Preface

by CARL HAMMER
Conference Chairman
Sperry Univac
Washington, DC

This is the second time that I have had the privilege of serving the computing community by assuming a role of major responsibility in a National Computer Conference. Dr. Harvey Garner, General Chairman of the First National Computer Conference, asked me in the fall of 1972 to manage the Science and Technology Program for "his" '73 NCC in New York. Three years later, during the Nation's Bicentennial Year, I have returned to serve as Conference Chairman of "my own" '76 NCC.

This conference was carefully planned as a profound educational experience for all in attendance. We used an innovative approach throughout to make it a Landmark Event long to be remembered. Our programmatic activities include many unusual events such as hands-on demonstrations in computer networking, student computer projects from all over the country, computer graphics art exhibits from all over the world. We obtained some entirely new materials for our science film theater and we tailored special programs for the convenience of the handicapped.

The preparations for this conference commenced in the fall of 1974. We recruited a talented and dedicated team of professional volunteers to help us plan and manage it. The members of this Conference Steering Committee were our brains—and often also our arms and legs. It was *their* unbounded enthusiasm and *their* unflagging spirit which put this magnificent show on the road. More than once many of them toiled around the clock, or gave up weekends and even holidays. The community owes them much for their dedication to the cause. . . .

The transient nature of even the most successful conferences is not likely ever to change. But some of them, including these National Computer Conferences, make a permanent contribution in terms of the archival records of their Proceedings. Here we capture for posterity the most current reports on recent achievements and new applications, on advances at the frontiers of computer science and technology. We are justifiably proud of this volume which contains the papers that were selected for delivery at this conference. We acknowledge with deeply felt gratitude the leadership role of our program chairman, Dr. Stanley Winkler, who structured this exciting program and who assembled these proceedings. We who worked with him on the colossal task of designing this meaningful and balanced program will never forget this experience which has enriched our lives and strengthened many personal bonds as well.

We have striven to give this conference and these proceedings a quality which is appropriate for the occasion. As our country prepares for her bicentennial celebration we are also observing the hundredth birthday of the telephone without which interactive computing and distributed networks would be inconceivable. We remember with nostalgia the First (Inaugural, one might say) Joint Computer Conference held twenty-five years ago in Philadelphia; hopefully our efforts will be judged worthy of its great tradition and of all past FJCCs, SJCCs and NCCs. Another milestone comes to mind for 1951: During that memorable year the first commercially built computer was delivered to the U. S. Bureau of the

Census. 1776, 1876, 1951 were evidently years in which men of great vision pioneered unforgettable events with much impact. If indeed the "Past is Prologue," we should forever be motivated and inspired by this rich legacy of our nation and the computing profession.

For developing the stimulating materials which comprise these proceedings we are deeply indebted to our stalwart program chairman, Dr. Stanley Winkler. We are grateful to the circa two thousand persons who contributed to this effort by writing or reviewing these papers, or by participating in the program sessions as organizers, discussants and speakers. We thank all Conference Steering Committee members for giving so unstintingly of their time and resources; we also thank their employers or sponsors for allowing them to draw so heavily on their resources. We are also grateful for the support received from the AFIPS staff who most graciously coped with our many idiosyncrasies and scheduling difficulties. Finally, it is a pleasure to acknowledge the guidance we received from the NCC Committee and Board. The names of all who took part in this herculean effort are recorded in this monument to their tenacity and endurance. This was truly a team effort and it was well worth it.

As we commemorate the first twenty-five years of electronic data processing we observe that the introduction of computers into our society has already caused profound changes in everyone's life style. Digital communications today provide public access to the power of computers as readily as the earlier telephone facilitated human dialogue. Global communications systems span the earth as we probe the depths of our solar system and even of the universe. Electronic miniaturization is revolutionizing entire industries and radically new concepts of electronic systems architecture are evolving. Computers have become a new source of power, facilitating the transition from traditional management systems to those of a society which is data and information rich. Yet, as these Proceedings establish so well, we are still at the very threshold of electronic invention and innovation!

As we continue along a path of near-exponential progress—and there is little reason to doubt that we will do so for quite some time—the pervasiveness of electronic systems and their impact on societal structures is bound to exceed our cumulative experience with all earlier technological developments by several orders of magnitude. Whatever one cares to read into such prophecies, human values and the attainable quality of life for all mankind will and must emerge as the ultimate beneficiaries. Perhaps this is the greatest reward which posterity can bestow on us as we place this volume into the public domain. Hopefully the concepts and results espoused herein will help liberate mankind from the self-imposed yokes of rote and drudgery, ushering in a brighter future that knows how to make human use of human beings. . . .

INTRODUCTION

A view of the world of computing as seen at the 1976 National Computer Conference

by STANLEY WINKLER
IBM Corporation
Gaithersburg, Maryland

ABSTRACT

The twenty-fifth anniversary of joint computer conferencing and the bicentennial of the United States of America are celebrated during this 45th in a series of joint conferences. The Conference also commemorates the 25th anniversary of the introduction of commercial computing. The state of the computer profession and industry is mirrored in the conference program and these conference proceedings are a selected distillation of the program. The spirit of the American Revolution is reflected in the attention given to Computers and People in general and Societal Concerns in particular. About one third of the Conference is devoted to Computers and People and the remaining two thirds is divided almost equally between Systems and Science and Technology. The quality, scope and diversity of the papers in this volume, as they represent the state-of-the-art today, augurs well for the future.

INTRODUCTION

June 7, 1976, the opening day of this Conference, is the 200th anniversary of the introduction, by Richard Henry Lee, of the resolution for independence of the United States of America. It is, thus, proper in a bicentennial year that we recognize this connection with the American Revolution, and the dedication to Jefferson provides that recognition. However, in dedicating this volume to the memory of Thomas Jefferson, I also hoped to invoke that fierce spirit of the man who swore eternal hostility against tyranny over the mind of man. As we look at the state of our profession in the mirror of this conference, it is easy to see a maturity in the realm of technological capability. The equivalent maturity in the understanding of social impacts and public policy direction is not so easy to detect. Perhaps it is appropriate to recall the dictum of Norbert Wiener who wrote, ". . . danger to society is not from the machine but from what man makes of it."[1]

During our conference, we celebrate not only the nation's bicentennial, but also the 25 year anniversary of joint conferencing and the 25th anniversary of the introduction of commercial computing. On December 10–12, 1951, a relatively homogenous group met in Philadelphia to discuss the characteristics and performance of ten working, large-scale electronic digital computers. In many ways it was a remarkable meeting as may be seen from the contents of that first proceedings.[2] The Keynote Address for 1951 by W. H. MacWilliams of the Bell Telephone Laboratories is a very interesting sketch of the past, present and future of the computing industry as seen in 1951. The last two papers in that first program were a discussion of the applicability of transistors to digital computation, by J. H. Felker and a forecast of the future by J. W. Forrester. Elsewhere in this volume, Herb Grosch provides us with an highly personal view of that first conference and the succeeding twenty-five years of joint computer conferencing in which he captures the gestalt of these conferences.[2]

The program for this 45th Conference is structured into three areas. Each in a sense is a conference within the conference and each area is further divided into four affinity groupings or tracks. These are shown in the Conference-at-a-Glance which is reproduced here as Figure 1. The program is intended to mirror the current state of our profession and industry and this volume of conference proceedings is a selected distillation of the program.

PAST IS PROLOGUE

As everyone knows, the digital computer did not arrive from outer space in 1951. The story of the steady progression of machines from the Jacquard loom, the Babbage Analytic Engine, the Hollerith Electric Tabulating Machine, the IBM Electronic Multiplier and the ENIAC to present computer systems is familiar. In this volume, Professor Heinz Zemanek recounts the less known tale of pre-computer history in Central Europe.[3] The reader will discover that Jacquard had predecessors and that the 1890 Austrian Census used punched cards. This event had been made

PLENARY SESSIONS

The '76 NCC will include four special plenary sessions open to all conference attendees. Each will be held in the Grand Ballroom of the New York Hilton Hotel and will feature major presentations on issues of particular relevance to the computing field, and to concerned members of the business community and the general public.

Keynote Address
Monday, June 7
10:15 a.m.
J. Paul Lyet
Chairman of the Board
Sperry Rand Corporation

International Plenary Session
Monday, June 7
1:15 p m.
Chairman: Bob O. Evans
President
IBM System Communications Division
Session Participants
Professor A. S. Douglas, University of London
Dr. Anatoly A. Dorodnicin, Academician and Director of Computer Systems, USSR Academy of Sciences, Moscow
Dr. Heinz Zemanek, Director of IBM Laboratory, Vienna
Shiro Omata, President, Nippon Univac Kaisha, Ltd., Tokyo

The Computer Profession
Tuesday, June 8
1:15 p.m.
Chairman: Dr. Ruth M. Davis
Director, Institute for Computer Sciences and Technology
National Bureau of Standards
Featuring:
AFIPS Presidential Address
Dr. Anthony Ralston

Public Policy and Computers
Wednesday, June 9
1:15 p.m.
Chairman: Janice C. Lipsen
President, Counselors for Management, Inc.
Featured Address
To be Announced

Figure 1—(Continued)

possible by a remarkable, adopted Austrian engineer, Otto Schaeffler, whose capsule biography is delightful and fascinating. Another fascinating story, and not as well known as it should be, is the history of early computers in Europe. Richard Williams recounts this history with authority and rare candor. Machines were built in Germany, Holland, France, Scandinavia and Great Britain. It is very interesting to learn that the only German commercial computer development was by Konrad Zuse based on the control mechanisms for V1s and V2s. This paper contains many very interesting notes and remarks. Williams pays tribute to the foresight of Eckert and Mauchly in recognizing the business potential of computers. In England, influenced by Professor Hartree's remarks that computers would never be used for business purposes because there would not be enough scientists to run them, commercial use was delayed. During the 1976 Conference, we pay tribute to the development of the ENIAC at the Moore School of Electrical Engineering at the University of Pennsylvania in the Pioneer Day activities, organized this year by Dr. Harvey L. Garner, the director of the Moore School. It is a matter of regret, for the Program Chairman, that papers on the topics to be discussed on Pioneer Day are not available to be included in this volume. Personal accounts of the development of our profession are a valuable part of our heritage.

COMPUTERS AND PEOPLE

This area is introduced by the seminal paper by Professor A. S. Douglas who quite properly points out the necessity of separating Privacy, Confidentiality and Security. This, Professor Douglas does with decisive clarity in his discussion on privacy and data protection procedures in the U.K. Privacy, data security and electronic funds transfer are major societal concerns. Social impacts and technological aspects of these topics are addressed by a group of papers which are included in this volume. These papers are only a sample of the content of the program which expands these topics with panel discussions on policy questions and implementation problems. The program also includes panels on world environment for data processing, welfare payments and the computer, data banks in the federal establishment and data communication policy. The papers published here provide the background for these panel discussions.

The track on the Computer Profession contains papers on education and training, exciting developments in the use of computers to generate Art, and some very intriguing developments in the field of computers and the physically handicapped. The computer has great promise for providing educational and occupational opportunity for the physically handicapped. Clearly there is much good work being done, but equally clearly much more research, development and engineering is needed. A central difficulty is apparently the need both to understand the requirements of the handicapped and the levels of acceptability in equipment developed for them. The paper on a hand-held calculator for the blind reveals what can be accomplished by a combination of imagination and technical skill.

David Ahl organized a very interesting full day on the subject of Public Access to Computers. The three papers on that topic published in this volume give only a glimpse of what is happening. A few years ago the concepts of amateur computing, home constructions of computers and universal access to computer power, would have been dismissed as ludicrous. Today there are thousands of home built and operated computers.

In the track on applications serving people, there are papers in medicine and health care, criminal justice systems and architecture. The variety and versatility of the applications which are described is surprising to one who has been immersed in the development of computer systems. The computer technologist finds it hard to recognize "his" computer in the description of these applications. While we always said that truly remarkable applications would evolve, did we really suspect that they would be so remarkable? One task for the future, in which we must all participate, is to retain a common language through which we can communicate with one another. No Tower of Babel must be allowed to arise.

SYSTEMS

If there is one area in which the difference between the first and the forty-fifth conference is marked, it is in the area of systems. The program for the 1976 conference has 38 sessions in which the participants will examine and explore computer system design, microprocessors, minicomputers, computer system management and planning, computer system performance and evaluation, computer networking in the United States and Europe, word processing and office automation, computer-assisted manufacturing and computer-controlled publication. The evolution of the systems approach and the development of systems has occurred so naturally, that it is hard to recall now how we thought about such things in 1951. The preoccupation was in making the calculators and computers work, and little, if any, thought was spared for system design. Learning to think in terms of systems and implementing system designs is one of the great achievements of the past quarter of a century. Again, only a sampling of what is discussed in the program is printed in this volume, but that sample presents an interesting view of the current state of systems.

The track on Computer Systems begins with a perceptive paper by Margaret Butler. Four generations of computer technology ranged from the vacuum tube (1946) through the transistor (1959) and the integrated circuit (1965) to large-scale intergration (1971). During the same time frame, memory was evolving from the mercury delay line and the electrostatic tube through magnetic cores and plated wires to semi-conductor memories. The paper by Mrs. Butler is an interesting discussion of the development of large-scale computer systems. Another very interesting paper is the 1975 evaluation at the Control Data Corporation of the East German RYAD 1040 system. On the basis of the performance tests reported, there is an apparent lag behind Western technology in processors, memory, and peripheral equipment, but workmanship and reliability were, in general, very good. At the other end of the computer system spectrum is the application of a microprocessor to the handling of bowling scores. Microprocessor systems are being developed which combine low cost, small size and modest power requirements with high operating speed, a high density of logic and flexibility in configuration. It is now hard, if not impossible, to distinguish between a micro and a small mini on the basis of performance. The management of systems now requires greater technological skill as well as an understanding of the basic economic aspects. Quality control of software, reliability, and the evaluation and prediction of performance of computer systems are major management concerns. None of these subjects is simple, but the effective manager must learn to understand them. Improved performance and increased productivity are necessary for profitability.

A special feature of this year's conference is the particular attention paid to Networking. In addition to the ten sessions so ably organized by Ira Cotton and Franklin Kuo, there are also a demonstration of a commercial network and a professional development seminar on Networking. Taken together, these events present an integrated approach to Networking which should be useful to everyone with an interest in the topic. Fifteen papers on Networking and related subjects are printed in this volume. Included among these papers is an extensive review by Frank Martin of the FCC dockets which affect computer communication. Decisions already made by the Commission appear to indicate, if only vaguely, how they will distinguish between communications and data processing. But the issues are not settled and many hearings and court cases will transpire before the issues are settled. A proposed international packet-switched network protocol is discussed in a paper by authors from four countries (Rybcznski, et. al) and Louis Pouzin presents a somewhat different point of view. Network access techniques, network architecture, network design problems, and the measurement of network performance are also treated by papers in this volume. From a laboratory curiosity in 1972 to a commercially available capability in 1976 is an amazingly swift development in which many individuals participated and contributed.

In the business and industry systems, which are described in this volume, the importance and value of computer based systems is clearly indicated. Work processing and office automation, computer-controlled publication, computer-aided design, computers in shipbuilding, air traffic control, and the expanding role of computers in libraries are described in this volume. They are not, themselves, the totality of applications of computers in business and industry but they do represent an impressive sample of such applications. In reviewing these developments, one becomes acutely aware of the maturing of the computer from a scientific toy to a business necessity.

SCIENCE AND TECHNOLOGY

In the area of science and technology, we are in the more traditional realm of the joint computer conference. It is also the area in which one would look for the insights into what the future might bring. If the papers received for this conference are any indication, we are now in a transition period in which older ideas are being consolidated and new ideas have not yet emerged. In computer architecture, there is still much interest in pipeline computers, multiprocessors and in parallel processing. What seems to be lacking is the corresponding system software development. The concept of application oriented computer architecture is intriguing as is the idea of coupling small computers for performance enhancement. Undoubtedly the world-wide economic conditions of the past few years have had a dampening effect. The great interest in data base is reflected in the number of papers on that subject. Relational data bases remain interesting but there are still questions concerning their practicability and efficiency. Both performance and user acceptibility are important considerations. The papers on data base structures and on management information systems show that there are important problems to be solved although considerable progress has been made. Error detection in data bases and integrity aspects of shared data bases are topics that will continue to merit discussion.

In the computer science and application of computer science tracks, an interesting collection of papers appear. There are two fine papers on networks in the Operations Research sense of that term. Computer arithmetic and numerical methods are addressed as well as algorithms for uncertain forms. Cynthia Solomon's case study of a child doing turtle graphics in LOGO was fun to read. The two papers on fuzzy sets by James O. Bezdek and Richard A. LeFaivre, which are part of the session on Approximate Reasoning, seem to represent a future direction for the analysis of computer systems.

REMARKS

Each conference is, to paraphrase Emerson's remark, the lengthening shadow of its participants and attendees. The discussions and debates during the sessions are both the real substance and the ephemeral part of the Conference. In the past, recordings of the sessions have not seemed to capture the vital spirit of the meetings. Thus we are left with the Proceedings as the lasting record of the Conference. For the errors of omission and commission, the Program Chairman must accept responsibility. For what is fine and worthwhile in this volume, credit must be given to the authors and to the reviewers, to the members of the Program Committee and the Program Advisory Committee, and to the Steering Committee. Everyone has contributed in a significant way. There are five individuals without whose dedicated effort, repeatedly given over long hours, this volume would not have been finished. It is with most grateful appreciation that I mention Carl Hammer, who did more than all of us and provided leadership and inspiration as well, Norm Moraff, Lee Danner, Anita Cochran and Nelle Morgan.

Conference maketh a ready man
Or, twenty-five years in the better joints

by HERBERT R. J. GROSCH
Consulting Editor, COMPUTERWORLD
and *Vice President, Association for Computing Machinery*
Sunnyvale, California

ABSTRACT

The author rehearses, with much pleasure, the origins, physical circumstances, personalities, exhibits and papers of the Joint and National Computer Conferences, from December 1951 to the present meeting.

The Joints are no more, at least in name—but long live the NCCs! I suffered the agonies of grim Philadelphia at the very first Joint, not yet named "Eastern." I enjoyed the dubious sunshine of Los Angeles at the first Western, not yet named "Joint." I was on the JCC Board twenty years later, when, hoping to retrieve the big exhibitors of the Sixties, our Industry Advisory Panel told us

> "The time is out of Joint;"

and we replied, each one of us,

> "O cursed spite,
> That ever I was born to set it right"!

And we coined the name, National Computer Conference, to mark the creation of something new, yet old: still joint, but of all the AFIPS societies; no longer Joint, or Western, or Eastern, or Spring, or Fall. And, Disneyland coupon book in hand, I scurried off to the last of the old semiannuals: Fall, 1972.

So I may reasonably claim, I think, to have been as close to the Joints as any man could be, and to all the NCCs so far. (See Table I.)

There are 45 conferences, counting this one, and they stretch over a full quarter century. I attended 35, and would have gone to more except for a long sojourn in Western Europe in the early Sixties.

Recent comers to our trade can hardly imagine the novelty of a computer conference in 1951. The first production computer, a UNIVAC I, had just been delivered to the Census. The most powerful IBM machine in production was the ineffable Card-Programmed Calculator. The Association for Computing Machinery was only four years old, and was years away from its first formal publication series. The IEEE did not yet exist, and the two societies which

Key: CC=Computer Conference, E=Eastern, F=Fall, N=National, S=Spring, W=Western.

later merged to form it did not themselves care much for the miniscule computer activities of the time. The Institute of Radio Engineers had had an Electronic Computer Committee since early 1948, for which I had helped produce a bibliography (a few dozen entries) in 1949, under the direction of Bob Serrell. The American Institute of Electrical Engineers had a Committee on Computing Devices—and analog "devices" were also hot stuff in the Forties and early Fifties.

These two committees in turn appointed, in early 1951, a *joint* committee to arrange a conference. That first JCC met in Philadelphia, the world center of electronic computer activity at the time. The Moore School, the Eckert-Mauchly division of Remington Rand, the proximity to Aberdeen Proving Ground (the largest computer center of that day, with a huge differential analyzer, punched card machines, IBM and Bell Labs relay calculators, and of course ENIAC) and the relative closeness of Washington, all contributed to this judgment. Washington would have been suitable also, and was indeed the site of the third eastern meeting two years later. It was the source of most funding of one-off machines, the purchaser of most production computers, the nexus of enthusiasms for the Defense Calculator, IBM's yet-unannounced scientific computer (called Type 701 from 1952 on). Another main factor in the choice of Philadelphia was that attendees could actually see, feel, smell the equipment—and that excitement led to the exhibit idea, and to the National Computer Conference as we see it today.

In February 1952, delighted with the unexpectedly large attendance (almost a thousand) the committee published with AIEE help the first Joint proceedings. Figure 1 gives the table of contents; note the early appearance of British participants (both Cambridge and Manchester); note Jean Felker's paper on using transistors, then less than three years old; note that monuments such as Howard Aiken's MARK III, Sam Alexander's SEAC, and Jay Forrester's WHIRLWIND I were described. And note the first big drum-dominated 1100-series machine, already at work on cryptographic problems: ". . . the user is not free to talk about his classified applications."

A few last words about origins: there had been a jointly-sponsored meeting on electron tubes for computers in 1950 (Atlantic City, thus setting a horrid precedent), and except perhaps for an early lack of perspective that somewhat smaller gathering could have been labeled the first Joint Conference. And ACM, although interested more in hardware in 1951 than in later years, only "cooperated" in organizing the Philadelphia sessions. The title page of the very first meeting says "Joint AIEE-IRE"; of the second, "Joint AIEE-IRE-ACM"!

Figure 1

I remember rather faintly that hotel arrangements were pretty grim, and that social events were limited to privately-arranged tours to the UNIVAC, to Burroughs, and to the Moore School. I remember vividly buttonholing everybody I knew to tell them how great IBM's new machine was going to be—I was fresh from several months in far Poughkeepsie! I remember John Bennett saying there would be an Australian meeting the next year (and there was!). I remember there were a few senior women professionals present, but none on the committees or program. And I remember being impressed that Charlie Strang, a vice president of Douglas Aircraft, would come all the way from Santa Monica to gray Market Street to tell us a user's story—the only such paper. The weather? I don't remember. Did I bring my wife? No. Did I enjoy it? Well, yes; great stuff about several important new ventures, and hot news from England. But I didn't get to say anything myself!

In those days we read MTAC, "Mathematical Tables and other Aids to Computation," a *very* curious National Research Council publication. It still exists, in a much more esoteric format. Along with errata in printed tables, book reviews of new numerical analysis texts, and the like, the editors reviewed articles on computers and computing, described new machines and acceptance tests, and told about conferences and seminars. In 1952 they gave the program of the Philadelphia meeting, and in 1953 published a six-page review of the Proceedings, by Ed Cannon of the Bureau of Standards. This was the first appearance in the nonengineering literature of the many, many references over the decades, to our formidable conferences.

The second year the show really got on the road, in a manner of speaking. First of all, there were exhibits—and from that, in late 1952, we never receded. Then it traveled: met in New York. And clouds not much larger than a man's hand were visible: a 25 percent gain in attendees, and a Western Liaison subcommittee. Aided by the proximity to Galactic Headquarters at Madison and 57th, the various committees tapped IBM for personnel and other support: I had expected to be involved, although then based in Washington, but was extruded from the Body Economic for general recalcitrance only a few weeks before. This probably accounts for my rather specialized impression of JCC2: Jay Forrester offered me a job at Whirlwind!

Margaret Fox of NBS did most of the program, and there was a paper on SEAC offline input-output gear by Ruth Haueter: first major feminine influence. The whole program, in fact, revolved around peripherals, from magnetic wire(!) and tape equipment to Kimball tags. Paper tape, punched cards, photographic techniques (including a read-only disk), and the ubiquitous line printer all were discussed. And of great interest to me, of course, the first major papers on the IBM 701.

