequel. The measure of similarity in (4) is the norm $||\cdot||$; in this model it compares members of the data to each other indirectly via distances between them and the cluster centers.

Optimal fuzzy c-partitionings of X are defined as part of solution pairs $(\hat{U}, \hat{v})$ of the optimization problem

$$\text{minimize}\{J_m(U,v)\} \quad \text{over } M_{fc} \otimes R^{cd}. \tag{5}$$

Partitions arising as part of solutions for (5) are related to a well defined type of hard, compact, well separated (CWS) clusters for X in Reference 16. There are structured data sets whose clusters do not enjoy this property, but there is a wide class of patterns for which this criterion is very basic, and we adopt it here as implicit in our clustering goals.

Necessary conditions for solutions of (5) were derived[17] for the class of functionals in (4) whose norms were differentiable (e.g., inner product induced norms). It was shown there that for $m > 1$ and $x_k \neq \hat{v}_i \; \forall \; i,k$,

$$\hat{u}_{ik} = \left[\frac{1}{\sum_{j=1}^{c} \left(\frac{||x_k - \hat{v}_i||}{||x_k - \hat{v}_j||} \right)^{\frac{2}{m-1}}} \right], 1 \leq i \leq c; 1 \leq k \leq n, \tag{6a}$$

$$\hat{v}_i = \left[\frac{\sum_{k=1}^{n} (\hat{u}_{ik})^m x_k}{\sum_{k=1}^{n} (\hat{u}_{ik})^m} \right], 1 \leq i \leq c \tag{6b}$$

are necessary in order for $(\hat{U}, \hat{v})$ to be a local solution of (5). Full details for $m = 1$ and the singular cases $x_k = \hat{v}_i$ for some i and k may be found in References 16 and 17. At $m = 1$ requirement (6a) is replaced by a nearest neighbor assignment rule, $U \epsilon M_c$ is necessarily hard, the cluster centers in (6b) are merely the centroids of the hard subsets in U, and the resultant algorithm is essentially the hard ISODATA process of Ball and Hall.[25] For $m > 1$ equations (6) define the

Fuzzy ISODATA algorithms

Choose any $c \times n$ matrix $U_0 \epsilon M_{fc}$. (7a)

Compute the weighted means $\{\hat{v}_i\}$ with U_o and (6b). (7b)

Update $U_o \rightarrow \hat{U}$ with equation (6a). (7c)

Compute the maximum membership defect

$$\max_{i,k}\{|(\hat{U})_{ik} - (U_o)_{ik}|\}. \quad (7d)$$

If less than some prespecified tolerance ϵ, stop. Otherwise relabel $\hat{U} \rightarrow U_o$ and return to (7b).

Implicit in (7) are tie-breaking rules and resolution of singularities. These equations define an iterative optimization procedure for locating approximate minima of J_m. It is convenient to recast this loop in the form of the iterative matrix operator $T_m : M_{fc} \rightarrow M_{fc}$ defined by

$$T_m(\hat{U}_k) = \hat{U}_{k+1} = (T_m)^k(U_o), k=0,1,2, \ldots . \quad (8)$$

Since U's which are part of optimal pairs for J_m must lie among the fixed points of T_m, we call approximate minima of J_m fixed points of fuzzy ISODATA. J_m has the descent property on successive iterates of T_m and the associated set of cluster centers they determine, but it is not now known whether the iterate sequence $\{T_m(\hat{U}_k)\}$ is theoretically convergent. We mention this because the numerical example below suggests an interesting conjecture about these fixed points. The possibility of using T_m to approximate a maximum likelihood operator for certain problems in unsupervised learning is discussed in Reference 26.

SCALAR MEASURES OF PARTITION QUALITY

Since optimal partitionings of X are defined as part of solutions of (5), an obvious way to rank competing partitions is by their corresponding values with J_m. Unfortunately, J_m is not an exception to the fact that global minima of objective functions may suggest very poor interpretations of substructure in X.[24,27,28] Consequently, values of J_m do *not* necessarily rank the merits of different $\hat{U}$'s in M_{fc} as worthwhile clusterings of X. It is here that fuzzy ISODATA departs from conventional clustering techniques, because with hard objective functions the functional values are the only information usually available for addressing this question. With fuzzy partitions however, the fuzziness of $\hat{U}$ allows one to associate various measures of partition quality with $\hat{U}$ which are independent of the method used to produce these partitions. Fuzzy ISODATA is used to generate likely candidates for optimal clusterings of X; their relative quality has been assessed by either of two scalar valued measures defined on M_{fc}:

$F_c(U) = \text{trace}(UU^t)/n$, superscript t being here transpose, (9)

$$H_c(U) = -\left(\sum_{k=1}^{n}\sum_{i=1}^{c} u_{ik} \log_a u_{ik}\right)/n, \text{ with } a\epsilon(1,\infty). \quad (10)$$

$F_c : M_{fc} \rightarrow [1/c, 1]$ was defined in Reference 17 as the *partition coefficient* of U; $H_c : M_{fc} \rightarrow [0, \log_a c]$ was defined in Reference 27 as the *average classification entropy* of U. Although the functional forms of F_c and H_c are quite different, they are related as follows:

$$F_c(U) = 1 \Leftrightarrow H_c(U) = 0 \Leftrightarrow U \epsilon M_c \text{ is hard.} \quad (11a)$$

$$F_c(\tilde{U}) = 1/c \Leftrightarrow H_c(\tilde{U}) = \log_a c \Leftrightarrow \tilde{U} = [1/c]. \quad (11b)$$

$$1 - F_c(U) < \left(\frac{H_c(U)}{\log_a e}\right) < \tfrac{1}{2}(c - F_c(U)). \quad (11c)$$

Equations (11) suggest that the equi-membership partition $\tilde{U} = [1/c]$, i.e., $\tilde{u}_{ik} = 1/c \, \forall \, i,k$, is the fuzziest or worst one can do (geometrically $\tilde{U}$ is the centroid of M_{co}); on the other hand, the ideal situation occurs when the substructure in X is so distinct that a fuzzy algorithm recommends a hard c-partitioning of X. Maximizing F_c over different fixed points of fuzzy algorithms minimizes the total content or overlap in pairwise fuzzy intersections; equivalently, minimizing H_c over the same choices maximizes the "information" extracted from U. In either case, we presume that values of these measures serve as a relative indication of the uncertainty an *algorithm* experiences in trying to assign memberships to the vectors in X. Note that F_c and H_c are well defined for partitions generated by *any* fuzzy clustering method, not just ISODATA; moreover, these functions convey no information about the relative merits of hard c-partitions of X, their usefulness depending entirely on the idea of fuzziness. Numerical evidence indicates that H_c is probably more sensitive than F_c in ranking U's; this has been attributed to the fact that the slope of the logarithmic curve on most of (0,1) is much steeper than that of the parabola (H_c is a sum of logarithmic terms, F_c a sum of parabolic ones). Nonetheless, both measures seem useful, since the lower bound in (11c) is a sharper indication than that in (11a) of how small $H_c(U)$ is.

In general the clustering strategy used with fuzzy ISODATA has been to minimize H_c over approximate fixed points of T_m for whatever alternatives have been considered, and regard the resultant c-partitioning of X as the most optimal one. If this partition is relatively fuzzy (as measured by H_c), we do not infer that X has no well defined substructure; we conclude that none of the algorithms tried have been successful at finding it.

A NUMERICAL EXAMPLE

Table I lists 11 symptoms of 107 stomach disease patients who have either hiatal hernia (patients 1-57) or gallstones (patients 58-107). Table I constitutes our binary data set X. The data was collected as part of a larger study at the Henry Ford Hospital in Detroit by Rinaldo, Scheinok, and Rupe.[30] Various studies utilizing the larger data set for computerized medical

diagnosis have been discussed in References 31-35; full details on the data are available in Reference 31. The 11 symptoms measured (present=1, absent=0) were:

Symptom	*Description or type of Abdominal Pain*
1	Male=1; Female=0
2	Epigastric Pain
3	Upper right quadrant pain
4	Back pain
5	Discomfort episodes of 1-4 weeks
6	Discomfort episodes of 0-1 days
7	Relief induced by food ingestion
8	Aggravation induced by food ingestion
9	Aggravation induced by position
10	Weight loss (at least 20 lbs. in 6 mos.)
11	Persistence (at least 1 month in length)

The calculations were made in single precision Fortrans IV using logarithms in (10) to base e=2.718. . . . The convergence threshold ϵ used in (7b) was $\epsilon=0.01$. Because fuzzy ISODATA—like all hill climbing methods—is susceptible to stagnation at local minima of J_m, it is necessary to test the stability of fixed points of T_m by varying the initial guess for U_o in (7a). Other studies report results concerning this parameter; for this example the only initial guess used is

$U_o=\alpha U+\beta\tilde{U}$, where $\alpha=\sqrt{1/2}$, $\beta=1-\sqrt{1/2}$, and

$$U=\left[\underbrace{\begin{matrix}1\,0\,.\,.\,.\,0\\0\,1\,.\,.\,.\,0\\ \vdots \qquad \vdots\\ 0\,0\,.\,.\,.\,1\end{matrix}}_{c\times c}\;\middle|\;\underbrace{\begin{matrix}1\,1\,.\,.\,.\,1\\0\,0\,.\,.\,.\,0\\ \vdots\qquad\vdots\\0\,0\,.\,.\,.\,0\end{matrix}}_{c\times(n-c)}\right] \tag{12}$$

U_o is an initial guess lying midway between $\tilde{U}$ and the hard c-partitions of X, as measured by the value of F_c, since $F_c(U_o)=1/2+(1/2c)$. Only one initial guess is used in this example to shorten the presentation of numerical results.

Finding c is often the most important and difficult problem in clustering. The use of fuzzy ISODATA for this purpose is discussed elsewhere; in this investigation we fix c=2 in the interests of brevity. The algorithmic parameters varied here are the weighting exponent m and norm $||\cdot||$ appearing in (4). Values for m are 1.10, 1.33, 1.67, and 2.00. Results with other values are contained in Reference 29. Three norms induced by the weighted inner product $\langle x,x\rangle=x^tAx$ on R^d were used. These norms were realized by different choices for the symmetric matrix A:

N1 (Euclidean) induced by A=I, the d×d identity. (13a)

N2 (Diagonal) induced by $A=[\text{diag}(\sigma_1^2,\ldots,\sigma_d^2)]^{-1}$, the inverse of the diagonal matrix of marginal sample feature variances. (13b)

N3 (Mahalonobis) induced by $A=[\text{cov}(X)]^{-1}$, the inverse of the sample covariance matrix. (13c)

Further discussion on these choices may be found in Reference 35. Having established the computing protocols, we turn to the numeric results.

Table II lists entropies H_2 and their lower bounds $1-F_2$ for the fixed points of T_m obtained by processing X with (7) under the assumptions above. These values are comparable only for fixed values for m, because as m→1, partitions obtained by fuzzy ISODATA are always "less fuzzy" in the sense of F_c or H_c. Since (7) represents an infinite family of algorithms, there is the practical question of which one to use. The only theoretical result concerning this to date appears in Reference 36, where an analogy to minimum resistance electrical networks is used to suggest that only J_2 extends the physical interpretation of J_1 made there. It will be seen in Table II that ISODATA proceeds from U_o to $\tilde{U}$ (quite rapidly) for every norm at m=2.00; for N2 and N3 at m=1.67; and for N3 at m=1.33 (recall from (11b) that with c=2, F_2=.500 if and only if evaluated at $\tilde{U}$). Whether or not other initial guesses for U_o would lead to this fixed point is a matter of speculation; the rather surprising conjecture suggested by this observation is that the size of stability domains of fixed points of T_m is dependent on both m and the norm in (4). Of course, as m→∞, $\tilde{U}$ becomes the *only* fixed point of T_m, as is evident from (6a). Table II shows that it may be necessary to experimentally decrease m towards m=1 until fuzzy ISODATA successfully begins to avoid equi-memberships for a given set of data.

The values in Table II also indicate a slight preference for the Euclidean norm over N2, and a definite preference compared to N3, so we infer that this data

TABLE II—Entropies for Data Set X

Weighting Exponent m	Norm $\|\cdot\|$	Lower Bound $1-F_2(\hat{U})$	Entropy $H_2(\hat{U})$
1.10	N1	.051	.088
	N2	.057	.095
	N3	.086	.162
1.33	N1	.253	.397
	N2	.274	.425
	N3	.500	.693
1.67	N1	.420	.608
	N2	.500	.693
	N3	.500	.693
2.00	N1	.500	.693
	N2	.500	.693
	N3	.500	.693

is most separable by N1 among the three norms considered. Accordingly, the norm in (4) for subsequent runs is now fixed at $||\cdot||=N1$, and in view of the results obtained at $m=1.67$ and 2.00, we drop these values for the weighting exponent.

In Table III are listed the membership functions corresponding to terminal partitions obtained with (7), $||\cdot||=N1$, and $m=1.10$, 1.33. Scanning these values, one quickly obtains a feel for which members of the data indicate a strong desire to be classified into one subclass or the other. As we expect, the partition of X associated with the smaller value of m is very nearly hard, while the second partition begins to exhibit clearly those subjects in X apparently causing the most difficulty to ISODATA in assigning memberships. This feature of fuzziness—*identification of the troublesome or distinguished individuals in the data*—is perhaps the most important reason for using fuzzy models. Information of this kind is simply not available when using hard classification procedures, for then all the entries in solution partitions are 0's and 1's.

Since any discussion of error rates presumes a comparison with hard labels, it is necessary to convert fuzzy partitions into hard ones before this is possible. An obvious (but not necessarily best) way to do this is via the maximum membership rule: assign each $x_k \epsilon X$ to the cluster in which it holds maximum membership. All error rates mentioned below are computed with hard 2-partitions of the data obtained in this fashion. With this convention in mind, we have from Table III at $m=1.10$ 23 incorrect labels, and at $m=1.33$, 25 mislabelled patients. We emphasize that these are *not* classifier performance rates, because we are clustering here; no attempt is being made to train a classifier for prediction with unlabelled samples. However, we presume these figures are indicative of error rates which may be obtained with fuzzy classifiers now under study. Of more immediate interest is the way we can use fuzzy ISODATA to attack the feature selection problem.

FEATURE SELECTION USING FUZZY ISODATA

Contrary to one's intuition, adding more features does not always lead to better classifier performance.[3] In some instances the converse is true; deletion of features may remove the source of confusion preventing an algorithm from detecting substructure known (or presumed) to exist in the data, and in any event, reduction of the dimension of feature space alleviates the computational burden imposed by using many features. In medicine, this amounts to asking for the minimum number of symptoms needed to detect a particular disease, or to discriminate between closely related ones. The basis for a technique of fuzzy feature selection using algorithm (7) is contained in the simple

Proposition Let X be any binary valued data set, $X=\{x_1, \ldots, x_n\}$ contained in R^d; let $\{\hat{v}_i\}$ be the cluster centers given by (6b); and suppose $\hat{v}_{ij}$ to be the j^{th} component of $\hat{v}_i$ for $1\leq i\leq c$; $1\leq j\leq d$. Then

$$0\leq \hat{v}_{ij}\leq 1 \ \forall\ i,j \tag{14a}$$

$$\hat{v}_{ij}=0 \Rightarrow x_{1j}=x_{2j}=\ldots=x_{nj}=0 \tag{14b}$$

$$\hat{v}_{ij}=1 \Rightarrow x_{ij}=x_{2j}=\ldots x_{nj}=1 \tag{14c}$$

Proof Rewriting equation (6a) in the form $\hat{u}_{ik}=(1/1+c_{ik})$, where c_{ik} is the sum in the denominator over $j=1,2,\ldots, c$ with $j\neq i$, we observe that $c_{ik}>0$ for every i and k, hence $\hat{u}_{ik} \epsilon (0,1)$ for every i and k. In view of this the denominator in (6b), $\sum_{k=1}^{n} (\hat{u}_{ik})^m>0$ for $1\leq i\leq c$. Now consider the component form of (6b) for any j;

$$\hat{v}_{ij}=\sum_{k=1}^{n}\left[\frac{(\hat{u}_{ik})^m}{\sum_{s=1}^{n}(\hat{u}_{is})^m}\right]x_{kj};\ 1\leq j\leq d;\ 1\leq i\leq c. \tag{15}$$

The coefficients of x_{kj} in (15) are all strictly positive, and since every x_{kj} is greater than or equal to zero, $\hat{v}_{ij}$ is also. Moreover, this also shows that $\hat{v}_{ij}$ can equal zero if and only if all the x_{kj} in (15) are zero. Finally, since every x_{kj} in (15) is less than or equal to one, that sum is bounded above by 1, the number obtained upon replacing all of the x_{kj}'s with 1. Since the maximum is attained when this occurs, the proof is complete.

We elaborate the implications of equations (14) for feature selection by the following series of observations:

(i) $\hat{v}_{ij}=0$: Since the proof is independent of i, it's easy to see that an even stronger statement holds: $\hat{v}_{ij}=0 \Leftrightarrow \hat{v}_{kj}=0$ for $1\leq k\leq c$ with $k\neq i$. From (14b) it follows that this occurs when and only when attribute j is absent from all n members of the data, in which case it is irrelevant to substructure in X (medically, no patient had symptom j).

(ii) $\hat{v}_{ij}=1$: As in (i), the stronger statement $\hat{v}_{ij}=1$ if and only if all the $\hat{v}_{kj}$'s with $k\neq i$ are 1 holds. In this event, feature j is a maximal descriptor of the n individuals in X (medically, all patients had symptom j).

(iii) $0<\hat{v}_{ij}<1$: Again, this can happen when and only when $0<\hat{v}_{kj}<1$ for all $k\neq i$. Ostensibly, feature j has a variable amount of influence in describing members of the c subgroups in X. This suggests that the relative magnitudes of $\hat{v}_{1j}, \hat{v}_{2j}, \ldots, \hat{v}_{cj}$ may rank the efficacy of j as a descriptor of each subclass (medically, some patients in each subclass had symptom j, and others did not).

(iv) Combining (i)-(iii), it is seen that one of the cluster centers $\hat{v}_i$ is *entirely* binary valued if and only if *all c of them are,* and this occurs if and only if all n members of the data are identical. In this eventuality there is no possibility for mathematical (or medical) detection of subclasses in X. On the other hand, we

find that if and only if a single cluster center has *no* component either 0 or 1, then all c cluster centers are of this type.

In view of these remarks, it seems natural to call the components $\{\hat{v}_{ij}\}$ of cluster center $\hat{v}_i$ the *feature centers* of class i. Table IV exhibits values of these centers for each of the fuzzy partitions listed in Table III. The ranking of symptom importance for patients with hiatal hernia (class 1) established by values of $\{\hat{v}_{ij}\}$ at either value of m is $2>6>1>9 \ldots >10$. We infer from this that among the 11 symptoms measured, epigastric pain (2) is most likely to occur in patients with this disorder, whereas they will exhibit weight loss (10) only occasionally. To see whether the magnitudes of the $\hat{v}_{ij}$'s really do this, let p_{ij} be the relative frequency of occurrence of symptom j in class i patients. From Table I we find that $p_{12}=0.982$, $p_{1,10}=0.035$. These frequencies should be compared to the values of the corresponding feature centers for class 1: for example, with $m=1.10$ we have $\hat{v}_{12}=0.985$, and $\hat{v}_{1,10}=0.021$. These comparisons seem to corroborate our supposition concerning the ability of the fuzzy feature centers to rank the significance of the features as descriptors of each class.

For patients with gallstones (class 2), there is some shifting in ranks established by changing m from 1.10 to 1.33; this seem to indicate that members of this class are somewhat less distinctive. Nonetheless, we find from Table IV that in both cases, the most important features are {3,6,8,2}; the least important are {5,7,9}. Of course, one may take the opposite view, and regard {5,7,9} as the features most important for deciding a patient does *not* have gallstones. This remark points up the fact that the $\hat{v}_{ij}$'s do not establish which features possess discriminatory power for separating class i from closely related classes, and at the same time, suggests a way to use the feature centers for *pairs* of subclasses to select optimal discriminators.