Don Davies, today the top man at the National Physical Laboratory, was a new but welcome visitor. General Electric made an appearance, threatening to build a nonimpact printer. And artificial intelligence, the advisability of standards, and economic modeling were all mentioned—just like 1976!

The scene now shifts to that hotbed of technical computing, Los Angeles. The tin airplane was flourishing, missiles were at least conceivable, and spies had been sent to the East and had reported, notably Harry Huskey and Dick Canning. The joint committee decided to try a western conference. And because the enormous later development of componentry, of peripherals and of systems had not yet flowered, most of the papers concerned applications (Figure 2). Canning had just come down from Mugu, McCann and Morton were pushing hardware at Cal Tech and Berkeley, the Northrop offshoots had incorporated (CRC, later to be a part of National Cash). There were exhibits: I particularly relish the memory of a Telecomputing point plotter that counted the lines on graph paper.

Figure 2

I also relish, perhaps comfortably in view of the dominance of digital ideas today, the comment I made to Arthur Vance, a prominent RCA analog man, that effort should preferably be spent on numerical analysis, and less on stringing "900 integrators on the end of one piece of wire. (Laughter and applause.)" *Plus ça change* . . .

Now that there had been a Western, and a reasonably successful one, the senior conference had to be relabeled. So from that point on, we had *Eastern* Joint Computer Conferences—nine of them, through 1961. And, as the third eastern conference was called "Eastern," so the third one on the Coast would be called "Joint," in 1955.

That first EJCC was held in Washington, still in early winter. I gave the after-luncheon speech, which does *not* read too well almost 23 years later. But the papers do, notably the first conference report on magnetic core memory, first mentions of life insurance "Electronic Data-Processing" and of numerical weather prediction. One of the very earliest interpreters, the Los Alamos SHACO (Short Hand Coding), was described, and discussion of open shop versus closed shop appeared. I remember the former: Allan Benson had worked up a three-address floating point package for the very first 701. And as for the latter, why, I had a great closed shop in Cincinnati and couldn't see why anyone would want the opposite: "it requires more tactful people," said the Los Alemite. What I wanted was core instead of electrostatic memory; *definitely* not tact!

This Washington meeting was keynoted by Howard Engstrom, and his presence was an early link to the National Security Agency. The next Western, two months later, saw some of the bedroom conferences that led to SHARE later that year (1954), and NSA, super-secret though it was, became a charter member.

The Washington meeting was perhaps the last in which *everybody* discussed reliability. There would be dour jokes in the trade for many conferences to come about specific hardware problems: air conditioning, head crashes, and so on, up into modern times. But increasingly there would be concern for software problems; the hardware was working.

There were exhibits, but in the small Statler environment; the day of the giant hall and the gorgeous booth bird had not dawned.

Well, there was one more Western Computer Conference to go, at the Ambassador in Los Angeles—I remember I ran my first major recruiting suite. The exhibit list was getting longer, and space was tight. There was heavy emphasis on control applications: machine tools, chemical processes, and feedback of management information—the earliest MIS discussion group. I was on it, boasting about Stan Rothman's machine shop scheduling work in General Electric.

Sybil Rock, Monty Phister, Herb Mitchell were all flourishing; Harry Huskey had gotten to UCLA, Louis Ridenour was playing his games at International Telemeter. It was a small but golden time.

That December, the Easterners turned back to Philadelphia, and I was program chairman. This was still the era of single sessions, mind you, and of one-man program committees. I chose small digital computers for a subject; tongue-in-cheek, no doubt, Charlie Adams did a keynote that mentioned a fictional giant machine: "Officially the giant brain was the SOCIAC, but . . . around the office it was known as Herbie." Alan Perlis, of all people, did the survey paper. How have the leaves fallen: the IBM 650, the Marchant Miniac, the Alwac! I read the other day there were "several hundred" minicomputer and microprocessor types in current production. In 1954 there were nine. Most were decimal, none were transistorized; one had an early cassette ("magnetic tape capsule").

Software? Not much, although Stan Gill had come over and was sharing his experiences. One 650 customer described an "automatic coding" technique; today we would call it an optimizing interpreter. And in the information retrieval field, one of the earliest appearances of the team of Perry, Berry and Kent, then at Battelle, was also a near-first for that subject at a Joint.

By this time the three sponsoring groups saw they had a Good Thing going, and formalized the joint committee's structure, prescribed the steering committees for the two annual conferences, and set up financial procedures (the surplus was divided equally, and each conference started from scratch, with volunteer workers and a small loan "from each of the sponsors"). Clearly, a machine had started to grind.

The seventh one, the first to be called Western *Joint*, I missed. ACM records say it was at the Statler in Los Angeles, and AFIPS records show 1500 registrants, double the 1953 startup number. There were trips and exhibits, and a big publicity thrust. Don Pendery of IBM was on a panel about common languages. On the other hand, there *was* a lot of analog material on the program, and in the Spring of 1955 I was helping persuade General Electric Syracuse, in the person of the famous W. R. G. Baker, to start its own computer adventure. So, although I had lots of travel money, and a continuing need to recruit—one of the major activities at all early Joints—I passed it up.

The papers list includes Charlie De Carlo and Willis Ware, Newell on chess machines, and Bob Johnson's doctoral thesis. Must have been a good meeting!

By this time SHARE was official, *Fortune* cared about computers, and IBM was delivering 704s. The president of Burroughs, no less, came to Boston for the 1955 EJCC and talked about computers as management tools: not too sensibly, as I remember it, but it flattered us all nevertheless. Indeed, the conference was quite strongly DP oriented; even Tony Oettinger, then a humble instructor at Harvard, did a piece, as did Bob Gregory. There were review papers on information retrieval and on data communications networks. Networks, yet! And I did my first-ever paper on standards; fortunately, it had been forgotten before I was interviewed for the NBS job ten years later! It was followed by a sound—soundly pessimistic—review of magnetic tape standardization problems by Ampex and ElectroData and telephone and government people.

Finally, Jay Forrester in a conference summary referred to computer toys and computer kits and electronic surplus gear, a prevision of the myriad hobby enterprises of LSI 1976.

Space of course doesn't permit a review of every Joint and National; moreover, after the first ten or twelve, media developments make information and impressions more easily available. Many libraries have the later conference proceedings; many libraries and individuals have access to the JCC issues of *Datamation,* which began covering the Joints in 1957. What I therefore will do from 1956 on is to skip along, recalling high points, personal or professional, and relating them to the rapidly developing world outside the three societies and their enterprises.

The 1956 WJCC was held at the Fairmont in San Francisco, beginning a love affair with that town which lasted until the exhibits finally outgrew available space in 1968. Shortly thereafter I moved to Phoenix to help GE enter the field, and was put on the Western Conference Committee. The 1956 EJCC reworked the organizational structure behind the conferences (they were growing at incredible speed), and created a National Joint Computer Committee. It was the existence of these initials, NJCC, for so many years thereafter that militated against adoption of NJCC in 1972, as the initials of the new once-a-year conference and exhibit. The letters "NCC" were chosen instead.

The 1956 conferences, taken together, were dedicated to great projects: BIZMAC, the DATAMATIC 1000, the Univac LARC, and the IBM STRETCH. The first IBM 705 was delivered, tubes and all, to Jack Jones in Atlanta: first time I'd heard of him. The 709, tubes and all, wabbled onto the scene. But in the forefront, in single copies but vastly significant, were the first powerful transistor machines: the MIT TX-0, with 65K words of core, and the Transac S-1000. Oh, and IBM brought out the first disk machine: RAMAC. I remember the latter not so much for its novel appearance but for the fact that the IBM engineer who described the machine actually quoted the rental!

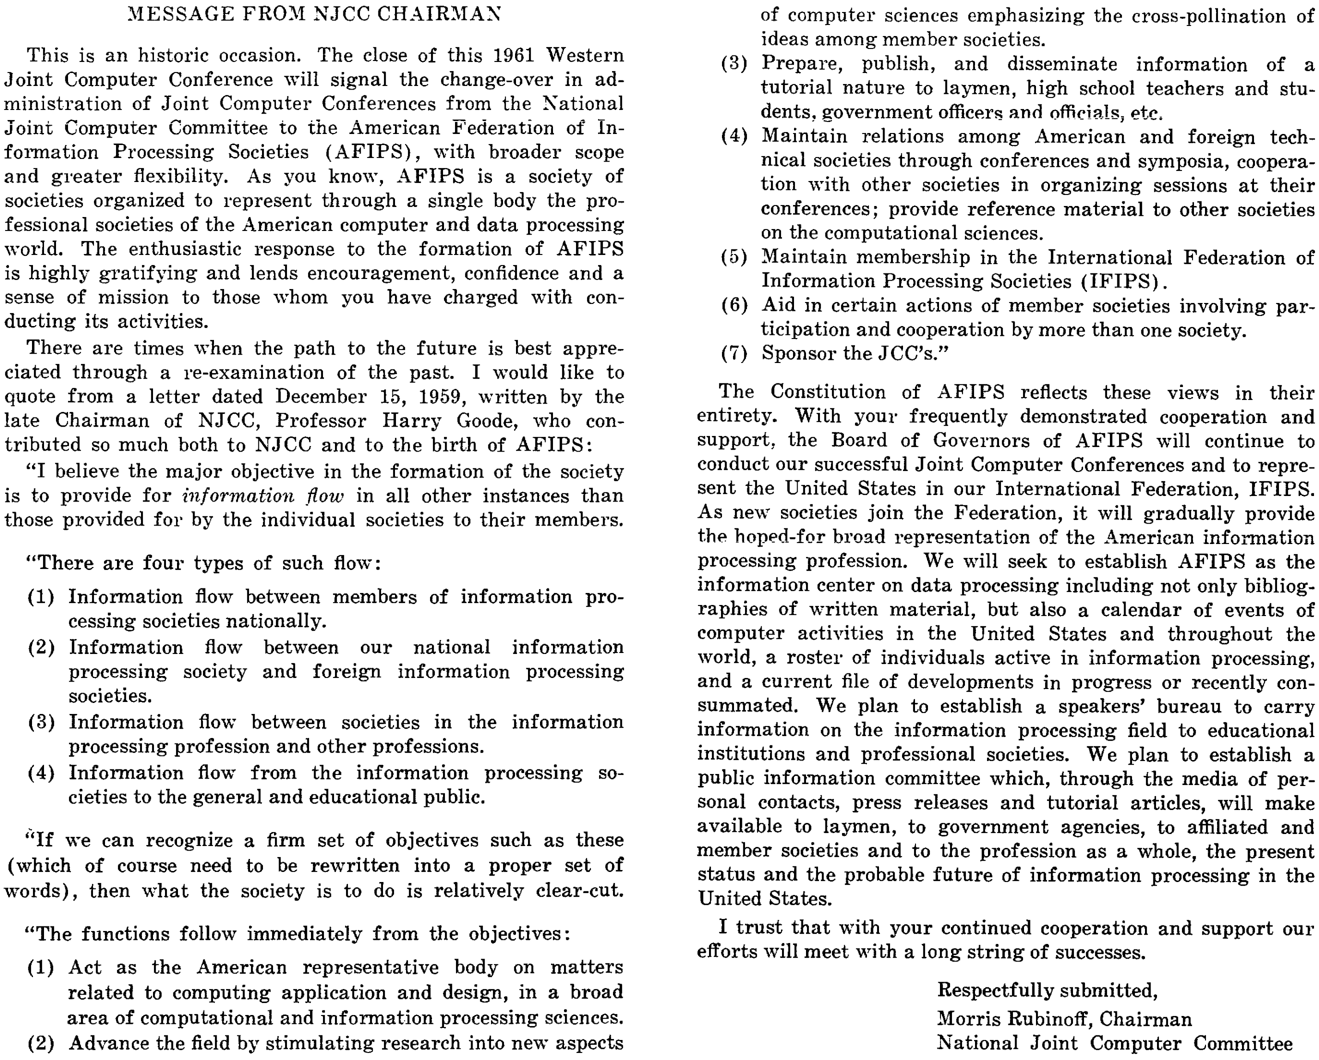
For the 1957 Washington conference I still have my registration receipt: $4.00. Those were simpler times: single sessions, straightforward entries like the Bendix G-15, open scandals like SAGE. For the first time, a fourth organization, the National Simulation Council, shoved its tiny nose into the tent.

In 1958, social implications: a great panel which I remember vividly, with a famous Yale professor, a great union man, and IBM's Cuthbert Hurd (severally identified in the Proceedings as "Nonmember AIEE"!) taking an early look at automation. For the first time, multiple sessions. And for the first time on any continent, the Bull Gamma 60, with Phillippe Dreyfus; I helped him a little. At the session that winter, in Philadelphia again, Heinz Gumin, now the top Siemens man in computers, came over for the first time, and described the 2002. I was more interested at the time, not realizing that I would soon be moving to Europe, in the paper on microprogramming by Maurice Wilkes, by now almost a fixture at the eastern meetings. Also, having served my time in Phoenix, I noted but did not attend the paper on the magnetic-character check handler, ex-ERMA.

Cal Mooers was in great form in San Francisco: information retrieval. And I did the ladies program. Also Charlie Asmus, for many years to follow the key figure in staging the ever-growing exhibits, began major participation at the meeting.

The next vivid memory I have is of EJCC 1960. It was held at the Manhattan Center and the New Yorker Hotel, just before Christmas. And the night before, December 12, it snowed. And snowed. And snowed! Most of the exhibitor trucks, and most of the attendees, missed the first day entirely. I lived in New York that year, and arrived promptly, by subway. It was this near-catastrophe, modulated of course by the several-year lead times now necessitated by the size of the Joints, that led to the changed pattern of the Sixties. From 1951 on, the eastern conferences had been held in December, and in the East the weather was frequently awful. The western conferences had drifted from February, too soon after the EJCCs, to May, when the weather was great everywhere. So in 1962 the old terms "Eastern" and "Western" were abandoned, the conferences were switched, and from that time to the end of the two-a-year Joints, the eastern meeting was held in May or so, and called "Spring," and the western one was held in November, always pleasant in the West, and called "Fall." In order to effect a transition without two meetings in a row on one side of the country or the other, the 1963 SJCC was held in Detroit; I came back from Europe to attend, partly because of the novelty, partly because, living overseas, I had missed three or four Joints in a row, and the friends I saw at them. That was the midpoint conference, in many ways: Number 23. NCC 76 is Number 45.

The next dislocation in the series was a simpler one: there was no Spring Joint in 1965. New York was the site that year of IFIP 65, the second of the triennial international meetings. The zeroth, pre-Federation, had been held at UNESCO in Paris in 1959, and the first, in Munich in 1962. So, preparing to sponsor the 1965 sessions and show, AFIPS gave up one Joint.



MESSAGE FROM NJCC CHAIRMAN

This is an historic occasion. The close of this 1961 Western Joint Computer Conference will signal the change-over in administration of Joint Computer Conferences from the National Joint Computer Committee to the American Federation of Information Processing Societies (AFIPS), with broader scope and greater flexibility. As you know, AFIPS is a society of societies organized to represent through a single body the professional societies of the American computer and data processing world. The enthusiastic response to the formation of AFIPS is highly gratifying and lends encouragement, confidence and a sense of mission to those whom you have charged with conducting its activities.

There are times when the path to the future is best appreciated through a re-examination of the past. I would like to quote from a letter dated December 15, 1959, written by the late Chairman of NJCC, Professor Harry Goode, who contributed so much both to NJCC and to the birth of AFIPS:

"I believe the major objective in the formation of the society is to provide for *information flow* in all other instances than those provided for by the individual societies to their members.

"There are four types of such flow:

(1) Information flow between members of information processing societies nationally.
(2) Information flow between our national information processing society and foreign information processing societies.
(3) Information flow between societies in the information processing profession and other professions.
(4) Information flow from the information processing societies to the general and educational public.

"If we can recognize a firm set of objectives such as these (which of course need to be rewritten into a proper set of words), then what the society is to do is relatively clear-cut.

"The functions follow immediately from the objectives:

(1) Act as the American representative body on matters related to computing application and design, in a broad area of computational and information processing sciences.
(2) Advance the field by stimulating research into new aspects of computer sciences emphasizing the cross-pollination of ideas among member societies.
(3) Prepare, publish, and disseminate information of a tutorial nature to laymen, high school teachers and students, government officers and officials, etc.
(4) Maintain relations among American and foreign technical societies through conferences and symposia, cooperation with other societies in organizing sessions at their conferences; provide reference material to other societies on the computational sciences.
(5) Maintain membership in the International Federation of Information Processing Societies (IFIPS).
(6) Aid in certain actions of member societies involving participation and cooperation by more than one society.
(7) Sponsor the JCC's."

The Constitution of AFIPS reflects these views in their entirety. With your frequently demonstrated cooperation and support, the Board of Governors of AFIPS will continue to conduct our successful Joint Computer Conferences and to represent the United States in our International Federation, IFIPS. As new societies join the Federation, it will gradually provide the hoped-for broad representation of the American information processing profession. We will seek to establish AFIPS as the information center on data processing including not only bibliographies of written material, but also a calendar of events of computer activities in the United States and throughout the world, a roster of individuals active in information processing, and a current file of developments in progress or recently consummated. We plan to establish a speakers' bureau to carry information on the information processing field to educational institutions and professional societies. We plan to establish a public information committee which, through the media of personal contacts, press releases and tutorial articles, will make available to laymen, to government agencies, to affiliated and member societies and to the profession as a whole, the present status and the probable future of information processing in the United States.

I trust that with your continued cooperation and support our efforts will meet with a long string of successes.

Respectfully submitted,
Morris Rubinoff, Chairman
National Joint Computer Committee

Figure 3

Yes, AFIPS; in order to simplify U.S. representation in the International Federation of Information Processing after its formation in 1960, the National Joint Computer Committee had transformed itself into AFIPS (see Figure 3). I had been involved as an ACM representative to the NJCC in 1959 and 1960, but was getting ready to move to Europe at the crucial moment. I remember Walt Bauer was the chairman of the last pre-AFIPS Joint, in May 1961, and that the death of Harry Goode, who had planned the changeover, cast a pall over much of the action.

I attended IFIP in New York as a recent immigrant; Generous Electric had reached out to Lausanne and hauled me back to lovely Santa Barbara just a month or so before. I had missed the first Las Vegas meeting while overseas, and hence doubly relished the 1965 FJCC. It was *huge;* Asmus was in his glory. The town was fun, to one who had been away for some years. The papers were fresh; I especially remember a panel on the overseas market (Norm Ream, Jim Miles and others)—I commented from the floor that it would be safe to let the Russians have big CDC machines, but only if they agreed to take the software too! And there was a great look-ahead panel that opened my eyes to the coming LSI revolution: Rex Rice had just gone to Fairchild.

This was the first Joint to publish its proceedings in two volumes; the San Francisco 1968 holds the record to date, with 3.5 inches of paper and bindings. The first nineteen Joints had paper-covered proceedings; bound library-style, they span ten inches. The volumes from 20 on, which were bound by AFIPS, span 53 inches: already, we have the proverbial five-foot shelf of books!

At the end of 1962, the IRE and the AIEE, founding fathers of the Joint concept, had merged into the

IEEE. The Simulation Council had become a smaller member, so AFIPS continued to have three partners, albeit rather disparate: the simulation people, the computer part of the giant IEEE, and all of ACM.

A horrid thing happened in 1967. Having outgrown all other eastern exhibit facilities, the Joints began meeting in Atlantic City—the SJCCs, that is. Five out of the six, through 1972, were held there; the 1969 was shoehorned into Boston, but hotel and exhibit facilities were completely swamped, and we retreated to Jersey. I remember the Boston meeting largely because I flew from the last moments of the ACM Council, to which I had been elected the year before, all the way to Tokyo—and made a major speech a few hours later. I was based at the Bureau of Standards by then, and flew the same year to meetings in Novosibirsk; it was 1970 before my jet lag wore off!

Shortly after I came to NBS, I had had the sad privilege of helping award the Harry Goode medal to Sam Alexander—three times. The award was to be made at FJCC 67, in Anaheim, but we all feared Sam, one of the great figures of all the Joints from the very earliest days, might not be able to make it. So we gave him a blank medal at ACM 67, which fortuitously met only a few blocks from his house in August. Then when the engraving was done, the director of the Bureau and I gave it to him again. And indomitable Sam flew out to California in November, and got it again, in formal ceremony. He died less than a month later.

Another departure, less tragic of course, was Charlie Asmus leaving AFIPS. More than any other person, he had built up the exhibits to the huge, multimillion dollar extravaganzas of the Sixties. He and I had worked together, inside and outside the Joints, since 1954. He still attends; he still organizes meetings all over the world—but the Joints missed him.

The last WJCC to meet in San Francisco was in 1968. There were nearly a hundred unaccommodated potential exhibitors, in addition to the 130 who showed. The hotels were swamped; people flew in from Los Angeles and went back the same night. Fees were up, to $20. There were complaints. Las Vegas was better, while the aerospace euphoria of the Sixties lasted, but in the end, with deflation, Puritanism prevailed: too many bosses thought the attendees, papers or exhibits, to the contrary, were really bucking the tables. Not true, in my opinion—but it was a dour time. No more Vegas!

We tried Houston, and the Astrodome complex held us nicely. But the hotel/motel accommodations were scattered; the personal and intellectual and sales contacts suffered. It was the era of the shuttle bus: the Joints were swollen!

They had eaten up the DPMA annual show and the ACM exhibits. They had completely changed the various electronic trade shows: pulled out the major systems, left components and modems and lemon-squeezers. Now they in turn began to suffer. "Too much," the manufacturers said, "We have overseas shows, where the market is skyrocketing, and where sales are actually closed at the booth. We can't afford two huge Joints every year, all the special shows for bankers and retailers, and Paris and London and Hannover." So they began to pull out. The papers poured in as always; the attendance stayed up; the income side of the AFIPS ledger, though, showed the strain. And by this time the Federation included other, less seasoned, societies, societies that were not so sure computers would keep on growing at the old, crazy pace.

So the JCC Committee, of which I was again a member, asked the big boys—the IBMs, the UNIVACS, the Burroughses—what to do. "Cut back to one national show a year, and hold it only in New York or Chicago or Anaheim," we were told. And, moaning and complaining, we did. Growth resumed.

Most of the big exhibitors came back—you will see them at NCC76. We have tens of thousands of attendees at the exhibits, thousands at the technical sessions. Ten or more sessions run in parallel, fiendishly planned (like prime-time TV) so that the best papers compete.

The booth birds are not quite so sexy; Women's Lib has had a say. The recruiting is not quite so vigorous. The hospitality suites are harder to find. Social issues flourish; we deplore EFTS in the panels, and sell its hardware and software like mad in the exhibit hall. Yes, the Joints are gone: the NCCs have taken over. I've been to most of them, and plan to go to many more. Nowhere in the world, not even in Tokyo or Paris or Hannover, do you smell the excitement, see the vigor of our trade as at these gigantic gatherings of the clan. We invented something good: the shared computer conference. It bridged the disparate interests of our organizations, and of the manufacturers. It let us join together in a common enterprise. And it was fun!

I would like to express my thanks to the Stanford University Computer Science library. They have everything, and are most kind besides.

Computer prehistory and history in central Europe

by H. ZEMANEK
International Business Machines Corporation
Vienna, Austria

ABSTRACT

An excursion is made into the history and prehistory of computers with special attention to Central Europe. Three historic periods are examined. The period of programmed automata is rich in the development of programmed clocks and musical instruments beginning in the 14th century and continuing through the 18th century. The period of programmed weaving to punched cards ranges from the Jacquard loom to the Hollerith card. It can be noted that the Jacquard card and the Hollerith card are the same width. Predecessors of Jacquard can be found in Austria as early as 1680 or 1690. The Hollerith card was used in census of 1890 in Austria, a fact not as well known as its use in the United States census of 1890. The story of Otto Schaeffler, the engineer who produced the equipment for the Austrian census, is a fascinating one. The third period is the period of programmed calculation. The computer is the product of two streams of development, calculating devices and programmed calculation, and contributions from Central Europe are prominent in both streams. Among the names which must be included are those of Petzval, Boltzman, Goedel, Morgenstern and Von Neumann. Attention is called to two contributions from the author's laboratories, namely, the 1954 fully transistorized computer, "Mailufterl," and the "Vienna Definition Language."

INTRODUCTION

New ideas are rarely really new ideas. Mostly, they are just another step on a long road from ancient times into the future; often an idea becomes known as a new idea, because at this moment the idea was suddenly supported by a possibility of technical realization or industrial exploitation. We tend to underestimate the skill and wit of our ancestors. Most ideas, furthermore, are only a part in a set of ideas which all together makes a scientific field or a technical application a flourishing subject. One "new" idea, in other words, depends very much on many other flanking ideas.

Nothing, therefore, can be understood without a knowledge of the relevant history, and any object, natural or artifact, carries elements and traces of its history. Understanding the present and judging the future of any science or technology, institution or company is only possible on the basis of knowing the past.

So the modernistic view that history is uninteresting except for historians or that history today proceeds so fast that it is not worth looking into the past, is totally wrong.

The impression of speed or acceleration, by the way, is a function of specialization. You might have heard the bon mot about the difference between the universalist and the specialist which says that the universalist knows nothing about everything while the specialist knows everything about nothing. That sounds symmetric—but only until you consider time. Because then the zero knowledge of the universalist holds forever, while the total knowledge of the specialist lasts for zero time. Rephrased less extremely, one could say that the less specialized the longer the truth lasts and acceleration is proportional to specialization.

Computers require a lot of specialization and abstraction, and we all should compensate for that by carefully cultivating our personal universality and by intentionally rehumanizing our technology and profession. This principle encourages an excursion into the history and even prehistory of computers with special attention to Central Europe.

Thus the paper is organized into three sections of different length:

(1) the period of programmed automata,
(2) the period of punched card development, and
(3) the history of programmed calculation.

PROGRAMMED EARLY AUTOMATA

Time is a steady flow without steps, but in order to indicate or measure it, steadily working or analog devices are less accurate than digital ones. This basic principle is very true of the computer, but it was first discovered for clocks and watches and implemented in the forms of the pendulum and the balance wheel. Once the step function is introduced, it takes a small step to use programs and to add programmed devices. The stroke of the full hour and of the quarter soon is followed by automatically moved figures or by chimes.

Music, of course, is typically digital, quantized in frequency, time and even in amplitude—from pp to ff. The musical notes and the score are digital programs, their realization in automatic musical instruments is well within the spirit of music, and the classic composers like Bach, Haydn, Mozart and Beethoven have written for automatic music machines.

In Northern Germany and in the Netherlands we find the oldest chimes, dating back to the 14th century. In Southern Germany, particularly in Augsburg, automata of very fine artistry have been produced during the 16th and 17th centuries. Museums in Dresden and Vienna are exceptionally rich in automata of this period. We have in Vienna even a programmed automatic piano of around 1600.

The 18th century brought great advances in mechanics, and the art of building automata and music machines flourished in Switzerland, Southern Germany and Austria—but also in France and England. Again, the museums in Dresden and Vienna are exceptionally rich, but one must also see the Swiss treasures in Neuchâtel, Lelocle, La-Chaux-de-Fonds and Auberson. It would be my pleasure to show many of those automata and to explain their history and their mechanisms, but I want to cover a much broader field and I must, therefore, restrict myself to a few hints. A couple of pictures, however, of the most beautiful automation I know, the so-called Knights-Fight-Clock in the Vienna Imperial Castle, I cannot suppress. This mechanical theater was built in the first third of the 18th century. The gate is only four inches high and the performance consists of the presentation of the role-cast including a small brass band on horse followed by three fights, where in the first fight the right knight is pushed from the horse, in the second fight the left knight loses his helmet and in the third fight the lancet of the right knight is broken. The last event is the piercing of the Moor's head, and because this scene is so nice, it is done twice. Before the gate closes again, the spectator gets a look at the rearrangement of the men.

FROM PROGRAMMED WEAVING TO PUNCHED CARDS

Programmed weaving is generally connected to the Jacquard loom, because Jacquard not only refined this technology but also brought it to industrial production and application during the Napoleonic time. But the ideas are much older.

Weaving is of more interest for information processing than we attach to it. That it is binary stems from the fact that each crossing of two threads means a natural digital-point. Many folkloristic weaving devices—in Europe, but also in Africa and Asia—are implementations of or tools for programmed processes. And weaving is in particular important in our present-day advance from serial to parallel processing: weaving, in contrast to mathematics, is a naturally parallel process and might give us more ideas than we think.

It is known that Jacquard had many predecessors, J.B. Falcon and B. Bouchon for instance, and Vaucanson, who is known by his two music players and his artificial duck, but whose main contribution was the preparation of Jacquard's success, the development of a punched tape-controlled loom.

Recently one of my Austrian friends discovered, however, a device which seems to be considerably older. It is called "Bröselmaschine," and there are two programming units in existence, both in the province of Upper Austria. They were made around 1740, and there are good indications that the invention was made between 1680 and 1690. Wooden bars are glued on a closed loop strip of linen, and the bars operate the weaving device. The name, by the way, does not seem to be derived from Brösel (crumbs), but from the diminutive form of Ambrosius, probably the family name of the inventor. It is interesting to note that Jacquard punched cards are of the same width as today's computer punched cards: certain measures change little over long times. There is the nice story that Mr. Watson answered the question of Mr. Hollerith what format he should choose for the punched card by opening his wallet and producing a dollar bill (of that time). But in all probability, Hollerith chose the size of the bill in order to be able to make use of certain sorting devices already in use for dollar bills, or much simpler: he started from a jacquard punched card in his development and found no reason to change the width.

Everybody knows that punched card equipment was introduced by Hermann Hollerith for the US census of 1890. Much fewer people know that the idea very probably comes from John Shaw Billings, a medical doctor of the US army assigned to the census office. He triggered Hollerith to construct census machines after the Jacquard loom idea; you will find this story in Herman Goldstine's book "The Computer from Pascal to von Neumann". Even less people know that there was one country where the census of 1890 was also done on Hollerith machines, and that country was Austria.

Again, it was not an engineer who triggered the enterprise, it was an economist of reputation, Professor Inama-Sternegg, head of the Austrian census office. How he had heard of the American development we can only guess, but Hermann Hollerith was on his honeymoon trip in Vienna at the right time, and it is probable that Inama got the idea by Hollerith's visit in the Vienna census office.

The engineer who made Inama's intention possible, who cooperated with Hollerith, introduced and produced equipment and maintained it, and who finally made a very big step forward, deserves a section of this paper. I dug up this man, so to speak, (who had been practically totally forgotten in Austria) during three years of a fascinating research. Here, I can give only a short version of my findings.

OTTO SCHAEFFLER

(Theodor Heinrich) Otto (Hermann) Schaeffler was not a native Austrian. Like many famous Viennese—Beethoven, Brahms, Maelzel—he came from abroad. He was born on October 15, 1838 to a Wurttemberg pastor family in Unterheimbach, east of Heilbronn, Germany. His parents sent him to the priest seminary of Blaubeuren near Ulm, but the boy wanted to become a mechanic. So he left the seminary at the age of 15 and entered a mechanics shop in Stuttgart. His aptitude for this profession is confirmed immediately. He received an award of second class in the first year and an award of first class in the second year, the latter for designing an electro-motor. In 1855, he traveled to Vienna and continued to learn in mechanics shops for four years. He then went in 1863 to London for another four years. He settled in Vienna for the remainder of his life.

He understood how to grasp opportunity. When the Austrian Post Administration in 1867 bought (for 40,000 Austrian Guilders) the patent rights for the Hughes printing telegraph, which, in the following year, was internationally accepted at the Second International Post Congress in Vienna, Schaeffler cooperated with the American inventor so successfully that he could start local production of Hughes telegraphs. He soon exported them to Serbia and Roumania, to Italy and Switzerland and even to Japan. Schaeffler established his own factory and in an advertisement of 1871 offered all kinds of telegraph equipment, railway signalling systems and physical measurement apparatus. The main customer was the Post Administration which in 1871 closed their own Central Telegraph Workshop (founded by the German inventor and Telegraph officer Steinheil in 1850) and turned to private suppliers. Schaeffler succeeded in getting the main contract, installed a contract workshop in the Post Administration building and ran the business of Post Telegraph and Telephone supply and maintenance until 1896. His successors continued this work until 1913. He supported the projects of the Post engineers. He let them publish; he let them earn all the glamor he produced and he sold. So there is little trace of his work in the technical literature; I had never heard his name during my studies and I had a lot of work to collect the facts about him. The result is fascinating.

At the Vienna World Exhibition of 1873 and at the Paris World Exhibition of 1878, Schaeffler showed, apart from his Morse and Hughes telegraph equipment and his railway signalling systems, a stock exchange printer of his own invention. His exhibit was one of the best at both events; he received gold medals and France made him Chevalier de la Legion d'Honneur and Officier de l'Academie.

In 1874, Schaeffler invented another printing telegraph, a quadruple system like the Baudot, but mechanically more sophisticated. The Hughes telegraph had two synchronously rotating fingers, one in the sender and one in the receiver. By a piano-like keyboard the operator selected a letter and thereby made contact with the rotating finger in the corresponding direction. Since the receiving finger was in the same direction at this moment, the receiver could print the correct letter. The Baudot and the Schaeffler printing telegraphs use a five-bit binary code. But while the Baudot operator must learn the code and apply it to a five-key board, Schaeffler had a Hughes-like piano keyboard for 26 letters (or signs and numerics) plus letter blank and sign blank; below the keyboard there are gliding bars like in a tele-typewriter of our days which produce the code. Schaeffler's code is a reflected binary code! What F. Gray patented in 1953 for PCM, Schaeffler had applied in his telegraph in 1874, and for a similar reason: reliability. He had contact fingers sensing on five cams consecutively all combinations; the right one triggers printing. If the fingers are to make a minimal number of movements, the solution is the reflected binary code. For Schaeffler, this idea was a minor one. More exactly, the code is described in a letter by the Austrian Post employee, J. N. Teufelhart, inserted there as a footnote and telling that Schaeffler found the code by combining wooden bars with the different combinations until he had the best solution. Another Post employee, Alexander Wilhelm Lambert of Linz, claims to have shown this code to Schaeffler as early as 1872, but this claim is not clear and cannot be checked.

The Baudot apparatus was successful, the Schaeffler apparatus was not; the Post Administration was not interested in proliferation of telegraph systems. Schaeffler soon turned to the next subject, where he saw and obtained his next big chance: the telephone.

Graham Bell and Elisha Gray had shown their inventions in 1876 at the Philadelphia World Exhibition. Two years later the first American telephone network opened in Detroit. Vienna followed in 1881. A private company got a license for a telephone network within a 10-mile circle around St. Stephen's Cathedral and started in December 1881 with 154 subscribers. Schaeffler constructed and built telephone stations. He supplied the exchanges for 500 subscribers in 1882, for 2,400 in 1884, to which he adds a second of the same capacity in 1890 and a third for 3,000 in 1892. In a report by J. Hopkinson, a member of the Royal Society of London, dated 1893, the Vienna network is classified as faster, better (except for some noise in the lines), and less expensive than the networks of London, Paris and Berlin. In 1895, the Post Administration bought the Vienna network (which now has 18,500 subscribers) for 1,300,000 Austrian Guilders, so that the Austrian telephone system was completely nationalized.

In 1880, Schaeffler married a Viennese and in 1883 became an Austrian citizen. Between 1874 and 1895, he filed 18 patents and in 1885 he fought the Bell patent with partial success. In 1884, he moved into a new factory where he employed 80 workers (plus 6 in the contract workshop at the Post Administration). He was known in Vienna as a progressive entrepreneur. He allowed no children's work and no Sunday work, which was not a normal procedure in those days. He financed health and employment insurance for his employees and was interested when they got medals (from the trades' union of lower Austria) for working 25 years in their profession.

In 1889, Hermann Hollerith received his patent for the punched card system. The director of the Austrian Census Office (Central Statistical Office), Professor Inama-Sternegg, an important statistical and economic scientist of his time, heard about the new machinery and wanted to apply it to the Austrian census of 1890. Schaeffler accepted the task of importing and servicing the Hollerith machines, providing for the power supply, organizing trial runs and using it for smaller tasks like cattle census and hospital statistics. In the spring of 1891, Emperor Franz Joseph I visited the Hollerith operation which processed 28 million punched cards using 12 machines during 667 days, thus carrying out almost 100 million counting steps. The emperor was very satisfied with his visit and after completion of the work, Schaeffler received a very high distinction (Ritterkreuz des Franz-Josephsordens).

Programming of punched card operations was extremely clumsy on Hollerith's early machines. An electrician had to wire the interconnections between sensors, counters, the relays and their contacts. Schaeffler, the experienced telephone exchange specialist, saw the way for the remedy and applied exchange technology, such as plugs and plug-in cables. On May 20, 1895, he got the Austrian patent No. 463 182 for this idea. He wired the different elements around the bar to make contact on plates of metal. He used 77 counters, 100 relays, 240 punched card hole sensors, and 5 batteries which were accessible and could be programmed by connecting neighboring elements with plug in cables and groups of sensors with metal sheet forms. The programming board could be moved out and the electrician had access in case of trouble. This patent clearly was the beginning of technical programming which could be carried out by the census employees without a requirement for an electrician.

In 1896, Schaeffler came home with a big surprise for his wife. He had sold his factory to Czeija & Nissl who then used the name United Telegraph and Telephone Factories Czeija, Nissl and Company and is now merged into ITT Austria. Schaeffler had requested the term "United" in the name to indicate the succession and, in fact, the new company continued the contract with the Post Administration until 1913. Schaeffler's big 7,800 subscriber exchange was replaced in 1898, but in remodeled form it was installed again in Prague and worked there for several years.

Before retiring, Schaeffler moved into an imposing house behind the factory he had built. Even today the guest of the present owner, who organizes chamber music concerts in Schaeffler's ancient rooms, are excited about the place.

Schaeffler died in 1928, at the age of 90, unknown, not as rich as he was at the end of the century, but after a life full of success and satisfaction.

With Schaeffler's retirement, the import and production of punched-card equipment obviously was at a provisional end; the machines of the Census office continued to work, the population register was made a continuous service operated on Schaeffler's punchers, counters and sorters. One or the other machine was still in existence at the end of the Second World War.

GUSTAV TAUSCHEK

A generation later, development started again. Gustav Tauschek (1899-1945) began around 1930 to develop accounting machines of a new type on punched-card basis. He used only the upper half of the standard card for a punched one-out-of-ten code, while the lower half served as written or printed document. There was a sorter running at 20,000 cards per hour; the calculating machine had 75 places for counting and printing, all four basic operations could be performed and also the total sum of the digits of a number. The throughput was at 4,000 cards per hour. Programming was done by plugboards.

Tauschek's machines remained single models, no production was made. But Tauschek sold 169 of his 200 patents to IBM, among which there was a set for an interesting reading machine.

JOHANN NEPOMUK MAELZEL

Another Austrian (again not born there) I want to mention shortly is Johann Nepomuk Maelzel whose life story has not yet been written. I have collected almost all material and I hope to write it soon. We cannot cover here his contributions to the Music Machine of the 19th century and his success in Artificial Intelligence. Maelzel had invented the Panharmonium, the first flute organ extended by trumpets and percussions, and the first automatic trumpet player. Maelzel had pushed Beethoven to write a Battle Symphony, the first stereophonic composition for two automata, intended for Maelzel's machines, but never performed on any. Maelzel himself convinced Beethoven to rewrite "Wellington's Victory" for two orchestras. The cooperation ended in a law suit which, however, was terminated by a friendly agreement. Maelzel bought the famous wrong Chess Player from the son of Herr von Kempelen, sold it to Eugen Beauharnais and got it back in 1817. Nine years later, he came over here to the US and performed with the Chess Player and other automata in simulating artificial intelligence. Kempelen's trick, to prove that an obviously man-driven chess player could not possibly contain a human being, was superbly staged by Maelzel. Once he was dead, the chess automaton was practically dead. That it was destroyed by fire in Philadelphia in 1854 is only the proper dramatic end of a fascinating story.

Maelzel, however, also introduced the master clock into music, and a standard for musical speed, much more efficiently than any modern standards committee. He started off by stealing the mechanical invention from D. N. Winkel, who had invented his chronometer in 1814. Maelzel not only got patents in London, Paris and Vienna, he started fabrication in all three places within two years after stealing the mechanical construction idea. Apart from his sales campaign, his main contribution was first, a good trade name, metronome, and second, the scale which made the device attractive. From the natural marks at 60 and 120 beats per minute, he derived a 16-step scale which is accepted by musicians to this day. All of that was accomplished in two years. Maelzel would give metronomes as presents to the most famous composers in London, Paris and Vienna, if they signed a declaration that they would mark future compositions by the Maelzel measure.

DIEDERICH NIKOLAUS WINKEL

D. N. Winkel (1777-1826) was very angry about Maelzel's total disregard of him as the real inventor. (It is true, however, that Maelzel made the mechanical idea a world success, which Winkel could never have achieved. This is a lesson for the engineer on the difference between a technical idea and its commercial exploitation). So Winkel decided to beat Maelzel in his (then) central field: in the field of musical machines. And Winkel built a music machine which could compose, and this is the first construction I know of to use a stochastical element. The trick is to distribute eight forms (the melody and seven variations) of a composition over two pin drums, two bars on one and two bars on the other in sequence. The stochastic element decides a stochastic path through the stored information which would repeat itself only after 5 million years, as the Paris Academy calculated.

The stochastic element is a 3″ wheel where the first and third quarter of the circumference is cut out. It is started and slowed down. When it stops, a finger finds out the decision (stopped at a cut-out quarter or at a full quarter) and correspondingly commands a move or not into the adjacent variation. Weaving, Music Machines and Census have prepared as many ideas for the computer as calculating devices. Only part of the history of ideas is collected and described in publications of our days and in our language. A lot remains to be done.

But let us now turn to programmed calculation.

PROGRAMMED CALCULATION

The computer, in fact, is the product of two streams of development, namely calculating devices and programmed calculation, and it should never be forgotten that a computer can be as well man as machine.

The prehistory of calculating devices is well known, from the calculi, the reckoning-stones to the abacus, which might be an Asiatic invention but might also come from Europe. The contributions of Pascal and Leibniz are known, but the fact that a professor of theology in Tuebingen, Germany, by the name of Schickart built a four-species device already in the year in which Pascal was born, had to be rediscovered several times. No Schickart machine survived, but we have some documents from which several reconstructions have been derived. The device contains an adder with carry plus cylindric multiplication tables which permit easy adding for multiplication and substraction for division. Since transmission is done by the operator, the system is less reliable than the later desk calculators.

Leibniz, by the way, not only described the binary system, which he got from the Chinese philosophical code connected to I-Ging, Leibniz also described the construction of a binary adder operating with metallic spheres. The case 1+1 yields zero, carry one, requires channelling one of the two spheres to the next binary place, while the redundant sphere falls through into the container which from time to time must be "poured" by hand into the "stock" above the added. Dr. Mackensen of the German Museum in Munich has built a model, restricting himself to the technical possibilities of the time of Leibniz.

But let me turn to programmed calculation. Certainly, there were many examples for it—let me tell you an Austrian story which had very practical consequences. Around 1840, there was a typical Viennese University Professor by the name of Joseph Petzval who was born in a German town in a Slovak province of the Kingdom of Hungary. He had worked in several fields of Applied Mathematics and Physics, and he had written an interesting mathematical theory of music.

At that time he had an idea how to produce high-quality lenses which would make the newly invented photography a real art and technology. But his idea would have required so many hours of calculations that a full crowd of calculators would be required which a University Professor never could afford to pay.

It was the Army who helped. One day, Petzval told his story to a Hapsburg, Archduke Ludwig, who then was the director of the Austrian artillery. Using bombardiers to calculate firing tables was already standard.

Some of these were very experienced specialists in numerical calculations. Petzval borrowed some of them and the result was first a landscape lens and later a portrait lens, manufactured by a German optician Voigtlaender who obtained a world-wide reputation based on these programmed calculations.

Petzval, to my knowledge, was the first one to use the term "thinking machine" and he used it properly. In his introduction to the paper on the programmed calculation of the lens, he says that pure mathematics is the construction of a powerful thinking machine.

A similarly powerful thinking machine is logical algebra, reinvented by engineers under the name of switching algebra. From 1895 to 1936, there is a full series of Austrian forerunners of Shannon. A contribution to the thinking tools around computers comes from Ludwig Boltzmann, the Austrian physicist who lectured on thermodynamics. His chapter on entropy contains a derivation of Shannon's formula $H=p_i \log 1/p_i$. (It is from Boltzmann that Shannon took over the letter H for entropy.)

Austria's contribution to the theory of computation is the revolutionary paper of 1931 by Kurt Goedel, then Assistant Professor at the Vienna University, on the undecidability of axiomatic systems above a certain degree of complication. The theory of games and economic behavior comes from Budapest-born John von Neumann and Vienna-born Oskar Morgenstern. The philosophy of information processing can be based, as I have shown, on Ludwig Wittgenstein's "Tractatus Logico-Philosophicus," written while he was in the Austrian Army. All these ideas are as important for the development of information processing as the actual construction of computer models and computers.

Let me close this paper with two paragraphs on Austrian contributions to the electronic computer which were achieved in my own environment.

In 1954, we started at the University of Technology in Vienna the development of a fully transistorized computer which was given the name "Mailüfterl" after a friendly Viennese May breeze—thus indicating its more modest parameters compared to the ambitious computers of those days called Whirlwind, Typhoon and Hurricane. But this Viennese development (which finally was, e.g., not that slow; with hearing aid transistors we could run it at a clock frequency of 130 Kilocycles per second) had several interesting features. The instruction word included van der Poel's functional bits (nine of them, in fact), could decide between binary and decimal operation, use flag-bits and attach one of 15 different conditions to any instruction.

The second development was the formal definition of syntax and semantics of PL/I, including the design of the Vienna Definition Language and an Abstract PL/I machine. The ANSI Standard for PL/I is written in this Vienna Definition Language, although there have been critical objections to this abstract method. But there is no easy way to describe a language of the size and sophistication of PL/I in English or in a half-formalized language. I think it is impossible, as a matter of fact, if one is unwilling to accept serious ambiguities. Obligation to formalization is as old as formal methods; reluctance is as human as the invention of formalisms. All is a matter of education, balance and respect for the human aspects of science and technology.

I have presented a sequence of highlights rather than a systematic paper. My excuse is that the material that exists on the subject is enough for many hours of lecturing and would require years of work to render it in a systematic form. It was not my intention to bore the reader with details. I wanted to invite him to glimpse fascinating adventure, to see not only more than the circuitry and the present status of the computer, but to understand this magnificent invention, the computer, as the result and combination of many hundred years of human efforts of many kinds. To trace these efforts back in history is as fascinating as it is useful.

Early computers in Europe

by RICHARD WILLIAMS
Computer Consultants (International) Limited
Llandudno, Gwynedd, Wales

ABSTRACT

This paper describes the early history of computers in Europe, notably in Germany, Holland, France, Italy and the Scandinavian countries as well as Great Britain.

Of necessity, in such a short paper, information is given in a fairly short form, but the paper also includes a detailed description of the birth and foundation of the most successful first British commercial computer company—Leo Computers Limited, and this gives an insight into the thinking which lay behind British early computer development.