TABLE IV—Cluster Centers for the Membership Functions in Table III

Exponent	Symptom	Feature Centers		Absolute
		(Hernia)	(Galls.)	Differences
m	j	$\hat{v}_{1j}$	$\hat{v}_{2j}$	$\lvert\hat{v}_{1j}-\hat{v}_{2j}\rvert$
1.10	1	.570	.269	.302
	2	.985	.668	.317
	3	.063	.929	.865

	8	.285	.839	.553
	9	.527	.103	.423
	10	.031	.118	.087
	11	.127	.198	.071

An obvious indication of "how separable" classes i and j are is their cluster center separation $||\hat{v}_i-\hat{v}_j||$. This measure, however, suppresses the information we want to use for reducing the number of features required to effect the classification. A more suitable measure is afforded by the vector of absolute differences of the components of $\hat{v}_i$ and $\hat{v}_j$: for all i and j let

$$f_{ij}=(|\hat{v}_{i1}-\hat{v}_{j1}|,|\hat{v}_{i2}-\hat{v}_{j2}|,\ldots,|\hat{v}_{id}-\hat{v}_{jd}|). \quad (16)$$

The components of $f_{ij,k}$ of vector f_{ij} measure feature center separations between the feature centers for classes i and j. Equations (14) lead to the following results for these components:

$$0\leq f_{ij,k}\leq 1 \text{ for all i,j, and k.} \quad (17a)$$

$f_{ij,k}=0 \Leftrightarrow$ Either all or none of the vectors in both classes i and j have feature k. (17b)

$f_{ij,k}=1 \Leftrightarrow$ All vectors in class i and no vectors in class j have feature k, or vice versa. (17c)

We presume feature k to be either useless or optimal as a discriminator between classes i and j according as (17b) or (17c) respectively occurs. (17a) shows these to be the extremes, intimating that the values $f_{ij,1}$, $f_{ij,2}, \ldots, f_{ij,d}$ rank by their magnitudes the relative utility of the d features for discrimination between classes i and j.

To test this speculation, the vector f_{12} defined by (16) corresponding to the cluster centers in Table IV was used to identify the optimal feature subsets of dimensions 1,2, and 3, and the data set X was reprocessed with fuzzy ISODATA using only these features. The last column of Table IV reports the values of $f_{12,k}$: evidently symptom 3—upper right quadrant pain—is implicated as the most powerful attribute for distinguishing between gallstones and hiatal hernia. The feature center values $\hat{v}_{13}=0.105$ and $v_{23}=0.686$ suggest that very few hernia patients suffer from symptom 3, while most gallstones patients may be expected to have it. Indeed, from Table I we find that the relative frequencies of symptom 3 are $p_{13}=0.123$ and $p_{23}=0.680$ respectively. Continuing in this fashion, we deduce that either {3,8} or {3,9} would be the best 2-dimensional subset of features to use; that {3,8,9} is the best set of 3 features at either value of m; and so on.

The results of clustering these feature subsets are reported in Table V as numbers of misclassifications stemming from the hard 2-partitions realized by maximum membership conversion of the associated fuzzy fixed points of T_m. Using symptom 3 alone results in exactly the same hard partitions as using symptoms 3 and 9; moreover, it will be seen that the overall error rates achieved with either of these subsets is at least

TABLE V—Misclassifications * Using Reduced Feature Spaces

Symptoms	m=1.10			m=1.33		
	Galls.	Hernia	Overall	Galls.	Hernia	Overall
Used	n_1=50	n_2=57	n=107	n_1=50	n_2=57	n=107
1-11	17	6	23	13	12	25
3	16	7	23	16	7	23
3,9	16	7	23	16	7	23
3,8	13	23	36	13	23	36
3,8,9	13	23	36	10	17	27
Deleted#	n_1=43	n_2=41	n=84	n_1=43	n_2=41	n=84
1-11	0	7	7	0	7	7

*Based on hard (maximum membership) partitions.

#Data X with patients {23-26,55-57,67-75,94-100} deleted.

as good as the rate attained using all 11 features. Note that symptoms 3 and 9 are much less effective than 3 and 8, and the error rate using {3,8,9} is in between the best and worst ones shown. From these results it appears that the feature selection method proposed above successfully extracts a small number of features which possess essentially the same information relevant to substructure in X detected by fuzzy ISODATA as the original ones.

SUMMARY

Fuzzy clustering, and in particular fuzzy ISODATA, has been reviewed, and is proposed here as a basis for a new technique applicable to the problem of feature selection. Specifically, equations (14) and (17) seem useful in ranking the effectiveness of binary valued features both as subclass representatives and as discriminators between pairs of fuzzy subclasses in X. A numerical example was presented which seems successful enough to warrant further investigations into the plausibility of the method. We note that this technique is applicable *only* for binary data sets: in fact, (6b) shows that the cluster centers $\{\hat{v}_i\}$ lie in the linear subspace generated by the data, so when the features have continuous domains, (14) and (17) are invalid.

As a means of computerized medical diagnosis, the technique described above is incomplete in the sense that it is a clustering method, not a classifier. Nonetheless, it seems fair to assert that our example exhibits the promise fuzzy sets may hold for this problem. Our conviction is that fuzziness is the premise needed as a basis for pattern recognition; more precisely, we think it an appropriate generalization of the conventional strategies criticized in Reference 5. The reason for this lies with the fuzzy membership values generated by algorithms like fuzzy ISODATA; not only do they indicate a patient's relative affinity for having every disease represented by members of the data; but perhaps more importantly, low memberships can be used to identify those patients whose symptoms indicate further personal attention. For example, the values in Table III suggest that the 23 patients whose Table I labels are {23-26,55-57,67-75,94-100} are—by virtue of their relatively low memberships—the ones most affecting the computer's success at separating the two subclasses. If these 23 individuals are deleted from X, and the remaining 84 patients are processed with ISODATA, the results reported in the last row of Table V indicate an increase of about 14 percent in the accuracy of labelling obtained on all 11 features with either value of m. This appears to confirm that low memberships signal troublesome patients. (Note that processing this deleted set with only feature 3 results in a recognition rate of 100 percent: the 23 patients identified above are precisely the 23 subjects having the "uncharacteristic" labels for members of their classes with respect to feature 3 alone). Of course, it is not the business of the medical community to *delete* troublesome patients from data sets for the convenience of a computer: on the contrary, these are the patients that doctors want most to *identify*, and we believe that fuzzy methodologies will eventually be useful in realizing computer assistance and counseling for people in this profession.

Procedural representation in a fuzzy problem-solving system

by RICHARD A. LeFAIVRE
Rutgers University
New Brunswick, New Jersey

ABSTRACT

This paper addresses the problem of developing new representational structures for use in problem-solving domains which are imprecise or uncertain in nature. The incompatibility of precise representations with complex systems is discussed, and an argument is made that the inability to arrive at symbolic representations, not any inherent "complexity," is what makes natural reasoning difficult to model. The programming language FUZZY, which provides a number of facilities for representing and manipulating fuzzy information, is described briefly, and the use of "procedure demons" to specify global control regimes is examined. The procedural mechanisms available in FUZZY are then used to analyze a simple problem of fuzzy deductive inference.

INTRODUCTION

The ability to effectively utilize information which is vague, imprecise, or uncertain is of inestimable importance to a problem-solving system which is confronted with a world view even approaching the "real world" in complexity. It is clear that human problem-solvers are able to function in inexact domains long before they can manipulate the abstract symbols we create to represent "exact" reasoning (e.g., consider how you were able to recognize your mother as a two-year-old). But it is precisely the kind of vague, imprecise reasoning which humans seem to do so well which perplexes researchers in the developing field of cognitive science* who are concerned with understanding and modeling the thought process. Relatively well-defined problem domains such as game playing and theorem proving have been most amenable to analysis and successful simulation. Problem areas which are somewhat more imprecise—that is, whose "rules" and solution algorithms are vaguely specified—have proven to be more difficult to model at a level approaching that of human performance (consider simple scene description and speech understanding). And other domains even less amenable to precise analysis have yet to be even considered by researchers in artificial intelligence, although they constitute the bulk of the average human's reasoning effort (how does one judge that a particular face is "pretty"; decide whether or not to get married, and to whom; figure out whether to go to a play or a movie tonight, and, if so, which one?).

The problem of representation

Zadeh[24,25] describes what he calls the *principle of incompatibility,* which states that the complexity of a given domain is more or less inversely related to the precision (exactness) with which it can be analyzed. Although this tenant seems to hold true in many situations, and can indeed be made a truism by utilizing it as a definition of the ill-defined term "complexity," it is somewhat unsatisfying. Do we really believe that the ability to recognize a chair as a chair and not a table, bench, footstool, etc., is a more complex action than proving a theorem in predicate calculus or playing a reasonable game of chess, simply because we can analyze the latter more precisely than the former? It appears to me that the problem lies not in the underlying complexity of the task, but in the level at which we can (symbolically) *represent* our knowledge about the particular task and its problem domain. It happens that we have developed precise mechanisms for representing our knowledge about the complex reasoning utilized in game playing and theorem proving (involving constraints, rules of action, searching techniques, etc.), whereas the simple task of recognizing a chair (much less a pretty face) has defied attempts at symbolic representation. The reason, of course, is that games and formal logics exist in artificial domains which are *of necessity* described symbolically. Dealing with the real world involves a *natural* form of reasoning which must be developed well before artificial symbolic reasoning appears, and the resulting mechanisms involved in such natural reasoning are correspondingly harder to introspect about (and, therefore, to translate into symbolic representations).

Unfortunately, the only mechanisms we have available for artificially representing knowledge are sym-

* We are indebted to Bobrow and Collins[3] for the popularization of this term.

bolic in nature—a situation which will in all likelihood remain unchanged for some time to come. Our task is thus to develop more general and powerful representational structures, along with techniques for integrating and utilizing these structures to their best advantage. At the same time we must search for ways of representing so-called "real-world" (i.e., naturally non-symbolic) knowledge in such a way that it can be effectively utilized in the problem-solving process. It is this problem that the research reported here addresses.

Previous research

Past investigations into the problem of representing knowledge which is vague, imprecise, uncertain, inexact, or probabilistic in nature can be grouped into four major classifications:

(1) Philosophical and logical foundations—Philosophers of language have long contended that any symbolic system (i.e., language) used to describe the real world must, of necessity, admit concepts which are ill-defined. Indeed, it can be argued that it is precisely the fuzziness of natural language (and the underlying cognitive structure upon which it is built) that allows us to communicate in a meaningful way. The infinite complexity of our world makes it necessary for us to summarize, generalize, compress, and otherwise eliminate the mass of irrelevant detail with which we are continually confronted. Formal logicians, who are concerned with representing knowledge in a formal system, discovered quite early that classical logic with its true-false dichotomy was not sufficient to represent the full range of human knowledge. Various attempts were thus devised to liberalize this dichotomy, resulting in non-standard systems such as intuitionistic logic, modal logics, many-valued logics, probabilistic logic, and fuzzy logic. Although such systems are certainly of interest in their own right, it now seems quite clear that formal, syntactically-based systems are not sufficient for use in a dynamic, problem-solving environment. For a further discussion of these philosophical and logical foundations, see LeFaivre[13] and McCarthy and Hayes.[15]

(2) Formal tools for representation and analysis—In the past decade a new set of formal tools and concepts for analyzing the process of approximate reasoning has evolved from the theory of fuzzy sets (Zadeh,[23] Goguen[7]). Such semantically-grounded concepts as fuzzy sets, fuzzy relations, fuzzy algorithms, linguistic variables, and linguistic hedges give us a new set of tools for symbolically representing and manipulating fuzzy information. At this time most of the work in this area has been theoretical in nature—we are just beginning to investigate the effect which some of these new concepts will have on actual problem-solving systems.