Three appendices are included which give the names and addresses of the early computer manufacturers and sales organizations in Europe, and short notes on the early computers and calculators.

The development of electronic computers started in Europe earlier than it did in the United States of America.

Developments in Great Britain occurred in the late 1940's at the end of the Second World War, but prior to that Konrad Zuse in Germany, as far back as 1934, started development work on program-controlled machines, and in 1937, jointly with Dr. Schreyer, started development work on electronic computers proper. By 1941 they had completed the first fully operating Model Z3 in electro-mechanical technique; program on punched tape, binary system and floating point arithmetic.

During the Second World War, Konrad Zuse was involved in developing special devices and an improved universal computer, the Z4, with a mechanical memory. These devices were, in fact, the control mechanisms for the V1s and V2s which almost played a decisive part in the war. Fortunately for the British, Zuse had as many bureaucratic troubles as they had encountered, and the delays seriously affected his work.

The firm of Zuse KG was formed in 1949 and the development of other computers, the Z9, Z11, Z22, Z23 and Z25 took place.

As a matter of record, in 1964 Zuse KG became part of the Siemens empire and by 1969 had become wholly owned by Siemens.

It is strange, however, that apart from Zuse's efforts, comparatively little effective computer development took place in Germany on a commercially viable scale, although by now a great deal of IBM equipment is built in Germany.

What was happening elsewhere?

In Italy, Olivetti were becoming involved, in the early 1950's with the development of machines which were variations on their established commercial equipment, but their development was restricted by virtue of the fact that these machines made use of punched paper tape of Olivetti's own design, which had, in fact, square and not round holes and which had no clock track. This made the equipment as a whole incompatible with the competitors' equipment and this was markedly to the disadvantage of Olivetti.

In France, a considerable number of small electronic companies were trying to get on to the computer band wagon. The dominant company was Compagnie des Machines Bull, which could not quite make up its mind whether it wanted to outdate its existing punched card equipment by introducing computers, or whether it should disregard the future of computers altogether.

Everywhere there was confusion between just what a computer was and what a calculator was. The confusion was added to in Europe, as in America, by different tax structures, depending on whether a machine was, in fact, a computer or was classed as a calculator, and the universal practice grew of giving computers names made up from initial letters. The letter 'C' in a name could stand for computer or calculator as it suited the mood and purpose of the time.

In Holland, the Philips organization was involved in prototype computer development and a completely separate company later acquired by Philips and Electrologica, produced a small number of quite viable machines. Philips' problem was one of administration and bureaucracy, coupled with the fact that they supplied from their numerous other companies component parts which were used in computers and the sale of which they had no wish to lose on the basis of a bird in the hand is worth two in the bush.

In Denmark, three types of computers were built at a very early stage. These were reasonably successful, and would have been even more successful but for Denmark's inability to export them in significant numbers.

The Danish Institute of Computing Machinery built the DASK computer and the GIER computer. The GIER was the first built by Disa Elektronik in Herlev and was known as DISADEC. It was later taken over by the Danish Institute of Computing Machinery in Copenhagen and re-christened GIER.

Gallo Electronics also built a computer called GALLO which, although developed at a very early date, had, in fact, an early demise.

Computer development also took place in Norway, as well as Sweden, and this was geared to the activities of the Great Northern Telegraph Company and its equipment.

One of the fundamental problems with the computers mentioned in the countries above was that the countries all had their own national language and, because of the cost and lack of foresight of the companies concerned in realizing that to sell their machines outside their own country, they had to have a universal language, which as it turned out in the computer field is English, the difficulties of production and economic viability were very considerable.

The countries which had no such language problem were the United States of America and Great Britain, both of which produced computers, sold and operated them, making use of the international language of English, although American English, it must be said, is a little different from British English, both in its spelling and connotations.

Computer development in Great Britain started fairly soon after the Second World War and was particularly based on Manchester University and Cambridge University with off-shoots taking place in the Midlands and London.

It became very fashionable, and still is so, to say that Charles Babbage who about a hundred years ago was a mathematics professor at Cambridge was the father of British computers. This is one of those jolly myths which it is nice to have but is somewhat different from the truth. Presper Eckert told the author that neither he nor John Mauchly had heard of Babbage's Engines at the time they first started work on computers, and probably the same comment might have been made by those people who were working on computers at Manchester, although their Cambridge colleagues could, of course, be expected to have had some influence from Babbage.

Babbage was an individual who was very much misunderstood. He had relatively limited funds and he was accused by his critics of never finishing anything. What actually happened was that before he had finished building one of his many machines, he discovered a better way of doing things and, therefore, there was no purpose in completing that particular machine just for the sake of keeping things orderly. He had a girl-friend who was probably a better mathematician and engineer than he was, and it could well be that such reputation as Babbage enjoyed was as a result of her efforts rather than his own.

The original emphasis in Great Britain, as indeed it was elsewhere, was on the design and production of computers for scientific purposes, and those people involved in this activity delighted in using mathematical terminology instead of simple English, to confuse the public at large and enhance their own reputations and prestige. This had a back-lash effect in Great Britain in that the commercial use of computers was delayed for several years because businessmen did not understand them or realize their potential. Indeed, it was in Llandudno where the author lives, at a conference during the 1950's, that Professor Hartree told the assembled audience that, in his opinion, computers would never be used for business purposes because there would not be enough scientists to operate them. Fortunately, this state of affairs did not exist to the same extent in America, largely because of the practical ability and outlook of Eckert and Mauchly and the fact that Eckert, in particular, had a degree in business studies as well as in electrical engineering, and better understood the thinking and outlook of the American businessman.

Fortunately, in Great Britain also, we had some people of influence who saw a commercial future for computers. In particular, the name of Vivian Bowden, now Lord Bowden, and Principal of the Manchester College of Technology springs to mind. The author was privileged to enjoy his confidence when they published books at the same time, the books being very different. Bowden's was called "Faster than Thought" and the author's simply "The Electronic Office" which was a description of the use and possibilities of computers.

Since 1957, when Computer Consultants Limited was formed as the first independent consultancy company on computers in Europe, that company and its associated companies have produced almost a hundred internationally recognized reference books on computers which, because of the nature of the industry and its continuous change, had, of necessity, a very short shelf life. It is from these books that the appendices which form part of this paper have been taken, with the permission of the companies concerned.

The scientific computers developed at Manchester included MADAM and at Cambridge, EDSAC, and the English Electric Company produced an early computer called DUCE which had its origin largely in Cambridge.

Manchester University co-operated with the Ferranti organization and produced early machines like the PEGASUS, while EMI relied to a great extent on their own research and produced EMIDEC.

Elliott Brothers at Borehamwood showed a lot of initiative in producing scientific computers and at a very early stage sought to find ways of using these for commercial purposes with some success, but without the commercial sales back-up to further the enterprise sufficiently in a hardening market.

There were two punched card companies in Great Britain—the Power Samas organization and the Hollerith organization. Both of these companies invested large sums of money in developing machines which they were not quite sure whether to call computers or calculators, and both were surprised to find that what they had produced was already out of date. It is said that it was at that time that Prince Phillip made the pertinent comment that "if it works, it's obsolete." To seek to protect their position, the companies merged to form ICT—International Computers & Tabulators Limited, and some of their early machines made an impact, albeit a short one because of their inability to keep up with research and development.

It may seem strange to an American audience, but IBM had little or no impact in Britain at that time and, indeed, their British organization was very small. This, of course, has now changed, and by now other significant American companies such as Honeywell have made their appearance.

The author was privileged to be asked to make suggestions about Honeywell's entry into Britain, and later Europe, and amongst his working papers are reports that were prepared both for this development and for other significant mergers of European computer companies.

Unquestionably, the greatest single impact made on the British computer field was by an organization that was not concerned with computers at all. It sold cakes and bakery commodities, had some two hundred shops in the London area, and found difficulty in deciding what to bake each night. It was by virtue of the fact that they could not find a suitable computer to carry out their work that they came to design and build their own, and formed Leo Computers Limited. They successfully built and used Leo I for many years, and later produced very advanced versions of the machine before the company ultimately merged with other British computer companies and came under the control of ICL, the, by now, sole remaining British computer company.

The National Cash Register Company had also developed its own computers which were marketed in Britain, and an arrangement was entered into between that company and Elliotts to assemble NCR computers at Elliotts' factories in Britain. This arrangement was expanded to allow for Elliotts' continuing to sell machines for scientific purposes with the same machines, notably the Elliott 803, being sold for commercial purposes by NCR. This arrangement cannot be said to have been altogether successful.

However, to return to the Lyons story. In 1947, two men called Standingford and Thompson, both employed by the Lyons Organisation, decided to study the possibilities of electronic calculators in the office and, to this end, arranged to visit Dr. Goldstine of Princeton University.

Professor Hartree, who was also working on computers at Cambridge heard of this visit and invited Standingford and Thompson to visit him and Dr. Wilkes at Cambridge. Following the visits to Cambridge and America, Thompson and Standingford prepared a report for the Lyons Board and proposed that the company should take an active part in promoting the commercial development of electronic calculators. The Lyons Board decided to donate £2,500 to Cambridge and to lend a man for six months to assist Dr. Wilkes in the activity. Lyons continued their studies during 1948 and the building of EDSAC, the first electronic computer to be built at Cambridge, was nearing its completion.

By November 1948, Lyons had prepared an experimental payroll program which was to be tried out on EDSAC as soon as the computer was ready.

It became quite clear to Lyons by now that it was necessary for them to hold the initiative in this activity and, to do so, they needed staff of their own who were capable of acting on behalf of Lyons. To this end they advertised for the services of an electronic engineer and late in December, J. N. M. Pinkerton was appointed.

By January 1949 they had made practical arrangements for installing a calculator, as it was then called. The clerical staff were told that it was intended to start a computer project, and during the whole of the activity Lyons maintained an excellent staff relationship by keeping their senior, middle management and junior staff fully in the picture as regards their intentions and the progress the activity was making.

For a commercial computer, it had now become obvious to Lyons that it was necessary to have more input/output devices than were customarily intended to be involved with these scientific machines. In April, 1949, therefore, they recommended and, in May, implemented arrangements with Standard Telephones and Cables Limited at Enfield to develop, on their behalf, certain input/output devices.

In May, 1949, EDSAC did its first job of work and a significant step forward had been taken. By July, 1949, Lyons had entered into an arrangement with Wayne Kerr Laboratories Limited to produce panels of electronic circuits on their behalf and to their specification. By August of the same year, Standard Telephones had carried out a survey to ascertain what work was necessary to produce the input/output equipment, and a Mr. E. J. Kaye joined Lyons as assistant to Pinkerton. By the end of the month it had become apparent to Lyons that considerable research was required into the way the clerical work should be organized for the calculator and into techniques of programming. As a result, a start was made on a systematic analysis of clerical work and also on the basic techniques of data processing and programming. The initiative was very much in the hands of T. R. Thompson and it was his drive and perspicacity which largely led to the success of the operation, but it must be emphasized also that he had had the foresight to appoint excellent people to help him in the activity.

In September, 1949, Mr Simmons, one of the Directors of Lyons, christened the calculating machine "Leo" which stood for Lyons Electronic Office. The Coventry Gauge and Tool Company Limited were asked to commence the manufacture of large delay battery tubes which were going to be the computer's memory.

By the end of the year, Standard Telephones had completed their research work and had indicated the equipment which they considered necessary. All this activity was geared to the production of a pilot Leo computer and, in January 1950, Standard Telephones and the other people concerned with assembling the various units were given their head and the equipment required was to be completed and delivered to Leo by January 1951, that is twelve months later.

During March of 1950, demonstrations were given to the Director, office managers, supervisors and members of the Clerical Staff Committee on the way counting and addition was to be carried out on the calculator, and talks were given to the Lyons office staff on the philosophy of electronics in offices.

The first of the delay tubes were received from the Coventry Gauge and Tool Company and Lyons considered the possibility of having the initial records of their data prepared in binary form to be read by photoelectric readers developed by them for that purpose. The activity was now assuming considerable proportions and in April 1950, Thompson was released by the Lyons Board from his other commitments and allowed to devote his entire time to the Leo project. His first step following this was to appoint Mr. D. T. Caminer to take charge of the programming for Leo.

It is significant that the majority of those who played a part in the early days of Leo, went on to remain with the company, and the tradition of almost joining the Lyons organization for life continued strongly in the computer division also. This differs from the approaches in some other companies. To stay with one company for a very long time may have its virtues, but it also has its drawbacks, because it tends to narrow the experience of the group as a whole unless fresh blood is imported from time to time.

By August 1950, discussions had taken place with Standard Telephones to ascertain whether they should develop Leo on a joint basis, but Standard Telephones were not particularly enthusiastic about this and, in fact, the electronic companies at this time must have been quite diffident about the possibilities of using computers in business, in the face of opposition by such well-known organizations as the National Cash Register Company Limited and other office machine organizations.

There were signs at this time that the question of rights to patents were beginning to raise their heads. It was agreed by Standard Telephones and Lyons that neither party should enter into arrangements for supplying equipment similar to that which had been developed without the agreement of both parties. By October 1950, the progress being made was not satisfactory and was behind schedule. To try and correct this, Pinkerton spent a lot of time at Enfield trying to accelerate production, but this was to no avail. By the end of the year, rethinking was taking place in connection with the Standard Telephones/Lyons arrangement, and Lyons agreed to pay Standard Telephones some additional costs in connection with equipment which had been overlooked in the original specification. Standard Telephones agreed to allow Lyons to obtain equipment previously commissioned from them, elsewhere if it was necessary for them to do so.

While the computer was by no means complete, there were working portions of it which could be seen by January 1951 and, in February 1951, Her Royal Highness, Princess Elizabeth, now Queen Elizabeth II, went to Cadby Hall to see Leo carrying out a simple test program.

By April, it was possible to give demonstrations to the Lyons Directors of Leo doing clerical work, and although they were very behind schedule with their activities, Standard Telephones felt that it would be in the interests of both parties if the patent applications of the two companies were considered together.

In May 1951, a memorandum setting out the scope of the Lyons patents was sent to Standard Telephones and a demonstration was given in June by Standard Telephones at Enfield to some of the Lyons Directors and Executives of the partly assembled auxiliary equipment in operation.

However, despite the difficulties which were arising, by the end of August, Leo was doing some real clerical work, albeit very slowly, and the Cadby Hall Bakeries job was being done on the calculator by September and producing accurate results. However, the difficulties arising from the late delivery of the Standard Telephones equipment had not been resolved by October and, regretfully, Thompson and others discussed the possibility of developing other input/output systems using paper tape in order to keep the work going on schedule.

The Leo computer had engendered so much outside interest by November that the Ministry of Supply was seeking to find out whether Lyons could carry out some ballistic computations on the computer. In November 1951 also, the Cadby Hall Bakeries job, which was the scheduling of an overnight bakery programme for the whole of the production at Cadby Hall, was carried out on the computer completely successfully, and the job was carried out regularly from then on.

At this time, the Leo machine was still being referred to as a calculator and, in February 1952, a wages demonstration program was carried out on the machine using magnetic tape for the first time. The records on magnetic tape were subsequently printed by teleprinter and more outside enquiries were being made for time on the machine, in particular, the Meteorology Department and the Ministry of Supply.

In May 1952, Professor Hartree made the remark that computers would never be used for business purposes with any degree of success. This undoubtedly carried a lot of weight with people in authority in Britain and must surely have delayed the use of computers in Britain for a significant period.

Up to about this time the Lyons machine had used punched paper tape and magnetic tape, but in June 1952 began the collaboration between Lyons and the Hollerith company. Originally Lyons had intended that the computer should be used for their own activities and they were pursuing the requirements for their own work. Their next objective was to carry out the provisioning of all the London Lyons Tea Shops, as they were called, some two hundred and fifty in all. In this comparatively short space of time, they had also developed their own photo-electric tape reader and this was in use. An increasing number of enquiries were being received from outside organizations for the use of the machine and the range of enquiries were substantially wide.

By October 1952 Lyons had decided to go ahead with building their own high speed input/output equipment as an alternative to the Standard Telephones equipment because there were increasing fears that this would prove to be unreliable. By the end of the year, early production payroll work was being done and pay slips, produced on pre-printed forms, were being used within the Lyons organization. In January 1953 came a successful full-scale trial of a payroll program and, although there were minor computer faults which were later amended, the operation was initially a success.

The writer believes that much of this success by Lyons with computers arose from their readiness to face realities, and the fact that they themselves had for a long time, as a company, been engaged in organization and method work, and were aware of the necessity for study and planning their operations, rather than just patching them up and doing them in the same old way, albeit with new equipment. In May 1953, the first tabulator was delivered from BTM and a card feed was also delivered the same month. Both pieces of equipment operated successfully, and later that month a demonstration payroll was carried out, printing the result, not on a teleprinter as previously, but on a Hollerith tabulator. By August a draft plan had been prepared in respect of the London Tea Shops Provisioning Application and sufficient use had been made of the computer to appreciate what improvements could be made to the existing equipment. For example, future mercury delay lines would use shorter tubes in which the pulses would be one quarter of a microsecond in width and so reduce the access time to a quarter of that operated in the early days without any loss of capacity. About this time Standard Telephones decided to abandon the project with Lyons and arrangements were made for the re-siting of the equipment.

By the end of 1953 Leo I was operating more than ninety per cent effectively, and a significant number of people were approaching Lyons from outside the organization with a view to hiring computer time and finding out what their future plans were. These included plans for building Leo II, and in February 1954 the amount of coverage given to the success of Leo I, increased enquiries for the new machine.

Outlined proposals for Leo II were finalized and new equipment such as Ferranti Fast Tape Readers were added to the early machine. Lyons then announced that they were prepared to build Leo II for sale or hire to other organizations and that they were forming a subsidiary company, Leo Computers Limited.

The number of staff on the Leo payroll by August 1954 was slightly under ten thousand, and the work for the provisioning of the Tea Shops had been put on the machine, first of all with forty two shops, and later on with nearly two hundred, and this was a success from the start.

By the end of 1954 Bull tabulating equipment had been added to the computer, and the number of enquiries for the purchase of computers and computer time on Leo's own machines, had grown to significant proportions. By now, of course, Leo Computers Limited, have become part of International Computers Limited through various mergers. In the meantime Standard Telephones & Cables Limited (part of ITT) had, in 1958, built their own small computer, the Stantec Zebra. A new transistorized prototype was built six years later, but the company then withdrew from computers. That Leo Computers Limited was a success story was unquestionable. Why was this, when so many computer companies have run into difficulties? Much must have depended on the quality of the people concerned, but the author believes that it was mainly because they knew from the start what they wanted to do, and they went ahead and did it. And eventually knew when to stop trying to keep up with the big boys.

CONCLUSION

What of the future of computers in Europe? The dominant computer manufacturer is undoubtedly IBM, with Honeywell a close second, and with ICL being moderately successful. All the remaining small, individual companies have been swallowed up by these empires, but as competitors there still remains Burroughs, NCR and other American oriented companies.

The future of any individual computer company is damned by the cost of development and the lack of marketing facilities, but there remains the thought that since the early 1960's, with the advent of computer memories, using laser and other techniques, all existing computers are dated—and the size of IBM, for example, makes it virtually impossible for that company ever to switch from these out of date computers to newer, more imaginative equipment which we know is technically possible, and certainly economically viable.

Who knows what the future is?

APPENDIX I—THE NAMES OF MANUFACTURERS AND SALES ORGANIZATIONS OF COMPUTERS WHICH WERE BEING SOLD IN EUROPE IN 1965 AND SHOWING THE ORIGIN OF SOME OF THE EARLY COMPANIES

Aktiebolaget Addo, Malmo, Sweden.
Svenska Relafabriken ABN., Tyreso, Sweden.
Alwac Computer Division, El-Tronics, Inc., California, U.S.A.
A.E.I. Automation Ltd., Manchester, England.
Bunker Ramo Corp., California, U.S.A.
International Systems Control Ltd., Wembley, England.
Burroughs Corp., Michigan, U.S.A.
Burroughs International S.A., Fribourg, Switzerland.
Cambridge University, Cambridge, England.
Centre National d'Etudes des Telecommunications, Seine, France.
Clary Corp., San Gabriel, California, U.S.A.
Collins Radio Corp., Dallas, Texas, U.S.A.
Compagnie Bull-General Electric, Paris, France.
Compagnie Europeenne d'Automatisme Electronique, Seine, France.
(CIT) Compagnie Industriel des Telecommunications
(CAE) Compagnie d'Automation Electronique
(CSF) Both Subsidiaries of Compagnie de Telegraphie Sans Fil which formed a joint company with Compagnie General Electric.
Computer Engineering Ltd., Hitchin, Herts, England.
Control Data Corp., Minnesota, U.S.A.
Control Data AG., Luzern, Switzerland.
Danish Institute of Computing Machinery, Copenhagen, Denmark.
A/S Regnecentralen, Copenhagen, Denmark.
Disa Electronik A/S, Herlev, Denmark.
Electronic Association Inc., New Jersey, U.S.A.
Electronic Associates Ltd., Burgess Hill, Sussex, England.
Electronic Machine Controls Ltd., Thornton Heath, Surrey, England.
English Electric-Leo-Marconi Computers Ltd., Kidsgrove, Staffs., England.
Elliott Bros. (London) Ltd., Borehamwood, Herts, England.
Facit Electronics AB., Stockholm, Sweden.
Atvidabergs Industrier AB., Stockholm, Sweden.
Ferranti Limited, Hollinwood, England.
Friden Inc., San Leandro, California, U.S.A.
Friden International S.A., Fribourg, Switzerland.
General Electric Corp., Arizona, U.S.A.
International General Electric S.A., Geneva, Switzerland.
General Precision Inc., California, U.S.A.
General Precision Systems Ltd., Ealing, London, England.
General Precision France, Paris, France.
Eurocomp GmbH, Minden, Germany.
Schoppe & Fraeser GmbH, Minden, Germany.
International Business Machines Corp., New York, U.S.A.
IBM World Trade Corp., Paris, France.
International Computers & Tabulators, London, England.
Marconi Instruments Ltd., London, England.
Mercedes Buromaschinen AG., Thuringen, East Germany.
Minneapolis-Honeywell Regulator Co. Inc., Massachusetts, U.S.A.
Honeywell Controls Ltd., London, England.
Monroe International Inc., New Jersey, U.S.A.
Monroe International (UK) Ltd., London, England.
Monroe Calculating Machine Co. France, Paris, France.
Deutsche Monroe/Sweda GmbH, Dusseldorf, Germany.
Monroe Calculating Machine Co. Holland N.V., Amsterdam, Holland.
National Cash Register Co. Inc., Ohio, U.S.A.
National Cash Register Co. Ltd., London, England.
National Physical Laboratory, Middlesex, England.
N.V. Electrologica, Den Haag, Holland.
Olivetti-General Electric SpA, Milan, Italy.
Olympia Werke AG., Wilhelmshaven, Germany.
Philips Gloeilampen Fabrieken N.V., Eindhoven, Holland.
Pisa University, Toscanna, Italy.
Raytheon Corp., California, U.S.A.
Scientific Data Systems Inc., California, U.S.A.
Compagnie Europeenne de Calculateurs Industriels et Scientifiques, Paris, France.
Siemens & Halske Aktiengesellschaft, Munich, Germany.
Societe d'Exploitation et de Recherches Electroniques, Aubergenville, France.
Societe Europeenne pour le Traitement de L'Information, Massy S. et O., France.
Scciete Nouvelle d'Electronique, Paris, France.
Societe d'Electronique et d'Automatisme, Seine, France.
Solartron Electronic Group Ltd., Farnborough, England.
Sperry Rand Corp., New York, U.S.A.
Univac Division of Sperry Rand International Corp., Lausanne, Switzerland.
Standard Elektrik Lorenz AG., Stuttgart, Germany.
Standard Telephones & Cables Ltd., Enfield, England.
Svenska Aeroplan AKT., Linkoping, Sweden.
Technische Hochschule, Munich, Germany.
Telefunken GmbH Konstanz, Germany.
Teleregister Corporation, Connecticut, U.S.A.
Zeisswerke GmbH, Jena, Germany.
Zuse KG., Bad Hersfeld, Germany.