(3) Problem-specific AI systems—Although it is true that the overwhelming majority of systems developed by AI researchers have dealt with simplified domains, thereby ignoring the problem of representing real-world information, there have been some attempts to begin to come to grips with this problem. For example, Munson[18] investigated the general problem of dealing with the uncertainty encountered in the real world. Several systems which utilize semantic net memory structures provide mechanisms for handling various kinds of fuzziness (e.g., Quillian[19] and Becker[1]). Notable among these is the SCHOLAR system developed by Carbonell, into which a variety of different kinds of fuzzy reasoning capabilities have been placed (see Carbonell and Collins[5] and Collins, et al.[6]). The MYCIN system of Shortliffe[20] is also notable for its use of a model of inexact reasoning in medicine.

(4) Problem-independent AI systems—This final classification involves programming systems which are not oriented towards any particular problem domain, but rather provide general facilities for representing fuzzy knowledge. Lee[11] discusses the problem of creating a resolution theorem prover based on fuzzy logic (such a system could, in theory, be used as a general problem-solver—see Green[8]). To my knowledge, the described system was never implemented. Michalski[16] discusses the implementation of a "variable-valued logic" system which provides mechanisms for expressing and solving problems in discrete mathematics which are intrinsically nonlinear. In 1972 Rob Kling and the author began to discuss some of the modifications which might be made to a contemporary "AI language" (MICRO-PLANNER[21]) to allow it to effectively utilize fuzzy information. The resulting system (FUZZY-PLANNER) was subsequently developed on paper by Kling,[9] although it was never implemented. FUZZY-PLANNER, however, stands as the spiritual predecessor to the system described in this paper.

A BRIEF DESCRIPTION OF FUZZY

One of the more important trends in artificial intelligence in recent years has been the development of powerful new programming languages for use in AI research (see Bobrow and Raphael[4]). The research reported in this paper had as one of its goals the development of a new language which synthesized many of the good ideas of previous AI languages while providing facilities for the efficient storage, retrieval, and manipulation of fuzzy knowledge. The resulting language (called FUZZY) is a complex system which would be impossible to describe fully in a paper of this nature. I shall thus present here a brief overview of the language, and then concentrate in subsequent sections on procedural representation. Note that an early version of the system was described in Reference 12, and a complete description of the language may be found in Reference 13. A discussion of how FUZZY can be utilized to represent a variety of different forms of fuzzy knowledge, including explicitly and implicitly defined fuzzy sets, fuzzy relations, fuzzy algorithms, and linguistic hedges, appears in Reference 14. FUZZY is a LISP-based system, and has been implemented in both UNIVAC 1110 LISP and UCI LISP for the PDP-10.

Fuzzy expressions

FUZZY is in essence a many-valued programming language. By this I mean that, unlike traditional languages in which expressions evaluate to a single value, FUZZY expressions may return both a *value* and a "fuzzy truth-value," or *Z-value.** The Z-value range is specified by the LISP variables ZLOW and ZHIGH, and may be changed by the user as desired (the initial values are 0 and 1). Primitives are available for retrieving the value (VAL) or Z-value (ZVAL) portions of an expression, and for computing logical combinations of fuzzy expressions (ZAND, ZOR, ZNOT). In all cases a default Z-value of ZHIGH is provided by the system if no Z-value is present explicitly.

In addition to being able to return values and Z-values, FUZZY expressions may either *succeed* or *fail* in a manner similar to other AI languages (see Reference 4). Failure is caused by simply returning a value of FAIL, with any other value constituting success. Several variations of a standard IF-THEN-ELSE mechanism are available for controlling success and failure of individual expressions, and a user-controlled backtrack mechanism is available via the SAVE, RESTORE, and FOR statements.

The associative net

In addition to standard LISP data structures, FUZZY allows fuzzy knowledge to be explicitly represented by maintaining an associative network of *assertions* with optional Z-value modifiers. Standard ADD and REMOVE primitives are available for maintaining this net, while the FETCH primitive may be used to access the net via a powerful structural pattern-matcher. The net is automatically ordered by Z-values, and options are available in FETCH to place constraints on the Z-value range to be accessed and to specify whether the assertion with the highest or lowest Z-value in the range is to be retrieved. One variation of the FOR statement allows the user to iterate through all assertions in the net which match a certain pattern and have a Z-value in the desired range.

Fuzzy procedures

It is often the case that knowledge is complex enough to prevent it from being stored explicitly in the form of simple assertions. FUZZY thus provides a powerful method of *implicitly* representing fuzzy knowledge via the specification of procedures (using the PROC statement). The procedural mechanisms of FUZZY will be discussed more fully in a later section of this paper.

Deductive mechanisms

Like other AI languages (see Reference 4), FUZZY allows assertions to be implicitly defined via the specification of *deduce procedures.* The primitive DEDUCE is similar to FETCH, except that instead of searching for an assertion in the associative net, it searches for a procedure which allows the desired assertion to be *computed.* A GOAL primitive is also available which first performs a FETCH, utilizing DEDUCE only if the assertion is not present explicitly in the net. The pattern-directed procedure invocation mechanism of FUZZY is similar to that of other AI languages, except that FUZZY allows Z-value modifiers to be computed and returned along with assertions. Variations of the FOR statement are available for iterating through assertions generated by deduce procedures, and a simple mechanism is available for writing *generators*—procedures which compute an assertion for use by a higher-level FOR statement but which can be restarted to compute an alternative assertion if necessary.

INFERENCE IN A FUZZY ENVIRONMENT

Classical and fuzzy detachment

In order to provide some motivation for the procedural mechanisms described in the next section, let us consider briefly the problem of deductive inference in a fuzzy environment. Like other AI languages, FUZZY provides facilities for automatically "deducing" information via the use of procedures. In nonfuzzy domains, the use of deduce procedures to represent deductive arguments is relatively straightforward. For example, the classic argument "all humans are mortal; Socrates is human; therefore Socrates is mortal" may be succinctly represented by the FUZZY statements:

* The term "Z-value" was chosen so as not to give any semantic connotations to the usage of this numeric modifier, since it can represent a conventional truth-value, a fuzzy set grade of membership, a degree of certainty or belief, a simple weight, or anything else the user wishes.

```
(ADD DEDUCE:                        ; Define deduce procedure stating
 (PROC (MORTAL ?X)                  ; that humanity is sufficient to
  (GOAL (HUMAN !X)))))*             ; prove mortality.
(ADD (HUMAN SOCRATES))              ; Assert Socrates' humanity.
(DEDUCE (MORTAL SOCRATES))          ; Request proof of his mortality.
```

This argument is an example of the *rule of detachment*, which is represented in classical logic by the theorem:

(A *and* (A *implies* B)) *implies* B

In other words, given that "A" is true and "A *implies* B" is true, we may deduce that B is true.

Consider, however, the role of detachment in a nonstandard (e.g., many-valued) logic. Here the formulas "A" and "A *implies* B" may be only partially true—how then are we to compute a truth-value for B? We need to define a "detachment operator" which lets us combine the truth-values of "A" and "A *implies* B" in some way to arrive at an estimate of the truth-value of B. The importance of the selection of this operator, which is discussed more fully in Goguen,[7] Kling,[9] and LeFaivre,[13] can be illustrated by the following example.

A paradox

Consider the following two premises:

(1) 1 is a small integer.
(2) If n is a small integer, then $n+1$ is still a small integer.

Certainly these seem to be reasonable statements. We would all agree that 1 is a small integer, and surely adding 1 to a small integer doesn't magically make it not small. But given these two innocent premises, we are able to prove by an appropriate number of applications of the rule of detachment that *any* positive integer N is small. This deduction is an example of the classic "paradox of the heap" discussed by Black[2] and Goguen,[7] and illustrates one of the major shortcomings of classical logic. The problem, of course, is that the set of "small integers" is not sharply defined—we have attempted to impose the laws of classical logic on a nonclassical (i.e., fuzzy) problem.

Paradox resolved

We can make use of fuzzy detachment to resolve the above "paradox" by noting that the result of adding 1 to a small integer, while still small, is not *quite* as small as it was before. In other words, premise (2) above is not quite true—let us say that it has a truth-value of 0.99. If we assume that the truth-value of (1) is 1.0, and we use multiplication for our detachment operator, it is trivial to show that the truth-value of the statement "N is small" is 0.99^{N-1}, which is an intuitively satisfying result. Hence, the "paradox" of classical logic becomes a valid deduction when formulated in many-valued logic. Let us now consider how such a problem might be represented in FUZZY.

PROCEDURAL REPRESENTATION IN FUZZY

We saw in the preceding section an example of a problem in which a multiplicative combination of truth-values led to a satisfactory representation of a simple fuzzy deduction. It is natural to ask whether we wish to *always* combine truth-values multiplicatively. The answer seems to be no. For example, the theory of fuzzy sets makes use of the minimum and maximum for various numeric computations, and one can envision situations where the sum or average might be desired. The point is that a fuzzy problem-solving system must not force decisions of this type upon the user, but should make it easy for him to experiment with a variety of forms of control.