APPENDIX II—LIST OF AND SHORT NOTES ON DIGITAL COMPUTERS USED IN EUROPE IN 1963. (SPECIAL ONE-OFF MACHINES, OF WHICH THERE WERE MANY, ARE NOT INCLUDED)

Name	Manufacturer	Price
Ace	National Physical Laboratory	£ 400,000
Advance II	Advanced Scientific Instruments Inc.	£ 300,000
AEI 1010	Associated Electrical Industries Ltd.	£ 250,000
AEI 959	Associated Electrical Industries Ltd.	
Alwac II	Alwac Computer Div. of El-Tronics Inc.	£ 35,000
Alwac III	Alwac Computer Div. of El-Tronics Inc.	£ 37,000
Alwac IIIE	Alwac Computer Div. of El-Tronics Inc.	£ 40,000
Alwac IV	Alwac Computer Div. of El-Tronics Inc.	£ 50,000
Alwac 800	Alwac Computer Div. of El-Tronics Inc.	

Name	Manufacturer	Price
Amdec	Addressograph Multigraph	£ 30,000
AN/UYK-1	Thompson Ramo Wooldridge Inc.	£ 40,000
Apollo	Ferranti Ltd.	£ 35,000
Arch	Elliott Bros. (London) Ltd.	£ 17,000
Argus 100	Ferranti Ltd.	£ 20,000
Argus 200	Ferranti Ltd.	£ 20,000
ASI 210	Advanced Scientific Instruments Inc.	£ 40,000
ASI 420	Advanced Scientific Instruments Inc.	£ 150,000
AV 41	North American Aviation Inc.	
Atlas		£2 million
Basicpac	Philco	
Bendix D-12	Bendix International Div. of Bendix Corp.	
Bendix G-15	Bendix International Div. of Bendix Corp.	£ 30,000
Bendix G-20	Bendix International Div. of Bendix Corp.	£ 210,000
Bendix G-25	Bendix International Div. of Bendix Corp.	£ 300,000
BESM 1	Made in Russia	
BESM II	Made in Russia	
BISMAC I	Radio Corp. of America	£ 500,000
BISMAC II	Radio Corp. of America	£ 500,000
BRLESC	Ballistic Research Laboratories	
Burroughs 204	Burroughs Corp.	
Burroughs 205	Burroughs Corp.	£ 67,500
Burroughs 220	Burroughs Corp.	£ 160,000
Burroughs 250 VRC and 251 VRC	Burroughs Corp.	£ 140,000
Burroughs 260 and 261		£ 70,000
Burroughs 270 and 271		£ 130,000
Burroughs 280 and 281		£ 140,000
Burroughs B5000		£ 200,000+
Burroughs D825		
Burroughs E101		£ 16,400
Burroughs E102		£ 10,000
Burroughs E103		£ 10,000
Burroughs F2000		
CAB 500	SEA of France	£ 23,675
CAB 600	SEA of France	£ 30,000
CAB 3900	SEA of France	
CE 55	Computer Engineering Ltd.	£ 2,000
CE 102	Computer Engineering Ltd.	£ 10,000
Cellatron SER 2	Mercedes Buromaschinen	£ 9,000
CIFA-3	Institute of Nuclear Physics, Roumania	
CIFA 101	Institute of Nuclear Physics, Roumania	
CITAC 210B	Compagnie Industrielle des Telephones	
Clary DE-60	Clary Corporation	£ 8,000
Clary DE-60M	Clary Corporation	£ 7,000
Computer Control DDP 19	Computer Control	£ 40,000
Computer Control DDP 25	Computer Control	£ 40,000
Control Data 160	Control Data Corp.	£ 30,000
Control Data 160A	Control Data Corp.	£ 50,000+
Control Data 924	Control Data Corp.	£ 110,000
Control Data 1604	Control Data Corp.	£ 380,000
Control Data 3600	Control Data Corp.	£1 million
Control Data 6600	Control Data Corp.	£1,600,000
CXPQ	Philco International Corp.	
D21	Svenska Aeroplan Aktiebolaget	£ 60,000
Datamatic 1000	Honeywell Corp.	£ 584,000
Datatron	Electro Data Corp.	£ 39,800
DB 10	Standard Elektrik Lorenz AG	
DB 40	Standard Elektrik Lorenz AG	£ 50,000
DB 70	Standard Elektrik Lorenz AG	
Deuce I	English Electric Co. Ltd.	£ 45,000
Deuce II	English Electric Co. Ltd.	£ 50,000
Deuce IIA	English Electric Co. Ltd.	£ 55,000
Disadec	Disa Elektronik A/S	£ 41,500
ELEA 2001	Olivetti SpA

The U.K. privacy white paper 1975

by A. S. DOUGLAS
The London School of Economics and Political Science
London, England

ABSTRACT

It is now some years since the formation of the Younger Committee, set up to study the question of Privacy and its protection as it related to the private sector. The Committee published its report in 1972. Shortly after the Younger Committee was set up, an interdepartmental working party was set up within central Government to study the problem as it related to the public sector. This working party's report has now been issued along with a Government White Paper, which makes specific proposals for action in the computer field. In the meantime other countries, including the U.S., have taken significant steps in the direction of defining Privacy and introducing data protection procedures.

INTRODUCTION

The White Paper has been promised for some eighteen months, but there have been successive delays and it has long been an open secret that disagreements over its content have existed in official circles.[1-2] The final version[3] issued owes a great deal to Alex Lyon, the Minister of State at the Home Office, who sat on the Younger Committee and whose minority report is incorporated in the report of that Committee's findings. The White Paper was drafted by a lawyer, Mr. Paul Sieghart, who spent considerable time in wide-ranging consultation beforehand under the aegis of the Home Office and no little time in subsequent amendment to take account of comments and objections!

In discussing the various reports and the White Paper it is essential to distinguish clearly between Privacy, Confidentiality and Security. These three concepts are often confused. However, there are important differences involved, not only in the topics covered, but also in the attitudes to them which can and should be adopted by the professional community, and in the acceptability of those attitudes to the general public. For a brief but clear statement of what is involved see "The Application of Computer Technology for Development."[4] The question is discussed at more length in the Younger Report and elsewhere.[5]

WHAT IS MEANT BY 'PRIVACY'

It is sufficient here to point out that Privacy concerns the rights of an individual, personal or corporate, to enjoy protection from unwarranted and unauthorised intrusion into his affairs. It is not related in any specific way to computers.

It is a social phenomenon and depends critically on public opinion. In a democracy it is clearly a political matter, to be dealt with by our elected representatives —under the (hopefully!) watchful eye of the electorate. It defines *what* is to be protected, not how this is to be done.

Every professional is a citizen also. In that capacity he has a right to speak on privacy, but only on the same basis as every other citizen—his professional status confers no special virtue on any pronouncements he may make. However, in regard to the legal definition of what is to be protected, or to the methods of protection of data regarded as private, professionals in whose area the matter lie may speak as experts and carry an appropriate degree of authority. This authority carries with it a responsibility to explain the nature of any problems involved—in language laymen can understand—and to warn of the probable results of abuse, misuse or omission of safeguards. It is in this spirit, I shall approach the rest of this paper.

CONFIDENTIALITY

Confidential material is data entrusted to an individual, corporation or agency, whether local, national or international, the possession of which imposes a duty on that agency to protect it from disclosure except as authorised by the protocols under which it may be collected. It may include, but is not limited to data about individuals. The protocols creating confidential status for data may be statutes, contracts or customs recognized by the Courts or by common consent. The protocols sometimes conflict with other protocols, when the individuals involved may well be placed in an invidious position. A journalist asked to reveal his sources when these are connected with criminals, for example, may feel that he must preserve the anonymity of the sources partly to preserve them from retribution and partly to ensure that he is able to use similar sources at a later date—yet his action could be deemed to conflict with the criminal law and place him in jeopardy as an accessory to a crime. In some cases the conflicts have been resolved by the Courts in favour of preserving confidentiality except in specified circumstances—e.g., the doctor-patient and solicitor-client relationships, where the preservation of confidentiality is generally acknowledged to be in the public interest unless criminal proceedings are involved.

The protection of confidential material is, of course, closely related to the preservation of privacy in respect of data about an individual. The security considerations are similar. But in the case of privacy the rules under which disclosure may be made are not necessarily well defined, if they are defined at all. Since there is no right to privacy defined in English law, rules of disclosure must currently rest solely on any protocols which may exist or be created by, e.g., contract. It is interesting to note that this is not so under the Code Napoléon, on which French law is based, in which the point is covered to some extent by the 'droit de la personalité'. (For a comparative study of the position under different laws, see Reference 6.) A political move is now afoot in the U.K. to cover this 'open' position by Statute. It will be interesting to study the White Paper which will in due course, no doubt, emerge.

It is fair to say that the White Paper on Privacy discussed here does not directly define Privacy or Confidentiality but primarily addresses itself to the question of Security. However, there is one important point on which it is clear. This relates to the question of disclosure of the existence of data banks containing records concerning individuals. The White Paper proposes that disclosures should here be the rule (para 34 & 35) and that exemptions on grounds of national security would need a certificate from the Home Secretary (para 39).

SECURITY—SOME GENERAL REMARKS

There are two points to bear clearly in mind when examining any security system. The first is that there is no such thing as a perfectly secure system. In general, one gets the degree of protection one is prepared to pay for—and perfect protection has infinite cost. It is generally cheaper to design features into the system from the start than to add them later. The aim must be to ensure that penetration of the system costs at least as much as the possession of the data is worth to a penetrator, and to design the system so that penetration, if it occurs, is detected.

The second point is that the weakest link in any security system is the people involved in it. Almost all breaches of security involve the co-operation of someone inside the system. Thus the selection and control of personnel is a key issue in providing protection of data. Moreover, only those 'inside' a system are normally in a position to detect certain types of abuse, before these effect the public. Thus their cooperation is essential.

These points are implicitly recognised in the White Paper, and specific mention is made of the role that the British Computer Society could play in relation to any legislation which may follow from its provisions (para 43). But the mechanism involved has been left open for the present. We shall discuss this further below.

The essential elements of a security system must involve legislation, detection of breaches, and enforcement. The White Paper, whilst proposing legislation, is not definitive on the method to be used to detect breaches or by whom the law is to be enforced. However, one important aspect on which it is clear is that the mechanism of enforcement should apply equally to the public and private sector. The delay in prohibiting the Report of the Interdepartmental Working Party which completed its work in 1972, indicates that this view may not have been wholly shared by the official side. To understand this, it is perhaps necessary to review existing practices.

THE OFFICIAL SECRETS ACT, 1911

In the public sector, protection of data has been practised for many years, of course. Indeed, specific duties of protection are laid down in various statutes to preserve the interests of the individual. Cross-correlation of data relating to an individual has been controlled by a set of internal rules drawn up within the Civil Service. It is a fairly sophisticated code and takes account of the need to obtain valid statistics, whilst at the same time preserving the anonymity of the individuals whose records are used in those statistics. It is recognised that any such procedure can lead to a risk of disclosures about individuals, but there is insistence on this risk being minimised by the techniques employed.* It is fair to say that a specific case of unauthorised disclosure has yet to be proved, although it is not difficult to 'manufacture' situations in which it could take place. To this extent existing protection is to be commended as being effective and sensible.

Enforcement of the rules is by administrative fiat. The unauthorised disclosure of data by an individual Civil Servant not covered by any other protocol is covered by the Official Secrets Act,[7] under which every Government Servant who handles any confidential or private data operates. Signature of a declaration under the Act is not essential to its effect being binding on

* For some valuable comments on this aspect of matters see 'Report of a Working Party on Survey Research and Privacy' 1973, issued by Social & Community Planning Research, 16 Duncan Terrace, London N1 8BZ.

persons involved in handling such data, but helps to draw attention to its provisions. The Act is comprehensive and was drawn up with matters of national security in mind. There are thus "catch-all" clauses which can be extended to cover matters which might be considered to be secret only in a national emergency—and then only by the stretch of a very fertile imagination. It is, for example, possible to bring under the Act the important topic of whether and how often the grass is cut at a designated Government installation. Whilst one can undoubtedly construct an ingenious scenario in which such a matter is of crucial national importance, one can reasonably feel that, in normal circumstances, it is unlikely that this is of great concern to anyone—friend or foe—except perhaps an aspiring gardening contractor!

Use of the Act to support a case against reporters and others concerned with the Nigerian civil war led to some public concern a few years ago. There have been rumbles about its effect ever since, and a Departmental Committee set up in 1972 under the Chairmanship of Lord Franks recommended the repeal of Section 2 and its replacement by an Official Information Act.[8] But any alteration is naturally met by an equal concern about the effects which could flow from its repeal and a general uncertainty as to what amendments are really needed.

There are, no doubt, those who deem the Act necessary in some form, as I do myself. Many of them, like me, feel that it is a somewhat blunt instrument as it now stands. It is administratively convenient, because it confers wide powers to impede the flow of information both inside and outside Government on senior civil servants when they deem it necessary. Whilst I have no reason to doubt the sincerity of their intentions in the public weal, nor can I point to specific instances of abuse related to computer matters, the system could all too readily be abused, and there is at least circumstantial evidence that it is, from time to time, used more to cover up incompetence than to protect what must be protected for the good of all. To this extent the present system could usefully be amended.

The White Paper, if implemented, must necessarily impinge on the working of the Act in so far as it relates to computer-supported data bases concerning records of individuals. Since non-disclosure on grounds of national security of the existence and nature of such a data base would require the certificate of the Home Secretary, if the provisions of the White Paper become law the provisions of the Act could then only be used if that exemption were to be granted. This implies a review procedure which is not necessary at the moment. Furthermore, the mechanisms for enforcement considered by the White Paper both imply that, if complaints are made concerning the effects of the existence or use of such a data base to the enforcing authority, that authority will need to know of the existence of such an exemption order, and could ask for it to be reviewed by the Home Secretary if it felt that exemption was being abused.

While there are those who would welcome the abolishment of the Official Secrets Act or, at least, its substantial modification, it is encumbent upon them, in my view, to state how those of its provisions deemed essential to national security are then to be dealt with. For the most part, this has not been satisfactorily tackled by would-be amenders. Total abolitionists would not, I think, obtain a Parliamentary majority, and would undoubtedly be opposed by a majority of officials.

A partial answer might well evolve from the legislation proposed by the White Paper. Clearly the review mechanism introduced as described above would tend to reduce the unselective use of blanket security provisions, and a sensitive use of his powers by the Home Secretary could lead to greater openness overall, by insisting on a careful definition of what features of a system actually attract exemption, initially in relation to computer-based systems, but, in due course, by extensions to manual systems. It is to be hoped that this evolution will indeed take place.

ENFORCEMENT—THE PROPOSED DATA PROTECTION AUTHORITY

The White Paper describes two possible forms of enforcement agency, which it tends to contrast. The one with a tighter form of control would involve a process of licensing. The White Paper does not set out to determine whether this relates solely to the licensing of the organisation holding the data, the collection agency, the people involved, or all three. Nor is any specific mechanism proposed for ensuring the existence of a 'responsible person' in relation to the data, although this point is discussed at some length in the Younger Report. Any or all of these forms of control are possible under the suggested provisions, however.

The "alternative" seen by the White Paper envisages an agency which only reacts in response to a complaint of an abuse of the citizen's rights by virtue of the existence or operation of a data base. The proposed Data Protection Authority in this case would act only to investigate such complaints and take action to remedy them where they proved to be justified.

An interim Data Protection Committee is being set up to make recommendations on the form the Data Protection Authority should eventually take. The terms of reference of this Committee are not spelled out in the White Paper directly, but, by implication, include advice on the legislation to be enacted. They will almost certainly be required to define, at least provisionally, some of the individual's rights to privacy as well as spelling out the powers and duties of the Data Protection Authority. It is, perhaps, significant that Sir Kenneth Younger has been appointed the Chairman of this Committee. In the light of the work done by his earlier Committee, we may expect that the definition of privacy will follow the lines of its Report, modified by any impact made by inclusion of public sector considerations.

COMMENTS ON ENFORCEMENT

The problem of enforcement is perhaps best seen in relation to a real-life situation, albeit a hypothetical one. U.K. firms are currently subject to a Pay Code, forbidding the paying of increases in wages in excess of a fixed figure each twelve months. It is true that this does not exactly have the full force of criminal law, but a breach is certainly punishable, if detected. In all firms which use their computer for payroll one or more programmers are authorised to see the figures paid out, although these are regarded as confidential. The programmers concerned are usually asked to sign papers drawing their attention to the confidential nature of their work and under law can be dismissed by their employer for a breach of such confidentiality.

Let us suppose that one such programmer notices a breach of the Pay Code in the course of his duties, what should he do? He can, of course, report it to his superior. However, more likely than not he will be told to forget it and reminded of his obligations relating to confidentiality. He can resign, but with present employment prospects, he might find that, at the least, inconvenient. A threat to resign in order to reinforce his report to his senior, is clearly a dangerous course, bordering on blackmail at worst, and almost certain to rebound on him in due course. He can consult his professional Society—assuming he belongs to one. The Society can operate at a higher level than he is able to do, and stands some chance of getting the situation put right, but there is no way to avoid the finger pointing at a small number of people as containing the one responsible for the 'leak'. Naturally straight dismissal would be out of the question as the adverse publicity the Society would ensure would not be welcome. But it is difficult to see how some retribution could be avoided if the management were so minded. The least that would be likely would be a transfer to other work.

Clearly the dice are loaded against disclosure of the breach coming from anyone, however professional and public spirited, inside the system, unless they are on the point of resigning anyway. Moreover any tangible proof of their contention which could be produced by them would constitute theft of company property—all the more culpable if they took it with them on leaving.

The only possible counter to this seems to be to strengthen the 'outside' pressure on the individual professional to act according to a code of ethics and good practice and to protect him, if he does so, from reprisals by his employer. An enforcement authority would need to be equipped with wide licensing powers to do this, applicable equally to the conduct of operations and the personnel involved. It is also clearly practically desirable to have a named person to accept responsibility if things go wrong, who is empowered under the licensing procedure to enforce proper control even though this may not be in the direct interests of his employer. The parallel drawn in the Younger Report is to a mine safety officer, who is employed by the mine but has statutory powers and duties in respect of safety. The parallel is not exact, but illuminating.

It is, I think, clear that a 'complaints board', however strongly armed with investigative powers and sanctions on future action, would be unlikely to achieve a significant change in employee attitudes. But this is not to say that some complaints procedure is not desirable for a licensing authority. I do not myself see the White Paper proposals as strictly alternative. To an extent they are complementary. It is arguable, obviously, that it is possible to have a complaints handling procedure without licensing. However I do not think that, in practice, a licensing procedure will work smoothly without a complaints mechanism.

The British Computer Society, in addressing the Home Secretary on the subject, has come out firmly in support of a licensing authority (see Appendix). One form of such a system is already in operation in Sweden, under their Data Act.[9]

COSTS

The White Paper refers specifically to costs, and it is clear that the Data Protection Committee, in making its recommendations, will need to justify them on a cost/benefit basis. The Swedish licensing system does not involve a large central staff—25 at present, I believe, and direct costs are covered by charging a licensing fee. Some of the factors involved in implementing recent legislation in the U.S. are set out in a recent Rand Corporation report.[10] A similar study will be needed to assess the costs, both direct and indirect, incurred in implementing the alternatives proposed in the White Paper. Whilst, as in the Swedish system, central costs can be kept down and funded from license income, if this route is chosen, there are bound to be additional costs at each installation. This raises, in particular, the question of consultation of records by those about whom they are kept. Although the right to inspection is advocated in principle in the White Paper it is clear that the cost of this will need to be reviewed carefully and some arrangements set up that will enable the individual to be assured of the correctness of data held about him without either he himself, the data bank operator or the public purse being put to unreasonable expense. It is here that proper advance planning of the data base system for filing and retrieval in the light of security and accuracy requirements will have its most important role to play. A well planned system which satisfies a reasonable licensing requirement may well be little more expensive to construct and operate than one which does not. The main problem of cost is likely to arise in respect of existing systems, which cannot readily be replanned to serve the new requirement. Clearly, temporary measures may be necessary to deal with this problem. More study is certainly needed before costs can be determined.

Clearly the costs of a complaints system must also be carefully considered. At first sight it would seem that the burden will have to fall on the taxpayer, since charging the complainants would rapidly defeat the intentions of the system by discouraging complaint and a system of fines on firms found at fault used to fund the system might lead to over-vigorous pursuit of complaints if the 'quota' of fines had not been received.

In fact the method of financing has a deeper significance than a narrow question of cost/benefit of operations; it goes to the root of the independence of the Authority itself. Any arrangement depending for its finance on taxpayer's money can be influenced by the funding agency—no doubt in this case the Home Office. This is plainly undesirable if the Authority is to act even-handedly in both public and private sectors. It would, of course, be possible to insulate the members from influence by giving them the Status of Her Majesty's Judges who can only be dismissed by a vote in both Houses of Parliament—but this is unlikely to be considered appropriate at this stage. An institution dependent on license fees which it can levy as of right to recover its costs seems the more independent of the alternatives available. Financial independence is specifically commended in the White Paper.

PERSONNEL SELECTION AND LICENSING

Another important question, should the Authority become an established part of our national life, will undoubtedly be who appoints the members of the Authority. There is growing concern being evinced in the Press and Parliament about the nature and extent of Government patronage. This probably seems somewhat surprising to those who live in a country where rather more Government posts are filled by political patronage than in the U.K.—and perhaps we are rather too touchy on the subject. The concern is, I think, less over the influence exercised by Ministers themselves than over that being increasingly exercised by the Civil Service. To pretend that this does not happen in all bureaucratic systems would be hypocritical, but to condone an unnecessarily arbitrary and subjective practice would be equally so. The process of advertisement and competitive interview used in the Universities and in recruitment for the Civil Service itself still seems to be the most objective procedure available, but this is not used in practice for appointments to such bodies as the Data Protection Committee or the proposed Authority. I certainly hope the Authority will not emerge as a self-perpetuating body setting up its own system of succession. Obviously careful thought needs to go into this question.

So far as the licensing of personnel operating data banks is concerned, I have explained above why I believe it is important to 'control' the people involved as well as the organisation keeping the data bank. Here "control" can be assisted by the existence of a national professional body or bodies whose standards include a code of ethics and a code of good practice attuned to the needs of the situation. Whether or not the societies concerned maintain rigid restrictions on entry to qualified persons is perhaps less important than their members should accept the need for a degree of responsible discipline in their work. The Swedish Computer Society for example whilst subscribing to the latter concept has yet to embrace the former and may well never do so. But I have no doubt that its existence is of value in operating their Data Act.

The B.C.S. would not, I believe, wish to seek a monopoly under any licensing system, but would certainly seek to ensure that its membership at an appropriate level would carry with it automatically a license to practice at a licensed installation, and this would undoubtedly simplify and strengthen the implementation of a licensing scheme.

CONCLUSIONS

The White Paper has gone a considerable way in the direction pointed by the Younger Report, and, in particular, to satisfying the various concerns expressed by the British Computer Society in its submission to the Younger Committee, as developed subsequently by the Privacy and Public Welfare Committee of the Technical Board. As I have indicated, there are a number of matters still to be defined and worked on before an Act is finally introduced—indeed, more than I have had time to develop here. The various Committees of the B.C.S. within the Technical Board are already at work on these with a view to making a submission to the Data Protection Committee, with whose work they hope to be even more closely associated than they were with that of the Younger Committee. I am proud to be associated with this effort, which, I feel is helping to maintain in the U.K. the high standards of liberty and open Government for which we are renowned. I am also very grateful to the organisers of this Conference for giving me the opportunity to present this report to those who share our concern that computer systems should be used to the advantage and not to the detriment of individual liberty.

APPENDIX—BCS POLICY ON COMPUTERS AND PRIVACY

Preamble

The BCS has 22,000 members from all elements of the computing community, by whom it is guided and influenced. As such it is aware of the existing and potential impact of computing technology on the personal and economic lives of us all.

The BCS recognises that computing techniques have much to offer in improving the general quality of life of both the individual and the community. Computing technology is an asset of such power for assisting us to attain real wealth that it becomes essential for it to be used effectively.

Any source of power may be used or misused—the issue of privacy and computers is concerned with ensuring that control may be exercised in such a way as to avoid and prevent the misuse of personal data and in so doing also to encourage the beneficial use of such data.

Computing within our community has attained a stage at which legislative control is required as the White Paper of December 1975 acknowledges.

The policy

1. The policy of the BCS is to encourage the effective use of computing for the benefit of individuals and society and we believe that all regulatory measures to be introduced should reflect this positive attitude.
2. There is a need for legislation to control the use of personal data held on a computer.
3. The regulatory measures should apply to both the public and private sectors.
4. Regulation should be carried out by licensing.
5. Regulation should be associated with appropriate enforcement procedures.
6. The Regulatory measures should include a complaints and appeals mechanism available to organisations and the general public.
7. Regulation should involve the approval of the original purpose and any subsequent revisions thereto for which personal data is collected and processed.
8. The Licensing Authority should have the duty to disclose the existence and purpose of collections of personal data unless it is satisfied that substantial reasons exist to the contrary.
9. Regulatory measures should include the definition of the responsibilities and duties of individuals engaged in a licensed function affecting personal data, together with the authorisation of those individuals.

The Society believes it to be desirable that the Regulatory Authority should be wholly independent and preferably self-financed. However, although data processing costs are currently falling the expenses of the regulatory measures to be embodied should be arranged so as not to inhibit the wider exploitation of computers.

Human and organizational implications of computer privacy

by JERRY M. ROSENBERG*
Polytechnic Institute of New York
Brooklyn, New York

ABSTRACT

The computer was created to serve man. With increasing reason serious questions are being raised pertaining to the potential misuse of the computer. Specifically, the issue of privacy has come to the public's attention as cherished liberties and psychological needs are gradually being eroded as the technology of the computer expands.

Recent discoveries have shown how men desiring power can utilize data for their own benefit, leaving the person intruded upon with little recourse, or for that matter, any knowledge of the invasion into his private world.

This paper identifies the many implications of loss of privacy on man's ego, dignity and general ability to cope with these forces. Failure to possess privacy can lead to withdrawal, loss of productivity, lack of confidence, physiological deterioration and other conditions of mental and physical decline.

A significant portion of this paper details the protections that can be incorporated, primarily technical, to preserve the balance between the need for society to know and the need of the individual to remain independent. The basic conditions for man's well-being are being tested along with the foundations of our governmental traditions.

At present, computers have an almost limitless capability to store, intermingle and, at the push of a button, retrieve information on persons, organizations and a variety of their activities, all without the knowledge of those involved. Even now, stacks of punched cards and tapes store statistics about us that we may not know exist. We might never escape in time or distance the bureaucratic machinery keeping tabs on us.

With present technical capability, it is possible to develop a composite picture of an individual that can be stored in a single information warehouse. Each year we offer information about ourselves which becomes part of the record. It is often scattered across the continent and is usually inaccessible except after considerable effort. It begins with our birth certificate and is followed by a series of medical notations. Early in life we are documented as an added income tax deduction by our parents. Then there is information on what high school, public or private, and what college, public or private, we attended. At school, records are made of our abilities, grades, tests of intelligence and attendance. For some, there will be car registration and driver's license, draft status, military service or Peace Corps. Then job history is recorded —working papers, Social Security number, a first job, our performance with each employer, recommendations, and references—all this makes an interesting dossier. Then perhaps, a marriage license, a home mortgage, and when children come, the cycle begins anew. Should we divorce, the court records will be added. These would increase should we be arrested, convicted or serve time in prison. And of course, when we die, a last footnote is made.

In our daily activities we leave behind a trail of records: the credit card carbon for a luncheon meeting, the receipt from the hotel where we spent last night, our airline ticket, the check we cashed in a city bank, and the bill for the toys we charged for our children.

There are also government dossiers including tax returns over a number of years, responses to census questionnaires, Social Security records, passport files, and perhaps, our fingerprints and military intelligence reports. If we have worked for a defense contractor or for the federal government, there are lengthy files on us that may note our associations and affiliations.

Information is power. These records may at various times be of considerable interest to people inside and outside a specific government agency. Years after our birth, for example, an interested party may be happy to pay for information from our birth certificate which is officially confidential. And in a number of cities there are entrepreneurs who obtain and sell this in-

* Dr. Jerry M. Rosenberg is the author of "The Death of Privacy —Do Government and Industrial Computers Threaten Our Personal Freedom?" (Random House, 1969). *This paper is based on testimony before the Senate Judiciary Committee on Constitutional Rights.*

formation as well as hospital records, police records, immigration records, and so on.

Confronted with the erosion of his privacy, the individual American has until now had the consolation that all these files have been widely dispersed and often difficult to put together. It has been a time-consuming, expensive proposition to compile a sizable file on any individual. Giant computers with their capacity for instant recall of a great variety of available information are changing all this.

The evolution of computerized complexes without effective public participation and protest can have a serious impact on our democratic process. Under our present system, individuals are expected to make fundamental choices where the future welfare is at stake, as would be the case in an election. By alienating the people from the decision-making process, control of the computer technology is left in the exclusive hands of those in possession of organizational power.

The public itself should question the drift of these technologies. We should want to make certain that human dignity, psychological well-being and civil liberties remain intact. We should demand to know the precise nature of the information that will be stored and who will have access to it. The public has the right to know who will have the power to control the computers and most importantly, how confidentiality and individual privacy can and will be protected.

Liberty is never gained once and for all. It is forever in conflict with civilization—a conflict which has no clear-cut solution but which reappears in cycles, usually in different forms. Each succeeding generation must win it anew. Each must defend it against ensuing dangers. This is necessary because we are constantly changing our life environment; society may be altered so frequently that safeguards that in the past adequately protected our liberties become obsolete.

Science and technology are of immense benefit to society. These advances are so important to us that we would not want under most circumstances to impede their movement in advancing our knowledge of the world. But they may also expose us to potential danger—to a pollution that could curtail our anonymity, solitude and privacy. Unless certain practices in the technological exploitation of scientific knowledge are restrained, they will cost us more than we should be willing to sacrifice.

And we must constantly evaluate these technologies which are tools developed to increase man's power to understand his world. The mere fact that an innovation presents itself does not mean that we should surrender years of experience and values to its authority. Yet it is difficult to bring social pressure to bear against the control of potentially dangerous technologies. One reason is that those who have the use of the technology are influential enough to prevent societal, or for that matter, legal restraints.

That privacy will forever remain because it is implied in the Constitution and Bill of Rights is not credible to the new adult population. With growing hostility toward the dominating technology and the establishment, a segment of this group fear that the documentation of their so-called acts of rebellion will only show that the freedoms once assumed have been surrendered. Should our older citizens in power fail to come to grips with the issue of preservation of privacy, it can be expected that the last struggle will be made by those who question how their present behavior, if documented, could be used against them at some future time.

The computer cannot be blamed for the loss of privacy. It is but an instrument created by man. Computers and other advanced machine systems are not permitted to be in error, but man is not a machine and does not have to be as efficient as the tools he has created to serve him. If man loses his right to be wrong, will he react by withdrawing from society? Will his curiosity to experiment with life falter? If this happens, man truly becomes nothing more than a machine.

Of course, not all computerized systems contain potentially damaging information. Some operations merely act as accounting systems and high-speed calculators, while others at more sophisticated levels are depositories for internal decision-making; some store research information from diverse sources; and some are documentors for the purpose of assimilation and distribution of pertinent data to a large community.

Not all computerized complexes contain the "sensitive" or potentially "threatening" information that might be found in a computerized system designed to collect personal data. But the possibility of incorporating such information does exist. Even the rather elementary, antiquated computer has the potential for being an information storage center. It doesn't matter whether it is formally called a "bank" or a "single unit processor"—any capacity to collect, store and retrieve data instantaneously upon request may, if misused, infringe on personal privacy.

There is little doubt that as computerized communications systems spread throughout the nation and world, surveillance by data processing is bound to increase. If the trend continues, it will soon be possible to have all personal information about an individual gathered on a continuous basis and held indefinitely until requested. The snowballing effect is quite pronounced here. When the decision is made to purchase a computer, more data are gathered about the employees, customers or taxpayers who are of interest to an organization. Although this may provide for better services, improved decision-making and policy-programming, it also provides personal information about individuals never known before the advent of computers.

ALONG THE ROAD TO PSYCHOLOGICAL SUBMISSION

Today man lives in an atmosphere dominated by the machine. He brushes his teeth with an electric toothbrush; prepares his meals with mechanical toasters, ovens and broilers; works in an atmosphere of motors, switches, fans, typewriters; goes to and from home by car, bus and train; reduces the chores of home life with sewing machines, washing machines and drying machines. In the past only the craftsman used the tool. Today all of us take machinery for granted. As long as machines served us and did not threaten our rights as persons, we welcomed technology.

The charm of the horse-drawn buggy yields to the modern automobile; the candlestick maker is not needed in this day of electric power; the complexities of the abacus are incorporated into the computer's memory unit. Often we are glad to say goodbye to what we leave behind because many innovations free man from monotony, physical effort and waste of energy.

Computers are part of this advance, aiding us in ways that are valuable for our everyday living and essential for progress on all levels. Much of what has been achieved in medical research and outer-space exploration would have been impossible without the wide range of sophisticated computers.

Unfortunately, sacrifices frequently accompany these changes. With all the splendid wonders of the computer we find ourselves asking: has man become submissive to the computers of today? Can each individual profess to be more human in his actions than the complex system he has developed to assist in daily endeavors? Will there be a growing tendency to create a world where we treat each other as machines? Are we building more barriers which prevent the individual from having the opportunity to evolve his own unique potential—to be self realized?

Man submits more and more as his ability to make choices about and control his future is gradually taken away from him. He is willing to have the machine make numerous decisions for him about his future; he is willing to permit the machine to build towers of brick and metal, hoping that it will not fail him when he has to live or work in them; he is willing to have the machine process his life's facts, hoping that it will be accurate and objective.

It seems that we are not aware of what is happening to us—that we are losing a little each day to the machines. We are usually too busy to think about matters which seem on the surface not to be so "important" as whether our cars are safe, or the price of bacon or the way taxes are skyrocketing.

What is most disturbing to the American population is the undemocratic process which starts at birth to make people believe that they are unable to say "no" to divulging personal information, thus perpetuating a collection of data that will follow them for the remainder of their lives—"frozen in time and the computer."

People want to determine for themselves in every particular situation of life just how much of their complex beliefs, attitudes and actions they choose to disclose. To the American, this data is more than just statistics. It is the data of judgment, a possible last judgment that can affect their schooling, employment possibilities, promotion, or role in the community. The citizens of this country want to have the right to a personal diary that is away and free from the organization's outstretched hands. They plead the case that if all their actions were documented, including their mistakes, it would be difficult to close a page of one's life and start anew. It would be a tyranny over mind and destiny.

To maintain their dignity and fill their need for psychic distance, people construct mental walls around themselves. To be a total psychic being, with stability and confidence, forces people to reject being intruded upon without permission. Psychologically, privacy demands a delineation of the self, the acceptance that each of us is unique and separate from all others. It recognizes an empathy toward the finer qualities within man. It demands the perpetuation of a private psychic domain, displaying a defensive shield against psychological penetration, unless authorized.

There is a growing antagonism against people desiring power, who will through mental coercion try to intrude upon our concealed thoughts. Unfortunately, we have learned that the man who wishes to gain control will employ various techniques to influence and force individuals and groups into submission.

People have a right to remain unique and different. But there are many, and indeed the number is growing, who intentionally or by title of their office, are against the solitary man. They may envy his uniqueness. They want to keep a close watch on his behavior so as to anticipate future moves, often defended in the name of science or national priority. They too often regard his privacy as a denial of their own mechanized psychology which has a stereotyped and oversimplified answer for everything.

COMPUTER COMMUNICATION AND PRIVACY PROTECTION

A major problem in protecting our privacy is that too often we believe in the principle that the ends justify the means. When we consider that the goal is the greater good of our people, we cannot understand why a specific intrusion should be prohibited. The result: gradual erosion of the value we place on individual privacy. Sometimes we are confused and become easily convinced that a particular device that may lead to personal intrusion is warranted on other grounds, such as purposes of security. This is an inadequate argument I believe.

As computer networks spread throughout the country and world, science and privacy must be able to thrive together. We will be collecting thousands of facts about everyone, depositing these details into the unforgetting computers of the future. To date there are no adequate legal protections to safeguard the individual against computer leakage. Furthermore, laws alone will not offer satisfactory protection in the face of widespread use of these systems. Although laws can impose penalties for violation and can set the limits of proper safeguards, legislative actions have not always been effective in the control of surveillance activities like wiretapping and eavesdropping.

There is reason to hesitate before passing new legislation that might in fact backfire. Laws that give special agencies or departments the responsibility of investigating those who break the law would be introducing yet other bodies that decide who can know what, thus putting a new decision-power in the hands of a few.

We have to make sure that information given to a specific organization will not be shared in such a way that the person's identity will be discovered. It is necessary to specify those who may use certain technological devices. Neither the principal of a school nor a personnel director should be allowed to enter at will the dossier on a potential or present student or employee. The question of duration of surveillance is most important. In addition, we need to determine what kinds of electronic devices are appropriate and permissible.

We must define the penalties that would be imposed on those who disclose information improperly or without authorization, and we must regulate the use of information for purposes other than those for which it was originally obtained.

We must also bear in mind that we are dealing with a super-technology that will become increasingly complex and difficult to evaluate. It is safe to assume that probably the only persons who will understand the complexities and operations of these systems will be the computer designers and systems engineers who are directly responsible for the evolution of the industry.

Safeguards can be inserted into a system in use, but it would be more efficient and less costly to build them in at the time the computer is designed. The burden of a great deal of the responsibility must lie with the computer manufacturers. If they want to avoid external regulations, they will have to start thinking about how to design systems with built-in safeguards.

To date, the best attempt to identify the relationships between computer surveillance and invasion of privacy has been outlined by Petersen and Turn of the Rand Corporation. They visualize two types of disclosures of information—accidental disclosures resulting from failure of the computer, and deliberate disclosures from infiltration of the system. They suggest countermeasures to prevent surveillance of data within a computerized system.

Unfortunately, essential safeguards are not as easily attained as is suggested by some of these outspoken specialists. It is one thing to design countermeasures as they apply to the "general" concept of computer leakage; it is quite another matter to build in protections for a specific computerized system.

For example, few can find fault with Petersen and Turn's countermeasures but they are merely a theoretical framework for the complex changes that are needed. These countermeasures offer little assistance to those attempting to design a surveillance-proof computerized system in the medical field, in an educational community, for a corporation or for a government repository. Examples of a specific computer utilization within a defined framework are necessary. The rules that apply for one computer installation might be inadequate for another or might fail to respond to the more crucial or pressing needs.

There are certain general rules of conduct pertaining to *all* computerized data centers that should be followed in order to increase confidentiality and reduce information leakage:

1. Let people know what their records contain, how they are used and protected, and who has access to them.
2. Employ a verification process to insure accuracy of data; in addition, permit the individual to review the data for accuracy, completeness, current application, and freedom from bias.
3. Categorize all stored information as intimate, private and therefore non-circulating (such as physical, psychiatric and credit information); pertinent, but confidential and having limited distribution; or public, and therefore, freely distributed.
4. Regard personal data as personal property, requiring permission for its use, and punishment for its improper use.
5. Appointing an ombudsman agency—or a committee that represents all levels of the organization—to take major responsibility for hearing and responding to complaints, and to determine appropriate measures to minimize leakage.
6. Record each request for access that is made, along with the authorization.
7. Make security checks on computer personnel.
8. Assess, from time to time, people's attitudes toward and anxieties about the issue of invasion of privacy. Such studies could be useful in determining what form of records would be most acceptable.
9. Periodically review and update the adequacy of the physical safeguards. Employ capable outside consultants to attest to the safety of the

systems used, and to assist in the development of appropriate technical devices (such as scrambled data and code names), and

10. Allow psychological seclusion and withdrawal from accountability to remain as a permanent stronghold of our value system. The individual must freely choose whether or not he wishes to become submissive to the power of the computer.

A creative response by the computer industry to its technology will probably serve, and satisfy, the public better than rewriting our laws. In fact, one can doubt that legal measures—although necessary—will be as effective as technological adjustments in the protection of the public's privacy.

What is needed before the establishment of large computerized centers is a rigorous research effort to answer the following unresolved questions:

1. What are the purposes of a computerized central facility? What kinds of information are strictly relevant to these purposes?
2. How much information about an individual is required to guarantee that such services are useful to the person, community and nation? How accurate, objective and challengeable is the information?
3. What are the procedures for the sharing of the system?
4. How will individuals be protected from the creation and distribution of derogatory data caused by clerical mistakes or computer malfunction?
5. Will procedures be developed to permit individuals to see their files?
6. Will the cost of such a facility be justified in terms of future savings?
7. Will there be adequate safeguards to prevent penetration from the outside?
8. In whose backyard should computerized centers be physically established?
9. Will a computerized center officially created as a statistical system eventually become a storehouse of personal information? and
10. Does the concept of computerized communication centers suggest a changing value system and further intervention in the lives of Americans?

The burden of proof of the security of the data facility should lie primarily with those who propose it. They must demonstrate that they can create a virtually impenetrable and incorruptible system and justify its greater economy and expanding service.

The dialogue has just begun. The right to preserve privacy is a right worth fighting for. Events of the past several years clearly point to the need for a redesigning of our communications protections. Computerized systems offer great potential for increased efficiency; yet they also present the gravest threat of invasion of our innermost thoughts and actions. Transactions of our personal movement will glut the records and offer a very up-to-date picture of how we conduct ourselves in private. Some see this trend as leading to an Orwellian nightmare with Big Brother watching over us and reporting to the central record-control authorities any behavior adjudged out-of-line with stated policy.

We are slowly drifting into a world of nakedness. Each year an increasing number of technological devices invade the world that once we considered private and personal. In spite of this, we are still confident that our lives, activities, ideas, thoughts, and sensations are shared with no one unless we so choose. Will this confidence be perpetuated? Echoes of Watergate, CIA spying, domestic surveillance, wiretapping, etc. may well have shattered any future acceptance by the public. An uphill effort is required.

The snowballing effect of computers is very real indeed. The more you know, the more you want to know and the better your methods will become to get and integrate this information. In the end, will there be any place to hide?

Computers may continue to prove themselves the worthy servant of man. But the servant must yield to his master, and the necessary thought must be given to developing essential safeguards. The computer manufacturers have thus far shirked their responsibility, but they cannot long remain bystanders if they wish to continue to make their own decisions. Both the manufacturers and then the consumer must seek ways to control the all-documenting, all-remembering computer systems and demonstrate that machine technology need not necessarily bear the stamp of increased surveillance.

The ultimate submission must be of the machine to man. If we fail to act immediately to preserve our claims to anonymity, psychological independence and seclusion we may develop a permanent fear—a fear to enjoy the fuller opportunities of life. We will hesitate before experimenting with the challenges of the world. We could become carbon copies of one another—conforming, dull and psychologically equivalent to the computer—heartless and non-emotional.

A control systems model of privacy

by JOHN SALASIN
The MITRE Corporation
McLean, Virginia

ABSTRACT

Concerns about individual privacy, specifically in relation to automated data systems containing personal information, are considered in terms of a feedback control system model. This model provides a framework which appears to relate many separate concerns which individuals or groups have expressed about privacy. It also provides a framework which may be suitable for analyzing legislation or regulations promulgated for the protection of privacy. The model may assist in defining needed research on the need for privacy, or on the impact of inadequate protection of privacy.

The model posits that data systems pose various "threats" to privacy depending on the extent and manner in which the existence of such information systems hinders the ability of individuals or groups to provide feedback to systems which affect them.

INTRODUCTION

A recent workshop addressing "The Privacy Mandate"[1] reached consensus that "our current lack of understanding about specific needs for, and feasibility of, implementing comprehensive privacy laws indicates a need for continuing research in many areas." One of the areas of research suggested was the "privacy needs and desires of individuals as affected by situations, culture, and economic level." Comments from the floor, following presentation of workshop findings, included the statement that:

> *"Proposed legislation seek to deliver and protect a 'right of privacy.' Nowhere is such a right identified or defined. We recommend that present efforts be redirected, at least in part, towards the development of a clear and complete identification of the nature of privacy as a concept, perhaps several concepts, depending on varying situations."*

This paper presents a model which may be useful in developing an "identification of the nature of privacy," at least as the concept of privacy applies to the use of information systems containing personal data. The concept of privacy employed in developing the model is broader than that of information security. It is, rather, based on Westin's view that privacy is the claim of individuals, groups, or institutions to determine for themselves when, how and to what extent information about them is communicated to others.[2]

The model incorporates concerns which individuals have expressed about computerized data systems containing personal information and regulations which have been promulgated to address these concerns in the framework of a feedback control system.

The model attempts to separate concerns about the privacy impact of computerized information systems from inherent characteristics of such systems. These inherent characteristics include, for example, potential reductions in the cost of processing large amounts of data, the potential for updating and checking the accuracy of files more frequently (or for increasing errors due to improper coding and transcription), and the use of more "objective" (e.g., coded) information. These "characteristics" do not, in themselves, necessarily raise concerns about privacy. The model is based on the premise that such concerns can be explained (and studied) by viewing automated personal data systems as control systems, rather than through examination of such inherent system characteristics.

The material presented is based largely on testimony presented before the Secretary's Advisory Committee on Automated Personal Data Systems and on literature cited and recommendations made in that Committee's report.[3]

A CONTROL SYSTEMS DESCRIPTION OF INFORMATION SYSTEMS

Control systems can be roughly categorized as being of two types. The simplest type of control system employs "external" control, or control unresponsive to the output of the system being controlled. Many control systems which utilize personal data have traditionally been of this type.

The credit reporting industry, for example, controls the issuance of consumer credit by providing data to indicate an individual's eligibility to receive credit.

Until passage of the Fair Credit Reporting Act, however, individuals affected by the system were often not aware of its precise nature. They could object to the fact that credit had been denied, but had little opportunity to provide feedback to the control portion of the system (i.e., the particular credit bureau providing information). The difficulties experienced by individuals who have attempted to correct erroneous bills from gasoline companies or other credit-granting organizations indicates that someone affected by the system may not be able to provide input to the control system which determines, in this case, his ability to purchase goods using the credit instrument.

A second type of control system employs "feedback control," or a control which is determined partially by the output of the system being controlled. An automated oil refinery serves as an example of this type of control mechanism. External controls, such as market demands, availability of crude petroleum products, etc., are used to determine an "optimum mix" of output products. An attempt to operate the system considering only these external factors could, however, lead to a major explosion at the oil refinery, since the output products of the refinery must also be related to the current state of the chemical processes involved. While running the refinery without external controls would be uneconomical, running without feedback control based on the temperature and pressure of ongoing reactions would be catastrophic.

Feedback in the control of social systems can be taken to represent the ability of individuals or groups affected by a system to respond in a manner which might modify the behavior of the system. In the case of an information system containing personal data, this response is not a primary input to the system itself but, more accurately, a feedback signal to the control portion of the system. Any loss of feedback is, in this control system approach, equivalent to eliminating the potential for input from the persons affected.