Global control

The issue being discussed here might be characterized as the amount of *global control* a procedure exercises over its local computations. For example, most conventional programming languages (FORTRAN, LISP) exercise no global control—all decisions (e.g., when to exit from a function) are made at the local level by statements within the procedure. On the other hand, MICRO-PLANNER[21] monitors the execution of its procedures (theorems), looking for statements which fail (return NIL) and taking some global action (backtracking) when necessary. We are faced with the question of what form of global control (if any) should be built into a FUZZY procedure. Consider a typical example: we want a procedure to succeed only if each of its local expressions succeeds with a Z-value above some threshold value. Now, this could of course be done using only local control—by inserting tests of the Z-value of each expression into the procedure—but this would clutter up the routine with rather uninteresting and repetitive local computations, obscuring its overall structure. In addition, each procedure requiring this particular global control regime would have to have the necessary local computations built in—a clearly inelegant solution. We would like to be able to simply specify the threshold value and have the

* (MORTAL ?X) acts as the *pattern* of the given procedure, which will be matched against the requested assertion in the DEDUCE statement; the sub-pattern ?X will match anything (in this case SOCRATES), binding the item matched to the variable X; !X is then used to retrieve the matched value.

system perform the necessary manipulations:

```
(PROC THRESH: ⟨n⟩ ⟨pattern⟩ ⟨e1⟩ ⟨e2⟩ . . .)
```

A fixed procedure mechanism of this form would be the FUZZY equivalent of the simple control present in MICRO-PLANNER theorems. However, as mentioned earlier, there may be other forms of global control which might be desirable—for example: ignore all failures; succeed only if at least ⟨n⟩ of the statements succeed; succeed only if some *function* of the individual Z-values exceeds a threshold (e.g., a threshold operator); return as a Z-value the minimum (maximum, sum, product) of the individual Z-values encountered; etc. FUZZY procedures allow all of these forms of global control (and more) via the specification of *procedure demons.*

Procedure demons

A procedure demon is a LISP function which is associated with a procedure, and which is given control after each expression of the procedure is evaluated. The demon is passed the result of the evaluation, the threshold value associated with the procedure, and an "accumulated Z-value" which may be dynamically computed by the demon. When the procedure is exited the demon is called one last time with a value of DONE in order to make any necessary final computations (e.g., computing an average). For example, consider the case of succeeding only if all of the expressions in a procedure succeed with a Z-value above some threshold, keeping track of the minimum Z-value encountered. A procedure demon which exercises this form of global control might be defined as follows (this is in fact FUZZY's standard default demon):

```
(DE *DEMON (V TH AC)
           (COND [(EQ V FAIL) (FAIL)]
                 [(EQ V DONE) AC]
                 [(LT (ZVAL V) TH)
                   (FAIL)]
                 [T (MIN (ZVAL V) AC)]))
```

The value returned by a procedure demon is saved by the system and becomes the new accumulated Z-value upon the next call to the demon. Thus in addition to checking for statements which fail or fall below the threshold (and causing the procedure to fail if one is found), *DEMON keeps track of the lowest Z-value encountered, as desired. The final accumulated Z-value (i.e., the value returned by the demon after it is passed DONE) is returned as the Z-value portion of the procedure result. A procedure which uses *DEMON might be defined as follows:

```
(PROC DEMON: *DEMON THRESH: 0.5
        ACCUM: 1.0 . . .)
```

This indicates that the demon for this procedure is *DEMON, the threshold value is 0.5, and the initial accumulated Z-value is 1.0 (i.e., this is the value used the first time the demon is called after entering the procedure). The DEMON:, THRESH:, and ACCUM: fields are all optional, with default values of *DEMON, ZLOW, and ZHIGH, respectively, assumed.

If a procedure demon of NIL is specified, no demon calls are made (i.e., the procedure is evaluated in a manner similar to a LISP PROG, with only local control allowed). Other procedure demons may be written by the user to specify unique forms of global control (see Reference 13). The motivation behind the procedure demon mechanism is that once a library of frequently-used procedure demons is built up, the user may easily specify a variety of global control regimes. He is thus relieved of much of the "dirty work" of directly manipulating Z-values in the programs he writes. Indeed, in many cases the user need not even be aware that he is working with fuzzy information.

Paradox revisited

Recall the "paradox" of the small integers discussed earlier. Let us briefly examine the issue of fuzzy detachment in FUZZY by showing how the procedural mechanism just described can be used to represent this problem. We first define a procedure demon DETACH which represents the (multiplicative) detachment operator:

```
(DE DETACH (V TH AC)
           (COND [(EQ V FAIL) (FAIL)]
                 [(EQ V DONE) AC]
                 [T (TIMES TH (ZVAL
                   V))]))
```

We then add the two premises to the data base. As usual, the implication "if n is small then $n+1$ is small" is expressed as a deduce procedure which utilizes backward chaining:

```
(ADD (SMALL 1))
(ADD DEDUCE:
(PROC DEMON: DETACH THRESH: 0.99
      (SMALL ?N)
      (GOAL (SMALL &(SUB1 !N))) ))
```

(The prefix "&" acts as a LISP evaluation operator). A request like:

```
(DEDUCE (SMALL 20))
```

would then cause the proper Z-value (0.99^{19}) to be computed.

Note that all of the Z-value manipulations are carried out by the procedure demon. Except for the specification of a non-standard demon and a threshold value, which in this case is analogous to the truth-value of the deduce procedure, the representation of a fuzzy deductive argument is identical to the non-fuzzy example shown previously.

CONCLUSION

One of the major goals of artificial intelligence research is the search for powerful and efficient representations of knowledge. Certain types of knowledge are adequately represented in traditional forms, e.g., as strings, arrays, or lists. In other situations net structures which are accessed associatively seem to provide more power and flexibility. In recent years it has become apparent that much knowledge is of sufficient complexity to be best represented procedurally. Recent advances in language design have provided powerful new tools which allow knowledge represented in a variety of declarative and procedural forms to be integrated in a natural manner. The research reported here was concerned with extending these representational tools in yet another dimension—toward the efficient representation and utilization of knowledge which is imprecise and uncertain in nature.

It is clear that we are a long way from being able to represent and utilize the full range of non-symbolic knowledge available to the human problem-solver in his natural reasoning processes. In the past year, however, a new representational synthesis has begun to emerge among artificial intelligence researchers (e.g., see Minsky,[17] Kuipers,[10] Winograd,[22]), although its exact nature is not yet clear. It remains to be seen what direction the search for fuzzy representations will take in light of this new synthesis.

Subjective Bayesian methods for rule-based inference systems*

by RICHARD O. DUDA, PETER E. HART and NILS J. NILSSON
Stanford Research Institute
Menlo Park, California

ABSTRACT

The general problem of drawing inferences from uncertain or incomplete evidence has invited a variety of technical approaches, some mathematically rigorous and some largely informal and intuitive. Most current inference systems in artificial intelligence have emphasized intuitive methods, because the absence of adequate statistical samples forces a reliance on the subjective judgment of human experts. We describe in this paper a subjective Bayesian inference method that realizes some of the advantages of both formal and informal approaches. Of particular interest are the modifications needed to deal with the inconsistencies usually found in collections of subjective statements.

INTRODUCTION

One of the characteristics of human reasoning is the ability to form useful judgments from uncertain and incomplete evidence. This ability is not only needed for everyday activities, which people would normally never formalize, but also for tasks such as medical diagnosis or securities analysis, which have been subjected to formal treatment.

Because the general need to form judgments from incomplete data is so widespread, many techniques have been developed to aid or supplant people in this task. Probability theory and statistics provide a powerful framework for dealing with many inference problems.[1,2] In standard approaches, the link between alternative hypotheses and relevant evidence is represented by conditional or joint probabilities that are estimated from statistical samples. If the number of alternative hypotheses and the amount of relevant evidence are not too great, and if the available sample is sufficiently large, then probability and statistics furnish the preferred analytical tools. However, when many kinds of evidence simultaneously bear on an hypothesis, traditional statistical approaches become inappropriate because estimation problems become unmanageable.

Recent work in artificial intelligence has suggested other approaches to the problem of resolving hypotheses on the basis of a mass of uncertain evidence. Among the most attractive are *rule-based systems,* which use a large body of *inference rules,* supplied by experts, to provide the knowledge needed to distinguish among competing hypotheses.[3-6] Each inference rule defines the role of a particular set of evidence in resolving a particular hypothesis. Typically, an ad hoc scoring function is used to combine the effects of collections of uncertain evidence acting through several inference rules on the same hypothesis. Thus, rule-based systems attempt to substitute judgments distilled from long experience for joint probabilities estimated from prohibitively large samples.

Our purpose in this paper is to describe a subjective Bayesian technique that can be used in place of ad hoc scoring functions in rule-based inference systems. Our intent is to retain insofar as possible the well-understood methods of probability theory, introducing only those modifications needed because we are dealing with networks of subjective inference rules. The scope of the paper is limited; we shall not discuss here the more general issues of representation and control that must be faced when designing a complete rule-based inference system.

FUNDAMENTALS

In a rule-based inference system, the rules are typically of the form

$$\textit{If } E_1 \textit{ and } E_2 \textit{ and } \ldots \textit{ and } E_n \quad \textit{then } H$$

where E_i $(i=1 \ldots n)$ is the i^th^ piece of evidence and H is an hypothesis suggested by the evidence. Each inference rule has a certain *strength* measured by parameters that will be defined later. For now it suffices to say that the greater the strength, the greater is the power of the evidence to confirm the hypothesis. In most applications, the rules and their strengths are provided by carefully interviewing experts.

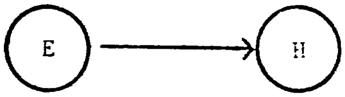
The individual pieces of evidence (the E_i) and the hypothesis (H) of a rule are propositional statements. Instead of being either absolutely true or false, the truth values of these propositional statements may be

* The work reported herein was supported by the Advanced Research Projects Agency of the Department of Defense under Contract DAHC04-75-C-0005.

uncertain. In this paper we shall represent these uncertainties by probabilities, so that associated with each propositional statement is a corresponding probability value.

To simplify matters, we shall assume (without loss of generality) that each rule has only a single propositional statement as evidence on its left-hand side. To reduce a conjunction to a single statement, we need a method for computing the joint probability, $P(E_1, \ldots, E_n)$ from the individual probabilities $P(E_i)$. Two simple alternatives are to assume independence of the E_i or to use the fuzzy set computation $P(E_1, \ldots, E_n) = \min P(E_i)$. More generally, the left-hand side of a rule could contain an arbitrary logical expression, E. The results of this paper do not depend on how the probability of E is computed.

We represent a rule of the form "*if* E *then* H" graphically by the following structure:



Here a propositional statement is being represented as a node, and an inference rule is being represented as an arc. A collection of rules about some specific subject area invariably uses the same pieces of evidence to imply several different hypotheses. It also frequently happens that several alternative pieces of evidence imply the same hypothesis. Furthermore, there are often chains of evidences and hypotheses. For these reasons it is natural to represent a collection of rules as a graph structure or *inference net.*

An example of an inference net is shown in Figure 1.

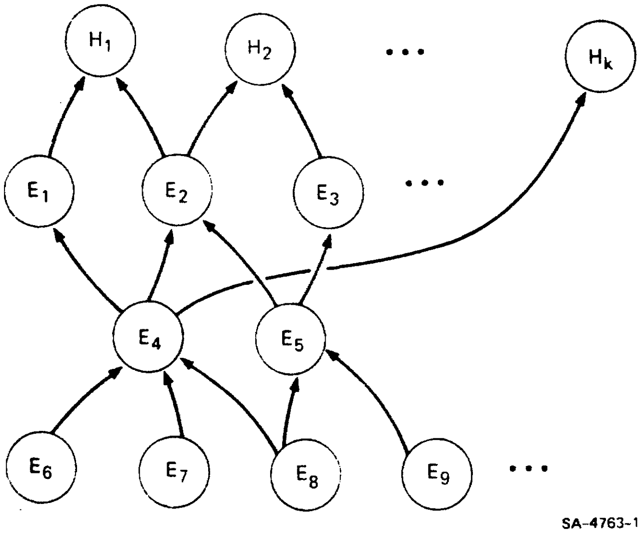


Figure 1—A simple inference net

The H_i at the top of the net are alternative hypotheses to be resolved. Each arc entering a node represents an inference rule and has associated with it a strength. Notice that a typical intermediate node like E_5 can play two roles: it provides supporting evidence for the nodes above it (E_2 and E_3), and it acts as an hypothesis to be resolved by evidence below it (E_8 and E_9).

The main problem to be considered in this paper concerns the propagation of probabilities through the net. Suppose for example, that a user of the net provides evidence by deciding that the probability of a node, say E_6, should be changed from its prior value to some new value. Obviously this should require updating of the probability of E_4 and, in turn, E_1, E_2, and H_k, and so on. Any mechanism used for propagating probabilities must be able to cope with a number of problems. The rules have uncertainty associated with them, and the evidence provided by a user may be uncertain. These two different kinds of uncertainty must somehow be combined. Multiple evidence typically bears on a single hypothesis, so that some form of independence must usually be assumed. Finally, the rules are provided subjectively by experts, so certain kinds of inconsistencies arise that can seriously jeopardize success. In the following sections we suggest a Bayesian updating scheme that addresses these concerns.

SUBJECTIVE BAYESIAN UPDATING

Suppose we are given a rule *if* E, *then* H. Let us begin with the simplified problem of updating the probability of H given its prior value and given that E is observed to be true. By Bayes rule, we have

$$P(H|E) = \frac{P(E|H)P(H)}{P(E)}. \tag{1}$$

For our purposes, a more convenient form of Bayes rule is arrived at by writing the complementary form for the negation of H

$$P(\bar{H}|E) = \frac{P(E|\bar{H})P(\bar{H})}{P(E)}, \tag{2}$$

and dividing Eq. (1) by Eq. (2) to obtain

$$\frac{P(H|E)}{P(\bar{H}|E)} = \frac{P(E|H)}{P(E|\bar{H})} \frac{P(H)}{P(\bar{H})}. \tag{3}$$

Each of the three terms in this equation has a traditional interpretation. We define the *prior odds* on H to be

$$O(H) = \frac{P(H)}{P(\bar{H})} = \frac{P(H)}{1-P(H)} \tag{4}$$

and the *posterior odds* to be

$$O(H|E) = \frac{P(H|E)}{P(\bar{H}|E)} = \frac{P(H|E)}{1-P(H|E)}. \tag{5}$$

Now the *likelihood ratio* is defined by

$$\lambda = \frac{P(E|H)}{P(E|\bar{H})}, \tag{6}$$

so Eq. 3 becomes the *odds-likelihood* formulation of Bayes rule:

$$O(H|E)=\lambda O(H). \qquad (7)$$

This equation tells us how to update the odds on H given the observation of E. For rule-based inference systems, we assume that a human expert has given the rule and has provided the likelihood ratio λ to indicate the "strength" of the rule. A high value of $\lambda (\lambda \gg 1)$ represents, roughly speaking, the fact that E is sufficient for H, since the observation that E is true will transform indifferent prior odds on H into heavy posterior odds in favor of H. Notice, incidentally, that the underlying probabilities can be recovered from their odds by the simple formula

$$P=\frac{O}{O+1}, \qquad (8)$$

so that the odds and the probabilities give exactly the same information.

Suppose now that we wish to update the odds on H given that E is observed to be false. In a strictly analogous fashion, we write.

$$O(H|\bar{E})=\bar{\lambda}O(H), \qquad (9)$$

where we define λ by

$$\lambda=\frac{P(\bar{E}|H)}{P(\bar{E}|H)}=\frac{1-P(E|H)}{1-P(E|\bar{H})}. \qquad (10)$$

Notice that $\bar{\lambda}$ must also be provided by the human expert; it cannot be derived from λ. A low value of $\bar{\lambda}$, $(0 \leq \bar{\lambda} \ll 1)$ represents, roughly speaking, the fact that E is necessary for H, since the observation that E is false will by Eq. 9 transform indifferent prior odds on H into odds heavily against H. Curiously, although λ and $\bar{\lambda}$ must be separately provided by the expert, they are not completely independent of each other. In particular, Eqs. (6) and (10) yield

$$\bar{\lambda}=\frac{1-\lambda P(E|\bar{H})}{1-P(E|\bar{H})}, \qquad (11)$$

so that, if we exclude the extreme cases of $P(E|\bar{H})$ being either 0 or 1, we see that $\lambda>1$ implies $\bar{\lambda}<1$, and $\lambda<1$ implies $\bar{\lambda}>1$. Further, we have $\lambda=1$ if and only if $\bar{\lambda}=1$. This means that if the expert gives a rule such that the presence of E enhances the odds on H (i.e., $\lambda>1$), he should also tell us that the absence of E depresses the odds on H (i.e., $\bar{\lambda}<1$). To some extent, this mathematical requirement does violence to intuition. People who work with rule-based inference systems are commonly told by experts that "The presence of E enhances the odds on H, but the absence of E has no significance." In other words, the expert says that $\lambda>1$, but $\bar{\lambda}=1$. Subsequently, we shall suggest some modifications that address this and other problems of inconsistency.

We note in passing that knowledge of both λ and $\bar{\lambda}$ is equivalent to knowledge of both $P(E|H)$ and $P(E|\bar{H})$. Indeed, it follows at once from Eqs. (6) and (10) that

$$P(E|H)=\lambda\frac{1-\bar{\lambda}}{\lambda-\bar{\lambda}} \qquad (12)$$

and

$$P(E|\bar{H})=\frac{1-\bar{\lambda}}{\lambda-\bar{\lambda}} \qquad (13)$$

Thus, whether the expert should be asked to provide λ and λ, $P(E|H)$ and $P(E|H)$, or, indeed, some other equivalent information is a psychological rather than a mathematical question.[7]

UNCERTAIN EVIDENCE AND THE PROBLEM OF PRIOR PROBABILITIES

Having seen how to update the probability of an hypothesis when the evidence is known to be either certainly true or certainly false, let us consider now how updating should proceed when the user of the system is uncertain. We begin by assuming that when a user says "I am 70 percent certain that E is true," he means that $P(E|\text{ relevant observations})=.7$. We designate by E′ the relevant observations that he makes, and simply write $P(E|E')$ for the user's response.

We now need to obtain an expression for $P(H|E')$. Formally,

$$\begin{aligned} P(H|E') &= P(H,E|E')+P(H,\bar{E}|E') \\ &= P(H|E,E')P(E|E') \\ &\quad +P(H|\bar{E},E')P(\bar{E}|E'). \end{aligned} \qquad (14)$$

We make the reasonable assumption that if we *know* E to be true (or false), then the observations E′ relevant to E provide no further information about H. With this assumption, Eq. (14) becomes

$$P(H|E')=P(H|E)P(E|E')+P(H|\bar{E})P(\bar{E}|E'). \qquad (15)$$

Here $P(H|E)$ and $P(H|\bar{E})$ are obtained directly from Bayes rule, i.e., from Eq. (7) and Eq. (9), respectively.

If the user is certain that E is true, then $P(H|E')=P(H|E)$. If the user is certain that E is false, then $P(H|E')=P(H|\bar{E})$. In general, Eq. (15) gives $P(H|E')$ as a linear interpolation between these two extreme cases. In particular, note that if $P(E|E')=P(E)$ then $P(H|E')=P(H)$. This has the simple interpretation that if the evidence E′ is no better than a priori knowledge, then application of the rule leaves the probability of H unchanged.

In a pure Bayesian formulation, Eq. (15) is the solution to the updating question. In practice, however, there are significant difficulties in using this formulation in an inference net. These difficulties stem from a combination of the classical Bayesian dilemma over prior probabilities and the use of subjective probabilities.

To appreciate the difficulty, consider again a typical pair of nodes E and H embedded in an inference net. It is apparent from Eqs. (7) and (9) that the updating procedure depends on the availability of the prior odds

O(H). Thus, although we have not emphasized the point until now, we see that the expert must be depended upon to provide the prior odds as well as λ and $\bar{\lambda}$ when the inference rule is given. On the other hand, recall our earlier observation that E also acts as an hypothesis to be resolved by the nodes below it in the net. Thus, the expert must also provide prior odds on E. If all of these quantities were specified consistently, then the situation would be as represented in Figure 2. The straight line plotted is simply Eq. (15), and shows the interpolation noted above. In particular, note that if the user asserts that $P(E|E')=P(E)$, then the updated probability is $P(H|E')=P(H)$. In other words, if the user provides no new evidence, then the probability of H remains unchanged.

In the practical case, unfortunately, the subjectively obtained prior probabilities are virtually certain to be inconsistent, and the situation becomes as shown in Figure 3. Note that P(E), the prior probability provided by the expert, is different from $P_c(E)$, the probability consistent with P(H). Here, if the user provides no new evidence—i.e., if $P(E|E')=P(E)$—then the formal Bayesian updating scheme will substantially change the probability of H from its prior value P(H). Furthermore, for the case shown in Figure 3, if the user asserts that E is true with a probability $P(E|E')$ lying in the interval between P(E) and $P_c(E)$, then the updated probability $P(H|E')$ will be less than P(H). Thus, we have here an example of a rule intended to increase the probability of H if E is found to be true, but which turns out to have the opposite effect. This type of error can be compounded as probabilities are propagated through the net.