While most physical systems allow a relatively clear distinction to be made between input and feedback signals, such differentiation may become difficult in social systems since both input and feedback information is often provided by the same person or group. In some state welfare systems, for example, eligibility is determined primarily from a declaration provided by the applicant. Such information could appropriately be considered as input. Feedback might take the form of an individual's objection to a decision reached in his case, or in a larger sense, societal reactions to the management of the welfare system. Feedback is thus characterized as representing input generated in response to prior system output. We emphasize that elimination of this feedback is not an inevitable consequence of automation. It can be avoided if care is taken in the design and operation of systems.

There are two types of concern about automated data systems. First is concern by an individual who is directly affected by the system (e.g., a welfare recipient), and therefore is highly concerned about his inability to provide feedback. Second is the concern of individuals who, though not directly affected by the system, are concerned about the institution's effectiveness in serving the interests of the public.

POTENTIAL HARMFUL EFFECTS OF AUTOMATED PERSONAL DATA SYSTEMS

An individual's feeling that he is unable to provide feedback to a system affecting him may reflect seemingly rigid and impersonal treatment of him by organizations maintaining data systems. This feeling can be heightened by the very nature of computerization. Computers are programmed by supplying specific rules for operations to be carried out on the data being processed. While any well-designed system includes provisions for processing both the normally expected data and all foreseeable exceptions, the data used for input must conform to pre-established rules. It is, for example, often expected that numerical values will be within a given range or that an individual's name will consist of alphabetic characters only. While such expectations are often reasonable, they do impose artificial limitations. The existence of rigid procedures may make it necessary for individuals to interact with the system according to *its* rules. This is, in itself, a block to providing feedback to the system.

An individual's feeling of inability to provide feedback may also be created by a system's reliance on records, as opposed to personal contacts, in making decisions about individuals and groups. Such reliance on records may be inappropriate if the record used to make a decision does not contain enough information or have enough reliability to be the basis for a "just" decision. Relying on records for decision-making will, because of economic necessity, place a much greater emphasis on stored, and hence possibly old, information. It is evident that a greater reliance on records is aided by the fact that the computer has made the records more readily accessible, often cheaper to obtain, and therefore more convenient to use than information collected and verified by personal contact. The economics of computerization makes it possible to rely on computers for low-level decision making (e.g., initial screening for job candidates) when dealing with large populations of individuals on whom one has readily accessible information.

As a side effect of this reliance on records, individuals are concerned that unequal treatment may accrue to various segments of the population because of the extent to which their lives are documented by automated records. The comprehensive record-keeping practices of such institutions as the military, psychiatric hospitals, and correctional institutions combine with the fact that poor, black, Spanish-speaking, and unskilled individuals are more likely to be drafted, have a criminal record, have a mental illness or deficiency treated in a state institution, be on welfare, and enroll in a government retraining or special education program. Thus these individuals will be trailed by a far greater volume of possibly derogatory computerized records than most middle or upper class Americans.

There is a diminished opportunity for individuals to "make a new start," free of the records of their past activities. The greater accessibility of more data, much of it obsolete (due to an increased storage, linkage, and retrieval capability without sufficient provision for expunging old records) leads, as was previously noted, to a greater institutional reliance on records. If there are no legal constraints on informal exchanges of data and on the amount of time that data can be maintained in a file, the danger is increased that institutions will use old and possibly inappropriate records in reaching decisions.

The two effects mentioned (i.e., rigid treatment of individuals and reliance on records) might cause other effects which contribute to the concern of individuals over their inability to provide feedback to systems. The rigidity of a system may lead to distorted interpretation of data by the compression, standardization, and oversimplification of data elements. This fitting of people to codes rather than codes to people leads to misinterpretation of the data. Thus, while a police blotter might show that an individual was arrested "for refusing to supply positive identification on request," the National Criminal Information Center (NCIC) may be informed, because of the required standard code, that the individual was charged with "resisting arrest." Poorly designed systems might be characterized by the statement that: "It can't be done if there isn't a code for it." People appear less likely to have feedback worries if they feel able to present "their side."

Individuals are also highly concerned that organizations will make decisions about them without their knowledge. People fear unwarranted, peremptory, or discriminatory institutional responses to non-conforming behavior which is detected covertly using computer analysis. They are concerned that institutions will use personal data contained in data banks to detect and respond to behavior considered (by the institution) to be undesirable. The ability of the computer to rapidly retrieve and analyze large masses of data facilitates "browsing" through records in an attempt to determine relationships among the data. For example, computers might be used to identify a small percentage of families in a given city that account for substantial portions of the serious crime and/or welfare caseload so that discriminatory action might be taken against these families. The significant element to this concern is that there is no opportunity for the individual to provide feedback to affect these actions.

As more social functions become controlled by data systems, it becomes harder for an individual to register objections about the fact of inclusion in a specific system. To participate in society we are required, depending on our age, class, education, etc., to be included in files of students, drivers, members of a particular profession, patients at a hospital, or other files pertinent to our activities. A student in a migrant farm worker's family appears to have little choice regarding whether or not his records are maintained in the "Uniform Migrant Student Transfer System." Even if he, his parents, or his teachers were able to provide feedback regarding the accuracy or completeness of information stored, could feedback be provided which registered his objection to being labeled a "Migrant Student"? While the computer may not have caused society's desire for information, it has made it more feasible to use this information in the control of social processes. The resulting pervasive nature of such computerized information systems, combined with the rigid classification procedures often applied, tends to limit the manner in which individuals can provide feedback to control systems employing the technology.

A feeling of individual powerlessness is, to some extent, contributory to the second type of concern about the use of automated personal data systems; that the use of such systems by institutions may weaken the institution's effectiveness in serving the interests of the public. If individuals do not feel they can have an impact on organizations making decisions about them, they may not believe the organization is fulfilling its social mission. This feeling may be evidenced in increasing distrust, fear, or frustration of individuals and groups in regard to institutions; these feelings may be promoting a notable reserve or hostility in dealing with record-keeping operations. If the process of computerization in a large organization is not visible to the individuals affected; the individuals may feel, correctly, that they are denied opportunities to provide feedback to the organization.

There is also growing skepticism about the effectiveness of the institutions in meeting their own organizational goals. The reduction of feedback can cause such skepticism by reducing the ability of individuals and groups to contest the acts of institutions, which, because of their control of large data bases, may claim to have "the true facts," "more persuasive evidence," or "more comprehensive view" of an issue. Distortions or misinterpretations of data which reflect assumptions underlying the design of the data system might result in policy ill-suited to the goals of the organization.

The tendency of institutions to "blame it on the computer," combined with the specialization inherent in computerized operations, may result in a diffusion of institutional and individual accountability for decisions and their effects. It becomes difficult for either an organization or an individual affected by the organization to assign responsibility for decisions arising from erroneous data or programs. For example, an error could occur because the input data were not correct, because input data represented a special case which the computer program was not designed to handle, or because the output data were interpreted erroneously.

Related concerns arise over the unintentional erosion of the autonomy and authority of institutions. As economies of scale cause institutions to pool data bases and computer hardware, it is difficult to determine which agency has the responsibility for maintaining the data or the right to access certain portions of it. Such an erosion of autonomy seems particularly significant in systems which combine police and court records or in data bases shared by Federal and State governments, since combination of these systems may result in a blurring of the separation of powers. It is currently common practice to allow private insurance companies access to drivers' license records maintained by State governments; such practices might weaken the distinction between the public and private sectors.

All of these effects create a concern that social institutions employing automated personal data systems are out of human control. The individual feels that he is unable to provide feedback relating to either the goals or method of operation of an institution.

LONG TERM SOCIAL EFFECTS

Feedback is generally designed into physical systems to provide stability in the face of varying inputs. The higher the "gain," or amplification factor, of a system is, the more necessary that feedback be employed to prevent small disturbances in the input from causing major perturbations in the output. Automated personal data systems, having the ability to process more records more rapidly than manual methods, might be thought of as processing a higher gain (i.e., variations in the system itself, or systematic changes in input data, may have a greater effect on a larger number of people).

In addition to the immediate effects of the misuse of automated personal data systems, any widespread feeling of individual powerlessness in affecting institutional behavior may result in major social changes. Such changes might include: increased social isolation accompanied by hostility between those responsible for social institutions and those served by them; increasing skepticism about the effectiveness of institutions, leading to a state of anarchy as the institutions cease being able to function; or the establishment of a new "ethic" which, contrary to western (American) tradition, negates the concepts of "free will" or "self-determination." While it seems improper for us to make value judgments respecting the nature of society in future generations, we have an obligation to prevent such changes from occurring without review. Individuals should be allowed the opportunity to provide feedback to the process of social change. If particular elements of automated personal data systems might induce such changes, people should be able to provide feedback which could modify those elements.

FEEDBACK CONSIDERATIONS IN THE PROTECTION OF PRIVACY

Just as the concerns of individuals about privacy can be expressed in terms of their ability (or inability) to provide feedback to systems, so regulations promulgated to protect privacy can be analyzed in terms of the ways in which the regulations foster or inhibit feedback from individuals or groups.

Information systems might be considered in two categories for determining types of feedback appropriate to a system. The first category includes those systems used for entitlement or classification of individuals, thus directly affecting the file subject. Examples might be credit files, school records, medical files, or police records. The second category, "statistical systems," includes systems which may not affect the individual file subject directly but are used by organizations for planning and evaluation. The decennial census of individuals in the United States is an example of such a system, since these data are used extensively for policy decision making.

Statistical systems may or may not contain sufficient information to allow data to be linked to specific individuals. Those which do not contain personal identifying information (e.g., name, address, social security number, etc.), cannot easily be used to directly affect individual file subjects. If such identification is maintained however, information in the system can be used in a manner which directly affects the individual. If a given system is used both for making decisions about individuals and for statistical purposes, several forms of feedback may be required.

Many of the factors which influence the design of feedback control to physical systems may also be applicable to ensuring feedback to information systems. It is, for example, extremely important that the output effects being used to determine the feedback control are, in fact, the "right" outputs. If the system being controlled is not understood completely, the relevant outputs may not be discernible. A simple example might be that of a husband and wife sharing a double bed with an electric blanket that has separate controls for each side. In this hypothetical situation, assume that the controls have been switched inadvertently, so that the control on one side of the bed controls the temperature on the opposite side. Considerable difficulty arises if the wife attempts to turn up the control on her side of the bed; the husband begins to get too warm and turns down his control. The wife, realizing she is not getting warmer, turns the control up further; how long the procedure continues depends on the tolerances of the individuals involved.

The problem in this situation is that inappropriate output is used to generate a feedback control signal.

Each person is providing feedback based on the temperature on his or her side of the bed, rather than on the temperature of the opposite side, which is actually what each controls. The appropriate output for each to react to would be the spouse's comment that one was either too hot or too cold. Adjusting the control based on this verbal input rather than on the temperature of one's own side of the bed would better insure that an appropriate control was applied. In a complex social system it becomes even more difficult to be sure that all relevant output effects are included in an appropriate feedback loop.

We are concerned not only with what output effects are measured, but also how they are measured. If effects are measured periodically, rather than continuously, we run the danger of being unable to tell what the true output is. Shannon's sampling theorem states that if a varying signal, or wave, is measured by sampling at time intervals, the sampling rate must be at least twice as great as the highest frequency of variation in the original signal if we wish to reproduce the signal. If we were to assume that bicycle theft varies cyclically, with a periodicity of one year and a maximum occurring in July, any conclusions which were reached about bicycle theft in this country might be biased if measurements were taken only in the month of July. An erroneous picture of system output can make any feedback employed ineffective.

The output effects measured and the method by which they are measured contribute to the effect which feedback has on the system. Control science differentiates between "positive" and "negative" feedback. While negative feedback will tend to dampen oscillations in the system, and thus promote system stability, positive feedback may accentuate such oscillations and lead to system instability.

The delay inherent in a feedback loop can have a major impact on the effect of feedback. A feedback signal which normally acts in a negative manner and, therefore, improves system stability may, if an appropriate delay is chosen, create system instability. While it becomes difficult to make firm analogies between a physical system and a far more complex and variable social system, we might consider court processes to represent a potential delay in social systems. If each feedback action initiated by an individual or group experienced a two-year delay while awaiting judicial action, the delay might be capable of causing system instability.

FEEDBACK ANALYSIS OF PRIVACY REGULATIONS

Recommendations made by the DHEW Secretary's Advisory Committee on Automated Personal Data Systems,[3] many of which were incorporated in the Privacy Act of 1974, can serve as an example of how regulations to protect privacy can be analyzed in terms of a feedback control system model. Thus, for example, the Committee recommended that individual data subjects be provided the following rights:

(1) To be informed of his (or her) right or privilege to refuse to provide data about himself and of the consequences of such refusal. Such notification should allow an individual to make an informed decision about whether or not he wished to be included in a given system. This most fundamental type of feedback, allowing an individual to decide about his own inclusion in a system, is essential to enabling feedback.

(2) To be informed (upon request) that he is the subject of a record contained in a system and to obtain the data contained in the record. Individuals must be aware of both their inclusion in a system and of the information stored about them if feedback is to be possible. While informing (automatically) an individual that he is a data subject without his requesting this information would go further towards facilitating individual feedback, the Committee found that such a requirement might be "needlessly burdensome to some organizations."

(3) To have assurance that data about him are not used for purposes other than the stated purposes of the system without his informed consent and to inform him (upon request) about the uses being made of the data. An individual should be allowed to provide feedback regarding the use of information about him. Individuals should be allowed to provide feedback relating to dissemination (and additional uses) of information about themselves; both because the dissemination itself may affect them and to alert them that another organization may be making decisions about them based on the data.

(4) To contest the accuracy, completeness, or pertinence of a record or data, and to alter the record or data as necessary to assure its accuracy, completeness, or pertinence (i.e., mechanisms will be established to allow feedback).

These requirements are designed to allow individuals to provide feedback regarding whether or not they wish to be included in a system; the accuracy, completeness, or relevance of data contained about the individual in the system; and potential uses of the record both inside and outside of the system.

For those systems defined as "statistical," whether or not personal identifying information is included, the ease with which an individual can assure himself of the accuracy, completeness, or propriety of a record about him may be less significant. Random data errors in individual records might not affect the statistical uses to which the data are put as long as the error rate was reasonable. The feedback capabilities provided for such systems must allow interested individuals or groups to assess validity of the decisions made on the basis of the records. The following might be required of such statistical systems:

(1) as in the case of systems directly affecting the individual, the individual should be informed of his right or privilege to refuse to provide data about himself;

(2) the individual should be informed that the information collected from or about him is to be maintained in a data base used for statistical analysis. The individual should be informed of the policies governing institutional responses to subpoenas or other requests for information contained in the data base;

(3) provision should be made to allow review by any interested party of all techniques used in arriving at a decision based upon analysis of data contained in the data system. Such review might include evaluation of the sample selection, data collection instruments or procedures, information storage policies, analysis techniques, and any other elements of the data analysis process;

(4) data used by the organization in making the analysis should be made available, in machine-readable form, to any individual or organization desiring to undertake independent analysis of the data. Individual personal identifiers should be removed from the data before such transfer occurs and, if due to sample size, sampling procedures, or other characteristics of the data base, a likelihood exists that individuals might be identified even in the absence of personal identifying information, data should be aggregated to a sufficient degree to make such identification impossible;

(5) the organization maintaining the data should be responsible for preventing transfer to, access to, or use of any data in personally identifiable form by any person or organization, including staff of the organization itself. Data collected for statistical purposes should not be used in a manner which could affect the individual directly.

The management requirements which might be placed on organizations maintaining data systems containing personal information are similar regardless of the type of system. They are designed to ensure that the organization provide for appropriate feedback and that, if information is collected for statistical purposes, that the information is not used in a way which would directly affect the individual file subjects.

Any organization maintaining an automated personal data system might be required to fulfill the following general management requirements:

(1) designate one person as responsible for the operation of the system and for assuring that appropriate feedback mechanisms are provided;

(2) take affirmative action to assure that each of its employees having responsibility for the design, development, operation, or maintenance of the system, or for the use of data contained in the system, is informed of all requirements relating to the operation of the data base and of all of the rules and procedures of the organization which are used to ensure adherence to the requirements;

(3) provide for sanctions to be applied to any employee whose willful or negligent conduct causes or significantly contributes to the denial of feedback to an individual or group;

(4) provide for sanctions to be applied to any employee who initiates any disciplinary or other punitive action against any individual who brings to the attention of appropriate authorities, the press, or any member of the public, evidence that opportunities for feedback have been denied to an individual or group.

The above examples of recommendations for the protection of privacy can all be viewed as guaranteeing that individuals will be able to provide feedback to systems which make decisions based on files containing personal data. Other potential recommendations, regarding the design of systems and the requirement that the public be notified of the system's existence, can also be viewed as protecting the right of individuals to provide various types of feedback to systems which employ personal files as part of their control element.

POTENTIAL MODEL UTILITY

The feedback control system model of privacy, as outlined in this paper, provides a framework which may help coalesce many of the separate concerns which individuals or groups have expressed about privacy. Similarly, the framework appears to provide a unified framework for analyzing the effectiveness of privacy legislation and regulation. The model can also provide guidance to those responsible for developing and operating information systems—does a system provide for adequate feedback from those affected by the system?

The model may provide a basis for conducting research on the need for privacy, or on the impact of inadequate protection of privacy. Individuals might be surveyed, or requested to participate in hypothetical scenarios, to determine, for example:

- the types of feedback which individuals feel are required for different types of systems (thereby providing a categorization of systems in terms of feedback required).
- the relative value of different forms of feedback

(e.g., feedback regarding accuracy vs. feedback regarding dissemination).

- potential "tradeoffs" which might be made between different forms of feedback provisions and other costs (or benefits) to data subjects.

Finally, a more fully developed model of privacy as a feedback function should provide guidance for the ongoing monitoring of privacy protection mechanisms.

Any assessment of the important system output effects or of the appropriate feedback mechanisms might prove, over time, to be somewhat in error. It is often difficult, even in purely physical systems, to determine exactly what output measures are appropriate to use for feedback control. The fact that output measures and feedback mechanisms chosen might be partially incorrect, or that the appropriateness of feedback forms could change with time, does not obviate the necessity of providing such mechanisms. The pervasive nature of regulations for the protection of privacy, combined with the fact that the public should be encouraged to use whatever feedback mechanisms are to be provided, makes it advisable that the types of feedback provided, and the implementation of regulations which ensure the feedback, should be continuously reviewed.

Ongoing review of feedback procedures might include monitoring organizations' compliance with regulations designed to facilitate feedback. Public perception of the availability and utility of feedback opportunities should be reviewed.

Regulations established to provide feedback should be evaluated continuously. Further knowledge of the processes involved may indicate the need for changes in procedures, regulations, etc. Social scientists might discover that recommendations have not, in fact, considered the most important output variables with respect to the stability of institutions or society. The mechanisms provided for feedback might act contrary to what is expected. Since most automated systems used today are highly complex and poorly understood, the continuing study of the efficacy of the feedback mechanisms employed is required.

Computer security—A survey

by PETER S. BROWNE
General Electric Information Services Business Division
Rockville, Maryland

ABSTRACT

With the growing requirements for protection generated by legislation such as the 1974 Privacy Act, the increasing complexity of computer and data communications applications, and increasing awareness regarding computer vulnerabilities, the discipline of computer security is achieving independent recognition. Current data processing literature is a rich source of information. Articles and papers regarding security, design of software protection, operational practices and auditing number in the thousands. Most of them are very narrow in scope or so general that they are of little use.

It is important to the data processing professional to be able to sort out the large body of material in order to gain perspective. This paper attempts that by relying on a carefully selected and fully annotated bibliography of 134 items, many of them of interest to the systems analyst or designer. These papers are referenced in the text, which attempts to carefully distinguish between the technical and operational elements of computer security, while providing an overall perspective.

INTRODUCTION

The computer has unleashed countless opportunities for industrial growth, new applications, labor-saving accomplishments, and improvement of the quality of decisions. Most industrial and governmental organizations could not survive without the processing capability of their computer systems, and it can be shown that society itself is dependent upon the computer.[23] At the same time, computer technology has spawned a whole new field of crime and has generated a series of problems for both designers and users of information systems.[2]

With the growing pervasiveness of computers, their increasing complexity and the development of sophistication regarding computer vulnerabilities, the discipline of computer security is achieving widespread recognition. Many organizations have created the position of DP security specialist or manager[87,92] and college courses in computer security are being taught.[69] There are a number of driving forces behind the interest, some of which are outlined below.

Historical

In the middle 1960's, Congress began discussing the issues of privacy and the computer. A national data bank was proposed. Congressional committees were established, and public testimony published.[132] The general consensus was that that technology had not advanced to the point where privacy could be maintained.

Concern over the inherent lack of controls in computer systems led to much discussion and some activity on the technological front. A landmark meeting of active professionals in computer security in 1972 set the stage for an understanding of the technological issues and led to intensive design efforts to achieve "secure" computer systems.[18]

In the meanwhile, activity on the legislative and social fronts saw a culmination in the Privacy Act of 1974 (Public Law 93-579). This act applied privacy requirements to most computer systems operating within the Federal Government. It also generated a number of papers regarding implementation requirements, [90,105,110] and attempts to determine the true cost of privacy, especially as applied to large, multi-use data banks.[10,57]

The need for computer security is also affected by technological factors. As systems become more complex and sophisticated, so do the problems of data integrity. Resource-sharing systems achieve their greatest advantage when used simultaneously by many customers. This also means simultaneous processing of data with varying needs for confidentiality and pervasive needs for accuracy.[6] The problems of management control also have increased as the flexibility and capability of systems improve.

The scope and complexity of the field becomes apparent when a survey of the literature turns up over a thousand articles dealing with physical security of computer assets, threats to the computer, protection against fraud, embezzlement, and other human failings, the need for insurance, software protection, hardware safeguards, legal considerations, risk assessment, auditing, computer system design and the principles of operating system software security.[1,11,107] A multidisciplinary approach is needed.[95]

Definitions

Computer security is a widely discussed subject, and a generally agreed definition refers to it as protection of data against accidental or intentional disclosure, destruction or modification. Security can be viewed as a problem of "comprehensive control," involving the development of means to insure that privacy decisions are enforced.[37]

Data confidentiality is "the status accorded to data which requires the protection from unauthorized disclosure."[92] It refers to the protection of data from unauthorized disclosure, whether the basis for such protection is agreement, law, policy or prudent judgment.[109]

Privacy is a legal and social concept, having roots in constitutional law and social justice requirements.[66,132] It refers to the right of an individual to control the collection, storing and dissemination of data about himself.[6]

Data integrity is the protection of data against accidental or intentional destruction or modification. It also is the ensuring of accuracy and completeness of data. It involves the need for all components to operate together in a consistent and reliable manner.[133]

It can be seen that the object is data. We have been discussing data security as contrasted with computer security. To include the broader-based definition of the subject, and the need to think of the other assets involved such as computer hardware, facilities and people, the term 'processing integrity' has been coined.[105] It is the property of having adequate processing capability, availability and reliability in order to provide the requisite services of data processing.