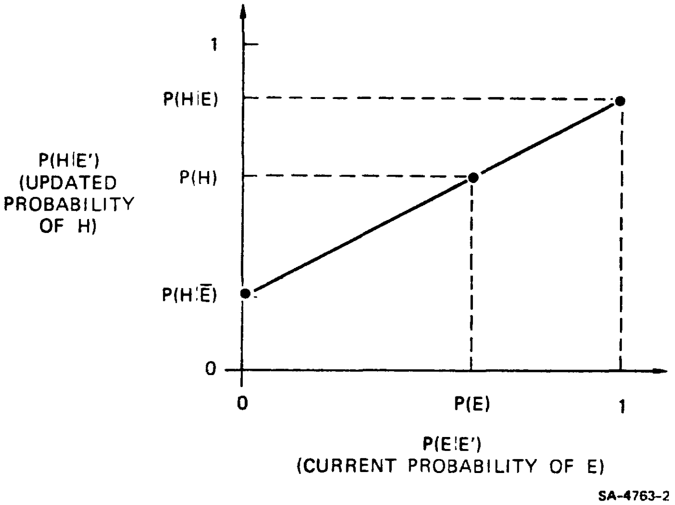

Figure 2—Idealized updating of $P(H|E')$

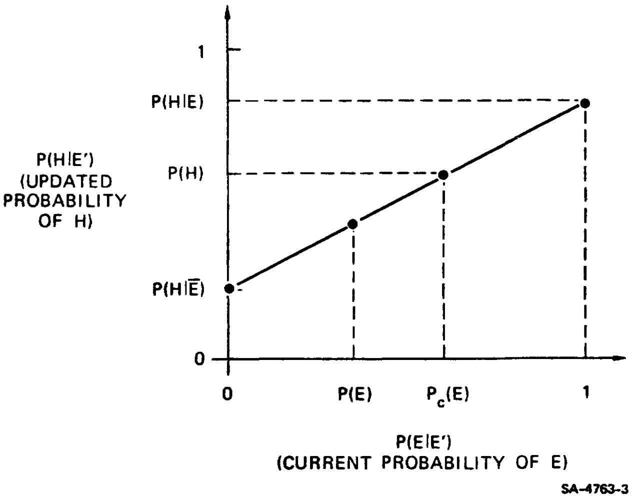

Figure 3—Inconsistent priors

Several measures can be taken to correct the unfortunate effects of priors that are inconsistent with inference rules. Since the problem can be thought of as one of overspecification, one approach would be to relax the specification of whatever quantities are subjectively least certain. For example, if the subjective specification of P(E) were least certain (in the expert's opinion), then we might set $P(E)=P_c(E)$. This approach leads to difficulties because the pair of nodes E and H under consideration are embedded in a large net. For example, in Figure 1, we might be considering node E_2 as the hypothesis H, and node E_5 as the evidence E. If we were to establish a prior probability $P(E_5)$ to be consistent with $P(E_2)$, we would simultaneously make $P(E_5)$ inconsistent with the priors on E_8 and E_9, which provide supporting evidence for E_5. Prior probabilities can therefore not be forced into consistency on the basis of the local structure of the inference net; apparently, a more global process—perhaps a relaxation process—would be required.

A second alternative for achieving consistency would be to adjust the linear interpolation function shown in Figure 3. There are several possibilities, one of which is illustrated in Figure 4a. The linear function has been broken into a piecewise linear function at the coordinates of the prior probabilities, forcing consistent updating of the probability of H given E′. Two other possibilities are shown in Figures 4b and 4c. In Figure 4b we have introduced a dead zone over the interval between the specified prior probability P(E) and the consistent prior $P_c(E)$. Intuitively, the argument in support of this consistent interpolation function is that if the user cannot give a response outside this interval, then he is not sufficiently certain of his response to warrant any change in the probability of H. Figure 4c shows another possibility, motivated by the earlier observation that experts often give rules of the form "The presence of E enhances the odds on H, but the absence of E has no significance." By keeping $P(H|E')$ equal to P(H) when $P(E|E')$ is less than P(E) we are

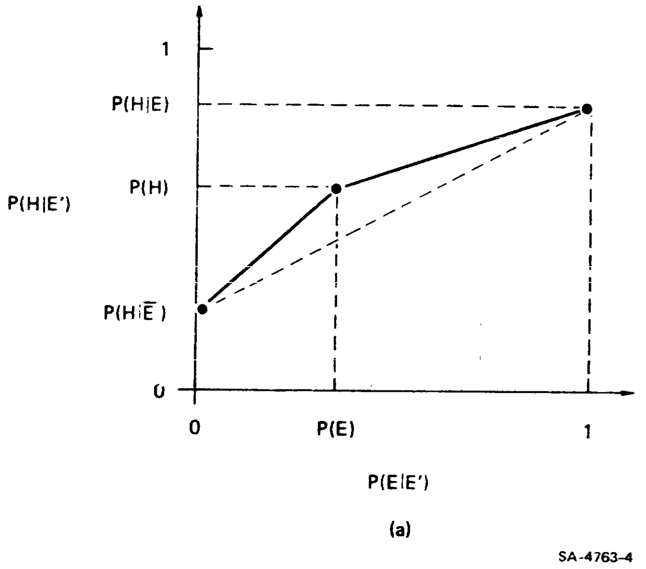

Figure 4(a)—Consistent interpolation functions

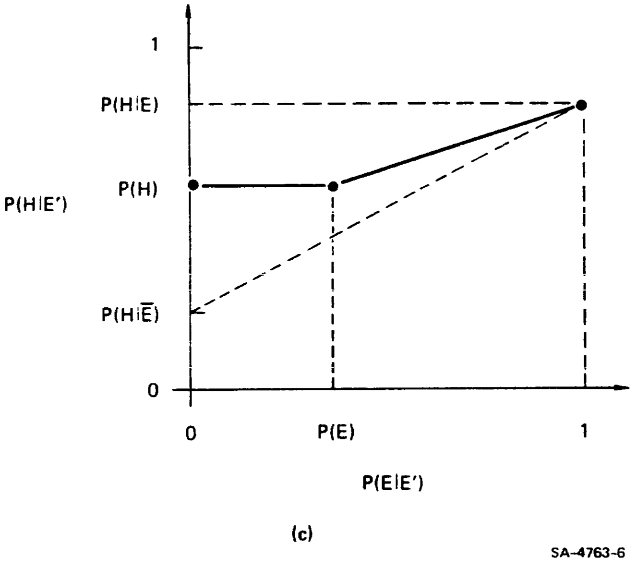

Figure 4(c)—Consistent interpolation functions (concluded)

effectively allowing the forbidden situation where $\lambda > 1$ and $\bar{\lambda} = 1$. In effect, this is equivalent to the method illustrated in Figure 4a under the assumption that $P(H|\bar{E}) = P(H)$.

It is interesting to compare these modifications with the procedure used by Shortliffe to handle uncertain evidence in the MYCIN system.[4,5] While the nonlinear equations that result from use of Shortliffe's version of confirmation theory prevent a general comparison, it is possible to express his procedure in our terms for the special case of a single rule. The result for the case in which the presence of E supports H is shown in Figure 5. Clearly, the solution is identical to that of Figure 4c except for the interval from P(E) to $P_t(E)$ within which Shortliffe's solution maintains $P(H|E')$ at the a priori value P(H).

The graphical representations in Figures 2 through 4 provide a nice vehicle for visualizing the discrepancies between formal and subjective Bayesian updating, and make it easy to invent other alternatives for reconciling inconsistencies. For completeness, the Appendix contains the easily computable algebraic representa-

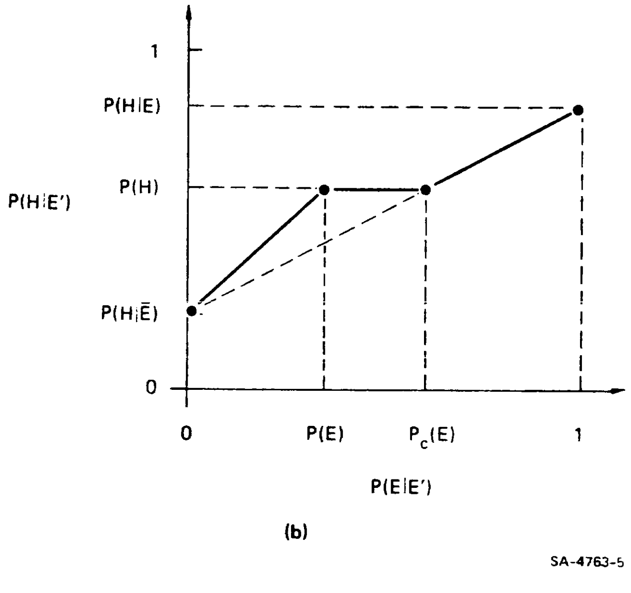

Figure 4(b)—Consistent interpolation functions (continued)

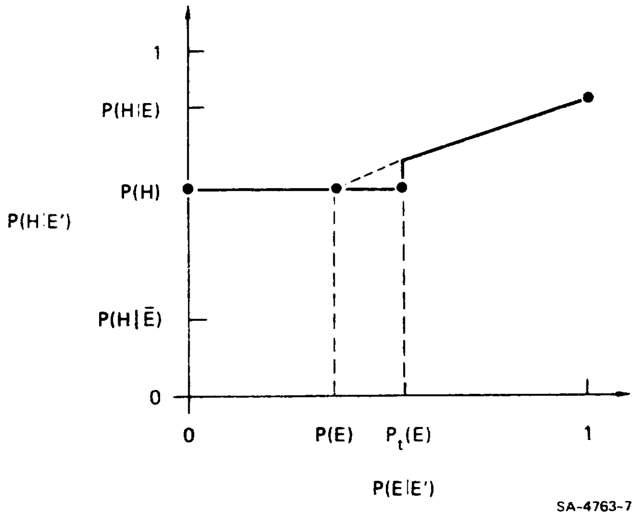

Figure 5—The interpolation function used in the mycin system $P_t(E) = P(E) + t[1 - P(E)]$. Typically, t=0.2.

tions of these functions, and also treats the complementary case in which the straight line given by Eq. (15) has a negative slope (the case in which $\lambda<\bar{\lambda}$). In a small experimental system, the function shown in Figure 4a has given satisfactory preliminary results.[5]

THE USE OF MULTIPLE EVIDENCE

We turn now to the more general updating problem in which several rules of the form $E_1 \rightarrow H, \ldots, E_n \rightarrow H$ all concern the same hypothesis H.* Since most nodes in actual inference nets have several incoming arcs, this is the case of greatest practical interest. In order to gain some insight about how multiple evidence should be used to update H when the evidence is uncertain and the priors are inconsistent, let us first consider briefly how updating would formally proceed in simpler cases.

Suppose the ith inference rule has associated with it the usual two quantities λ_i and $\bar{\lambda}_i$. For a first simple case, how should H be updated when all the E_i have been observed to be certainly true? This case is analogous to the case summarized by Eq. (7). Under the assumption that the pieces of evidence are conditionally independent (i.e., that $P(E_1, \ldots, E_n|H) = \prod_{i=1}^{n} P(E_i|H)$ and that $P(E_1, \ldots, E_n|\bar{H}) = \prod_{i=1}^{n} P(E_i|\bar{H})$), it is not difficult to reach an analogous answer. Specifically, the odds on H are updated by the expression

$$O(H|E_1, \ldots, E_n) = \left[\prod_{i=1}^{n} \lambda_i\right] O(H), \qquad (16)$$

where

$$\lambda_i = \frac{P(E_i|H)}{P(E_i|\bar{H})}. \qquad (17)$$

Similarly, if all the evidence is observed to be certainly false, we can under conditional independence assumptions again factor the joint likelihood ratio to obtain

$$O(H|\bar{E}_1, \ldots, \bar{E}_n) = \left[\prod_{i=1}^{n} \bar{\lambda}_i\right] O(H). \qquad (18)$$

Now let us consider the general case of uncertain evidence and inconsistent prior probabilities. We already know that the posterior odds $O(H|E_i')$ given a single observation E_i' can be computed using updating functions like the ones shown in Figure 4. We can therefore define, for a single inference rule, an effective likelihood ratio λ_i' by

$$\lambda_i' \stackrel{\Delta}{=} \frac{O(H|E_i')}{O(H)}. \qquad (19)$$

By making the assumption now that the E_i' are independent, we can obtain for the general case an expression similar to the simple updating formulas given by Eqs. (16) and (18):

$$O(H|E_1', \ldots, E_n') = \left[\prod_{i=1}^{n} \lambda_i'\right] O(H). \qquad (20)$$

To use this expression in an inference net system, we simply store with each node its prior odds (or probability), and store with each incoming arc an effective likelihood ratio λ_i'. Whenever a piece of evidence provided by the user causes $P(E_i|E_i')$ to be updated, a new effective likelihood ratio is computed and the posterior odds in favor of H is computed using Eq. (20). This procedure has the following consequences:

(1) If no evidence is obtained for a rule, then it will retain an initial effective likelihood ratio of unity, since prior and "posterior" odds are the same.

(2) The order in which evidence is obtained and rules are applied does not affect the final posterior probabilities.

(3) The same rule can be used repeatedly, with the same or different values for the probability of the evidence. In particular, if a user changes his mind and modifies an earlier assertion, the new assertion will correctly "undo" any effects of earlier statements.

CONCLUSIONS

The probability updating procedure presented here has several points to recommend it. It accepts subjective information that can readily be obtained from experts. The two conditional probabilities, $P(E|H)$ and $P(E|\bar{H})$, that determine the strength of an inference rule typically are intuitively meaningful measures, and the procedure is tolerant of the inevitable inconsistencies in subjective expert information. The basis in probability theory of our procedure provides a useful theoretical foundation for calculating the effects of uncertain evidence. One value of theory is that it makes us explicitly aware of certain underlying assumptions about such matters as conditional independence, prior probabilities, and inconsistent information. Finally, our procedure is straightforward computationally and can be readily implemented in inference net systems.

There are, however, some questions that remain to be dealt with. If the network contains multiple paths linking a given piece of evidence to the same hypothesis, the independence assumption is obviously violated. It is important to settle on a reasonable (if ad hoc) modification of our basic procedure that behaves appropriately in such situations. (A more extreme complication would involve being able to avoid the circular reasoning implied by inference nets with loops.)

* This should not be confused with the conjunctive premise mentioned earlier.

There are sometimes cases where some of the nodes in an inference net are related by a constraint not expressed in any given rule. For example, a subset of hypotheses may be mutually exclusive and exhaustive, in which case their probabilities must always sum to one, regardless of their individual values. Such a constraint may be inconsistent with the associated rule strengths given us by the experts. Perhaps a simple expedient, such as renormalization of probability values, can be justified in this case.

We have not addressed here at all issues of inference net control strategy: for example, which hypotheses should be pursued and which evidence should be sought at any step. The answers to these sorts of questions may be heavily dependent on the particular application. Another global question concerns rules containing logical statements that may include quantifiers and variables. But in whatever way these questions are answered, the basic updating procedure presented here would appear to be a useful component of rule-based inference systems.

ACKNOWLEDGMENTS

We have benefited from the comments of many of our colleagues, but would like particularly to acknowledge the contributions of Georgia Sutherland at SRI, and the stimulating and helpful discussions with E. H. Shortliffe, Bruce Buchanan, Randall Davis, and Dana Ludwig at Stanford University. This work was supported by the Advanced Projects Research Agency under Contract DAHCO4-75-C-0005.

APPENDIX

Complete analytical expressions giving $P(H|E')$ as a piecewise linear function of $P(E|E')$ are given in this Appendix. These expressions correspond to the three graphical representations illustrated in Figure 4. The simplest expression corresponds to Figure 4a:

$$P(H|E') = \begin{cases} P(H|\bar{E}) + \dfrac{P(E|E')}{P(E)}[P(H) - P(H|\bar{E})] & O \leq P(E|E') \leq P(E) \\ \dfrac{P(H) - P(H|E)P(E)}{1-P(E)} + P(E|E')\,\dfrac{P(H|E) - P(H)}{1-P(E)} & P(E) \leq P(E|E') \leq 1 \end{cases} \tag{A1}$$

Here it is important to note that the four quantities $P(H)$, $P(E)$, $P(H|E)$, and $P(H|\bar{E})$ are assumed to be estimates obtained from experts. Were the true probabilities to be used in this formula, it would reduce at once to the linear expression given by Eq. (15). The estimates of $P(H|E)$ and $P(H|\bar{E})$ might be obtained directly from an expert, but would more often be obtained through Bayes rule [Eqs. (7) and (9), respectively]. To be explicit,

$$P(H|E) = \frac{P(E|H)P(H)}{[P(E|H) - P(E|\bar{H})]P(H) + P(E|\bar{H})} = \frac{\lambda P(H)}{(\lambda-1)P(H)+1} \tag{A2}$$

and

$$P(H|\bar{E}) = \frac{[1-P(E|H)]P(H)}{[P(E|\bar{H}) - P(E|H)]P(H) + 1 - P(E|\bar{H})} = \frac{\bar{\lambda}P(H)}{(\lambda-1)P(H)+1} \tag{A3}$$

To obtain the equations for Figure 4b, we define $P_c(E)$ by

$$P_c(E) = \frac{P(H) - P(H|\bar{E})}{P(H|E) - P(H|\bar{E})} \tag{A4}$$

In general, this quantity will differ from the $P(E)$ value supplied by the expert. For Figure 4b we must distinguish between the two cases $P(E) \leq P_c(E)$ and $P(E) > P_c(E)$. The equations are as follows:

Case 1: $P(E) \leq P_c(E)$

$$P(H|E) = \begin{cases} P(H|\bar{E}) + \dfrac{P(E|E')}{P(E)}[P(H) - P(H|\bar{E})] & 0 \leq P(E|E') \leq P(E) \\ P(H) & P(E) \leq P(E|E') \leq P_c(E) \\ P(H|\bar{E}) + P(E|E')\,[P(H|E) - P(H|\bar{E})] & P_c(E) \leq P(E|E') \leq 1 \end{cases} \tag{A5}$$

Case 2: $P(E) > P_c(E)$

$$P(H|E') = \begin{cases} P(H|\bar{E}) + P(E|E')\,[P(H|E) - P(H|\bar{E})] & 0 \leq P(E|E') \leq P_c(E) \\ P(H) & P_c(E) \leq P(E|E') \leq P(E) \\ \dfrac{P(H) - P(H|E)P(E)}{1-P(E)} + P(E|E')\dfrac{P(H|E) - P(H)}{1-P(E)} & P(E) \leq P(E|E') \leq 1 \end{cases} \tag{A6}$$

Finally, there are also two cases to be distinguished for Figure 4c. The first case corresponds to assuming that $P(H|\bar{E}) \approx P(H)$, so that $P_c(E) \approx 0$. The second case corresponds to assuming that $P(H|E) \approx P(H)$, so that $P_c(E) \approx 1$. In effect, these cases correspond to the rules $E \xrightarrow{\lambda} H$ and $\bar{E} \xrightarrow{\bar{\lambda}} H$ taken separately. The corresponding equations are special cases of Eqs. (A5) and (A6):

Case 1: $E \xrightarrow{\lambda} H$

$$P(H|E') = \begin{cases} P(H) & 0 \leq P(E|E') \leq P(E) \\ \dfrac{P(H) - P(H|E)P(E)}{1-P(E)} + P(E|E')\,\dfrac{P(H|E) - P(H)}{1-P(E)} & P(E) \leq P(E|E') \leq 1 \end{cases} \tag{A7}$$

Case 2: $\bar{E} \xrightarrow{\bar{\lambda}} H$

$$P(H|E') = \begin{cases} P(H|\bar{E}) + \dfrac{P(E|E')}{P(E)}[P(H) - P(H|\bar{E})] & 0 \leq P(E|E') \leq P(E) \\ P(H) & P(E) \leq P(E|E') \leq 1 \end{cases} \tag{A8}$$

Ordinarily one would view this as a simplified approximation that is useful when one of the two likelihood ratios is dominant. However, it is interesting to observe that if both λ and $\bar{\lambda}$ are significant and if the two separate rules $E \xrightarrow{\lambda} H$ and $\bar{E} \xrightarrow{\bar{\lambda}} H$ are treated as if E and $\bar{E}$ were statistically independent, then Eqs. (A7) and (A8) yield the same result as Eq. (A1). This follows from the fact that when $P(H|E') = P(H)$ we have $O(H|E') = O(H)$, so that Eq. (19) yields $\lambda' = 1$. Thus, if $0 \leq P(E|E') \leq P(E)$ only the rule $\bar{E} \xrightarrow{\bar{\lambda}} H$ contributes to $P(H|E')$, while if $P(E) \leq P(E|E') \leq 1$ only the rule $E \xrightarrow{\lambda} H$ contributes to $P(H|E')$, the contributions being exactly those given in Eq. (A1).