PLANNING FOR COMPUTER SECURITY

Threats and vulnerabilities

The result of a security breach is what usually draws attention to a threat, a vulnerability or a particular countermeasure. The short history of computer security is spotted with numerous "horrible examples," fads such as the interest in magnets as a threat, the implementations of security measures that are anything but cost-effective.[80,101,131] A rational approach to the subject implies some sort of quantification of risks, and an analysis of the costs and benefits of countermeasures. Although some articles and papers have called for this approach,[23,30] only recently has there been a serious attempt to model the risk-cost interface.[20,40,79,87]

One of the key steps in devising protection is the classification of various threats. There are two sources of threats, people and natural hazards.[25] It is possible, though not easy, to quantify the threat of fire, earthquake, flood and storm.[79] On the other hand, those events that arise from human acts such as mistakes, disgruntlement, fraud and sabotage are not always possible to quantify, namely because of the complexity of motivations, environmental considerations and the effect of in-place countermeasures imposed.[100] The first step is to organize and classify the threats in a systematic manner.[87] Threats are usually part of the environment. On the other hand, the vulnerabilities of a particular computer system to those threats are dependent on a large number of factors relating to location, people, capabilities of the system, building structure, nature of the processing and operating practices.[79] Most security surveys and evaluations are designed to review these installation dependent vulnerabilities and postulate countermeasures accordingly.[84,102]

Adequate cost-effective protection against data security threats is uncommon. Usually the implementation of computer security is given low priority. It has suffered from inadequate attention and analysis, with too many existing measures lacking flexibility, consistency, completeness and redundancy. These attributes are all necessary in order to achieve protection that works when it is supposed to. One-hundred percent security or reliability is never possible. What is needed is a set of security measures that take into account the failures, errors, omissions and vulnerabilities of any given environment.[23,104]

Risk analysis

Risk analysis is the term applied to the systematic quantification of threats, loss exposures and countermeasure benefits.[20] The ingredients of a risk analysis are the postulation of threats and their probability, the calculation of loss exposures, including degraded productivity, usually on an annualized basis. It is important not to ignore the very low probability, high loss events that occur so infrequently that the annual loss potential appears negligible. A high loss exposure, regardless of the probability, should be evaluated carefully. In any event, the apparent simplicity is misleading. It is not easy to quantify all the potential losses, to postulate all the threats or to estimate their probability. It is also a complex and time-consuming task, which accounts for the relatively few completed risk analyses to date.

OPERATIONAL COMPUTER SECURITY

Computer systems are generally not designed with security as a primary objective.[18] Generally, the large main-frame manufacturers claim that users have been slow to request security. Current research effort by independent sources and manufacturers alike indicate that the next generation of computers will achieve adequate, measurable and certifiable protection in hardware and software.[111]

Much protection for computer systems can be implemented outside of the computer hardware and system software. Managers of computer installations have always been concerned with the problems of system integrity, processing availability and security. For them, physical security, backup and administrative controls are highly relevant.

Physical security

Physical security has been subjected to study and implementation long before the arrival of computers. Implementation of physical access controls to computer facilities represents a generally agreed first step in achieving threat protection. The reason is that many threats, especially of a human nature, can be reduced by limiting access.[28,131] To deal with the threat of fire, utility unreliability and environmental disturbances, numerous control and monitoring systems have been devised. All should be considered in the context of the overall DP security plan, even though responsibility for their implementation may be elsewhere in the organization.

Backup and recovery

Recovery planning to ease the pain if a disaster were to strike is important.[29] The objective is to assess the capability of the organization to respond immediately, and ensure that supplies, data files, programs, documentation and equipment are available off-site. The contingency planning must be of sufficient detail so that in case of disaster, all the elements can be pulled together in order to resume operations in as short a time as possible.[117]

Administrative controls

The administrative burden of proceduralizing and formalizing a security program is generally underestimated. It takes great clerical resources to ensure adequate maintenance of a selective access program, whether it be selective authorization to data files or physical areas. Other administrative aspects include the development and implementation of security policies, guidelines, standards and procedures. Again, these functions may be centralized or decentralized, but stand a greater chance of success if the latter.[39]

Security in recent years has been a major concern of computer operations groups. It is here that the organization can channel resources most effectively to deal with the lack of security in operating systems or in application system design. It is a necessary but not sufficient condition for providing true computer security.[24] One of the best guides for information about secure operating practices is the System Review Manual on Security, published by AFIPS.[102] Other guidance can be found in the more exhaustive of the many checklists and guidebooks on computer security.[44,61,79,84,87,92]

Audit

Audit has been defined as "an independent and objective examination of the information system and its use (including organizational responsibilities) into:

. . . the adequacy of controls, levels of risks, exposures and compliance with standards and procedures

. . . the adequacy and effectiveness of system controls versus dishonesty, inefficiency and security vulnerabilities."[18]

Independent and objective are the key words. Whether or not an auditor's objective is the detection of fraud in computer systems, his role is certainly one of reviewing the adequacy of system security. Many CPA firms have finally recognized their unique role in security assurance.[83,116] Some critics say their attention is still inadequate and not yet relevant.[110] Suffice to say that computer systems need auditing, both internal and external. It is not possible to even consider auditing "around the computer" because of the risks involved. Given the nature of computer related threats and vulnerabilities, the traditional independence and inquisitiveness of the audit profession and the requirement for independent assessment of controls, it is logical that much computer security activity will be a part of the auditor's domain.[26]

TECHNICAL ELEMENTS

Even though the first line of defense is to rely on secure operational practices and physical security, the elements of system design have always intrigued computer security professionals. Obviously things can go wrong with hardware and software. Data integrity, encryption and security surveillance must be considered in any complete computer security program. Understanding of these elements usually requires a person well-versed in systems programming and application system design. That the skills required in this area are completely different (and perhaps incompatible) with the skills required for handling operational security problems has not been well identified in the literature. In addition, no present commercially available operating system is immune from penetration, and so the prevalent attitude is that it is futile to attempt to provide protection against the determined technical penetrator. However, much research and vendor effort is being devoted to the appropriate technical safeguards in operating systems.[111]

Identification

Positive identification of people, devices, programs, systems and processes is clearly a requirement for adequate security. Holding a person accountable for his actions is one of the first principles in good design. This requires certain knowledge that he is who he says he is. There are three approaches to personal identification, (1) identification based on passwords (2) on credit card technology and (3) on personal characteristics of the requestor. Passwords are the most common method, but they suffer from some serious inadequacies.[66] They should be random in nature and of sufficient length to avoid compromise.[6] The use of credit cards, usually with a magnetically encoded stripe, is achieving great popularity, especially in regard to Electronic Funds Transfer Systems. This approach makes sense if the cards are controlled, used in conjunction with a unique personal identifier (PIN number) and if the system is made aware of lost cards so that casual retrieval of a card will not be an open invitation to access. Identification based on personal characteristics, such as voiceprint or fingerprints is still not a commercially popular methodology, but offers future promise.[38] Identification not only relates to personnel access, but also to other system entities. Security objects can be people, terminals groups of people (cliques), programs, terminals, data communications devices or segments of virtual memory.[85] Then one can specify restrictions based on a number of parameters such as the characteristics of the requestor (name, terminal, program, etc.) content of data (all salaries over $30,000), context of data (association of college grades, number of parking tickets and credit rating) or one can use procedures (formularies) based on the nature of the situation.[67]

Authorization

Once a system resource or person is identified, the problem of access of the identified subject becomes an important concern. Authorization refers to the establishment of allowable interactions among system elements.[52,59] The traditional concept of authorization in system design presupposes that any system entity automatically is authorized access to any other system entity unles specifically prohibited. The secure concept of system design takes the opposite view. The concept of "least privilege" holds; namely that any system entity is prohibited from access to another system entity unless specifically authorized. For example, there is no need for a peripheral allocator to be able to control or even have access to user data bases or other elements of the operating system. It should have knowledge of only those resources necessary for allocation of devices to jobs.[18]

The concept of an access matrix espoused by Conway, et al[36] appears to be the easiest way to implement access control, but the implementation is not clean.[59] There are a number of choices that one can make in defining the rules of access. For example, what level or degree of privilege should be permitted? Are we talking about control of access to files, records, elements within records or specific hardware or software elements of the computer system?[52,67,72]

Much of the early work in authorization technology is the result of research activities.[35,42,53] The academic environment has fostered some good studies[55,59] which have led to some actual efforts at implementation. Work at MITRE and the US Air Force on security kernels (provably small security reference monitors)[86] at Stanford Research Institute on proofs of program correctness,[91] at System Development Corporation for the DOD community,[128] at MIT Under Project MAC[112] and at computer system manufacturers,[52,54] has led to actual demonstration of computer and communications systems with security as a prime design requirement. An excellent but dated paper by Saltzer summarizes current (as of early 1975) research and development efforts.[111]

Integrity

Obviously, things can go wrong with hardware and software. Data can be (and frequently is) inconsistent or unreliable. Data integrity interfaces with computer security at almost every point. In fact, many observers see the two concepts as being nearly synonymous.[105] A high integrity operating system can by its nature provide security against unauthorized use of system resources. System integrity is the condition of proper and predictable operation of the total system, including hardware, software and human elements. It includes the physical and operational security mechanisms in place.

Part of the integrity solution lies in providing an operating system that does not treat every operation as "benevolent," but in fact assumes that users are going to attempt to get into supervisor state, and are going to overreach the limits of the software design. Other corrective elements can be found in attempts to enhance the reliability and availability of applications.[133]

System audit trails

System surveillance, measurement and auditing are critical elements in providing the technical base for adequate security and integrity. The effectiveness and operability of the entire system, especially the protection mechanisms, must be continually scrutinized and measured. Management must be assured that the protection is in place and effective. Management must also be able to detect and to respond to events that constitute system security threats. Many of the same mechanisms used for performance measurement also can be used for monitoring of the protection mechanisms and the integrity of the entire system. A properly functioning audit mechanism should allow the specification of certain system events (such as OPEN, LOGON, etc) to trigger an audit trail.[32] The interfacing of system measurement and surveillance activity with the auditor is the subject of much activity and research.[119]

CONCLUSION

As of early 1976, systems are in use which provide a high degree of computer security and integrity, and may provide the basis for systems accreditation. The MULTICS project at MIT has led to commercial marketing of the system by Honeywell and a multi-level security enhancement by MITRE and the USAF.[112] The General Electric Mark III® Service has long been known for its good security. Other operating systems have been designed with security as an objective,[53,86,94,106,113] and the efforts of IBM and Honeywell have been previously mentioned. Current research directions are outlined in the paper by Saltzer[111] and should see commercial reality sometime in the next few years. Awareness of the risks is being fostered by numerous seminars and conferences. Large organizations, both commercial and government, are funding the position of systems security officer or computer security manager. An association, the Computer Security Institute, has been formed to provide information to, and give voice to the growing number of specialists in the field.

Current state of the art would seem to allow quite flexible and cost-effective security measures. But in practice, protection is generally not elaborate, flexible or impenetrable.[37] As a result, most safeguards are imposed "after the fact", through a mixture of managerial controls and physical security. This type of control is largely ineffective, due to inconsistencies, lack of proper redundancy or incompleteness. It appears that this will be the case, even after computer systems come provided with flexible and effective protection mechanisms.

In 1969, Lance Hoffman said that much research is needed to design security controls and to evaluate computer access control methods.[66] Nothing has changed to alter this. When designers and implementors agree on the needs, and the computer and software providers supply the secure methods to use their products, it is still up to the user to provide the proper environment, the procedures and the management climate to implement the principles of "least privilege," compartmentalization, redundancy in controls and personnel awareness that are the necessary first step in provision of security, privacy protection and system integrity. Only then, shall we realize the goals of simple, economic, functionally capable and modular protection mechanisms.[114]

In conclusion, it is important to realize that we are talking about a complex technology, with many interfaces.[124] Because of the great need, the next few years should see a continued broadening of interest, the forcing of computer security protection because of privacy legislation, awareness of the economic consequences of security deficiences, increased risk management efforts by computer system implementors and increasing government regulation of the data processing industry.

COMPUTER SECURITY BIBLIOGRAPHY

1. Abbott, Robert P. et al, *A Bibliography on Computer Operating Systems Security,* Lawrence Livermore Laboratory, University of California, The RISOS Project, Report UCRL-51555, April 1974. Technically oriented bibliography of key articles and papers relating to internal protection for computer systems.
2. Allen, Brandt, "Danger Ahead—Safeguard Your Computer," *Harvard Business Review,* November-December 1968. One of the early, well publicized articles on computer security. Helped achieve an awareness of physical security requirements.
3. Allen, Brandt, "Embezzler's Guide to the Computer," *Harvard Business Review,* July-August, 1975. The author talks directly to the would-be embezzler and cautions him not to be concerned about getting caught. The real big embezzlement schemes are still working and the perpetrators are not being caught. Shows how to defraud through manipulation of payroll, accounts payables, inventory, shipping documents and accounts receivable records that are maintained in computers.
4. AICPA, *Audits of Service-Center Produced Records,* American Institute of Certified Public Accountants, Auditing Standards Division, New York, 1974. This is a guide for Certified Public Accountants for their use in examining and reporting on the financial statements of clients whose records are produced by a computer service center or time-sharing firm. It is the basis for third-party audit reviews of such firms, and is oriented toward security and controls.
5. Anderson, James P., *Computer Security Technology Planning Study,* USAF Electronic Systems Division (MCIT), ESD-TR-73-51, October 1972. The "classic" study of computer security requirements in the later 1970's.
6. Anderson, James P., "Information Security in a Multi-User Computer Environment," In *Advances in Computers,* Vol. 12, 1972, Morris Rubinoff, Editor, Academic Press, New York. Stresses the technical problems and prospects for protecting data or information in multi-user computer environments. Shows how it is possible and profitable to penetrate systems for purposes of manipulation or unauthorized viewing.
7. Baran, Paul, *On Distributed Communications: IX. Security and Tamper-Free Considerations,* Rand RM 3765, August 1964. An unclassified discussion of cryptography: It anticipates the distributed data network exemplified by the ARPA net. It also anticipates the need for secure communications links.

8. Bates, William S., "Security of Computer-Based Information Systems," *Datamation*, May 1970, pp. 60-65. A survey article, written by a Marine captain.

9. Beardsley, Charles W., "Is Your Computer Insecure?" *IEEE Spectrum*, January 1972. A survey article that updates the earlier work of Lance Hoffman.

10. Berg, John L. (Editor), *Exploring Privacy and Data Security Costs—A Summary of a Workshop*, U. S. Dept. of Commerce, National Bureau of Standards, NBS Technical Note 876, August 1975. On 2/20/75 nine informed DP professionals were invited to NBS to discuss the costs of implementing privacy legislation. This is an edited summary of those discussions.

11. Bergart, J. F. and Marvin Denicoff and David K. Hsiao, *An Annotated and Cross-Referenced Bibliography on Computer Security and Access Control in Computer Systems*, Ohio State University, Computer and Information, Science Research Center Report OSU-CISRC-TR-72-12, November 1971.

12. Bigelow, Robert P., "Legal and Security Issues Posed by Computer Utilities," *Harvard Business Review*, Vol. 43, September-October 1967, pp. 150-161.

13. Bigelow, Robert P., "The Privacy Act of 1974," *The Practical Lawyer*, Vol. 21, #6, September 1, 1975. Covers the 1974 Privacy Act in some detail, and shows the effect on computerized personal information systems.

14. Bingham, H. W., *Security Techniques for EDP of Multi-Level Classified Information*, RADC-TR-65-415, December 1, 1965. A classic study that predates much of the efforts in authorization technology. This was a study of military intelligence security control techniques for the Burroughs D825. Hardware and software techniques currently under study are explained in great detail.

15. Bisbey, Richard L. II and Gerald J. Popek, "Encapsulation: An Approach to Operating System Security," *Proceedings, 1973 ACM Conference*, San Diego, California, also, AD-771-758, October 1973, ARPA. Encapsulation is the removal of access controls from the host computer, and the placing of a mini-computer-based access control system at the peripheral interfaces. This is a logical extension of the hypervisor, or virtual machine monitor. It is one solution to problems of security in fourth generation computer architecture.

16. Bjork, L. A. and C. T. Davies, Jr., Technical Report: *The Semantics of the Preservation and Recovery of Integrity in a Data System*, International Business Machines, Inc., Systems Development Division, TR-02.540, December 1972, also in *Proceedings, SHARE Conference*, November 1973. Discusses a unified view of data base recovery mechanisms, and proposes a set of concepts and principles revolving around spheres of control.

17. Branstad, Dennis K., "Security Aspects of Computer Networks," *Proceedings, AIAA Computer Network Conference*, Huntsville, Alabama, April 1973. Discusses the relevant issues of communications protocol, switching techniques and protection techniques in relation to design of secure computer/communications networks.

18. Branstad, Dennis K. and Susan K. Reed (editors), *Controlled Accessibility Workshop Report*, US Department of Commerce, National Bureau of Standards, NBS Technical Note 827, May 1974. Presents the results of a three day workshop in San Diego, sponsored by NBS and ACM. About 75 computer security professionals were invited, and discussed at length the technical and managerial issues of protection in computer systems. The results are significant, because much developmental work since then can be traced to the workshop.

19. Branstad, Dennis K., "Encryption Protection in Computer Data Communications," *Proceedings: Fourth Data Communications Conference*, Quebec City, Canada, October 1975, IEEE, New York. Encryption can be an effective process for protecting data during transmission. The degree of protection depends on the encryption algorithm, the implementation of the algorithm, and the associated administrative procedures. Additional security requirements of user identification, access authorization and auditing may be satisfied by combining encryption technology with a network access control machine (computer). This paper presents the proposed Federal encryption standard and the security requirements satisfied by proper use of the algorithm. It also discusses implementation.

20. Brown, William (editor), *Computer and Software Security*, AMR International, New York, 1971. This book contains the essential contents of the AMR Seminar on computer security. Physical security, development of a computer security plan, backup, legal, auditing, insurance, software and cryptographic techniques are all covered with varying levels of competency and detail. Included is a key-word-in-context bibliography covering citations up to mid-1971.

21. Browne, Peter S., "Computer Security—A Survey," *Data Base*, Quarterly Publication of ACM Special Interest Group on Business Data Processing, Fall 1972. An annotated bibliography of over 100 items presents the 'state of the art' as of 1972. It makes reference to some little publicized material, and shows the importance of then classified Department of Defense activity in the field.

22. Browne, Peter S. and Dennis D. Steinauer, *A Model for Access Control*, 1971 ACM/SIGFIDET Workshop on Data Description, Access and Control, San Diego, Nov. 11-12, 1971. Authorization is discussed from the standpoint of requirements for access to given objects. A conceptual model, based on the work of Weissman is developed.

23. Browne, Peter S., "Computer Security—A Risk Management Approach," *Security Register*, December 1973. Overviews the problems of security, shows how to systematically approach a computer security program, and calls for a risk management approach.

24. Browne, Peter S., *Security in Computer Networks*, NBS Special Publication 404, U. S. Dept. of Commerce, National Bureau of Standards, 1974. Also in *Data Communications User*, January 1975. Makes the point that security in networks is an extension of security in multi-user computer systems. Physical and administrative controls come first, followed by the technical requirements of hardware, software and encryption security controls.

25. Buskin, Arthur A., *A Framework for Computer Security*, SDC Technical Memorandum, TM-WD-5733, System Development Corporation, McLean, Virginia, June 1975. Presents an overview of the computer security problem and an interrelated set of axioms and principles of computer security as the beginning of a top-down, structured approach.

26. Canadian Institute of Chartered Accountants, *Computer Control Guidelines*, Canadian Institute of Chartered Accountants, 1970. An early attempt to define controls in computer systems for auditor guidelines.

27. Canning, Richard G., "Data Security in the CDB," *EDP Analyzer*, May 1970.

28. Canning, Richard G., "Security of the Computer Center," *EDP Analyzer*, December 1971.

29. Canning, Richard G., "Computer Security: Backup and Recovery Methods," *EDP Analyzer*, January 1972.

30. Canning, Richard G., "Protecting Valuable Data," *EDP Analyzer*, December 1973, Vol. 11, No. 12. *EDP Analyzer*, January 1974, Vol. 12, #1.

31. Canning, Richard G., "Computer Fraud and Embezzlement," *EDP Analyzer*, April 1975, Vol. 13, #4. These issues, written by one of the world's experts in business

data processing, are each a concise yet complete exposition of current thinking on each topic.

32. Chastain, Dennis R., "Security vs. Performance," *Datamation*, November 1973. Scrambling devices, file access validation and subversion tests are all part of a security environment. The author discusses his measurement efforts at the Defense Intelligence Agency regarding the overhead of these mechanisms.

33. Clements, Don and Lance J. Hoffman, *Computer Assisted System Design*, Electronics Research Laboratory, College of Engineering, Univ. of California, Berkeley, CA, ERL-M468, November 1974. Describes a computer software package that partially automates the selection of security techniques applicable to a particular system design.

34. Computer Security Research Group, *Computer Security Handbook*, Computer Security Research Group, Douglas B. Hoyt, Chairman, Macmillan and Company, Inc., New York, October 1973. Provides detailed information on management's role in the accountability and reporting, hardware/software controls, computer risk insurance, auditing computerized systems and outside contract services. The Computer Research Group was sponsored by the Atlantic and New Jersey Chapters of Association for Systems Management. Authors are Arthur Hutt, Belden Menkus, Eugene Redmond, Seymour Bosworth, Ralph Jones, Herbert Dickson, Robert Daley, Dick Brandon, Joseph Wasserman, Theodore Christiansen, Guy Migliaccio and Stephen Falb.

35. Conn, Richard W. and Richard H. Yamamoto, *A Model Highlighting the Security of Operating Systems*, RISOS Project, Lawrence Livermore Laboratory, Proceedings, ACM 1974 Conference, San Diego, CA. Penetration of computer systems have led several authors to identify generic weaknesses in operating systems, but have not led to formal methods of analysis. An approach showing promise in identifying trouble spots, as well as characterizing existing operating systems in a more general sense, lies in forming graph models in which nodes are program modules or data structures, and arcs are access or shared resource synchronization paths. A given system should be capable of reduction to a graph of this sort by appropriate analysis of its load modules.

36. Conway, R. W., "On the Implementation of Security Measures In Information Systems," *Communications of the ACM*, Vol. 15, No. 4, April 1972. Excellent presentation of those concepts that are germane to authorization and efficiency. All authorization does not have to be accomplished at run-time. To the extent that privacy is data independent, the access function is inexpensive to implement.

37. Conway, R. W., W. L. Maxwell, and H. L. Morgan, "Selective Security Capabilities in ASAP—A File Management System," *1972 Spring Joint Computer Conference*, p. 1181, May 1972. Shows implementation of principles described in the previous article.

38. Cotton, Ira W. and Paul Meissner, "Approaches to Controlling Personal Access to Computer Terminals," *Proceedings of the 1975 Symposium, Computer Networks, Trends and Applications*, National Bureau of Standards Institute for Computer Science and Technology. Considers a number of approaches to protection against unauthorized access to computers. Surveys the current state of the art of personal identification. Explains how devices can be compared, and introduces criteria that can be used in personal identification system evaluation and/or comparison.

39. Courtney, Robert H. Jr., *Forty Commonly Found Deficiencies in the Security of Data Processing Activities*, IBM, June 1971. A common sense primer to management, outlining frequently overlooked security deficiencies.

40. Courtney Robert H., Jr., *Security Risk Assessment in Electronic Data Processing Systems*. National Bureau of Standards, Task Group 15, October 1975. An approach toward determination of risk to data processing is postulated. It shows how to quantify the potential benefits afforded by given security protection for comparison with costs.

41. Davies, C. T., Jr., *A Recovery/Integrity Architecture for a Data System*, IBM, Systems Development Division, May 1972. Discusses concepts of integrity as related to operating system and data base architecture.

42. Dean, Albert L., Jr., "Data Privacy and Integrity Requirements for On-Line Data Management Systems," *1971 ACM-SIGFIDET Workshop on Data Description, Access and Control*, Nov. 1971, San Diego, CA. Identifies security requirements for an on-line data base management system. Concepts were implemented in work by the author for the US government.

43. Denning, Peter J. (Chairman), *An Undergraduate Course on Operating Systems Principles (Module 6-Protection)*, Interim Report of the COSINE Committee of the National Academy of Engineering (Commission on Education), June 1971. Embodies the principles of protection as discussed in the paper by Graham and Denning.

44. Department of Defense, *ADP Security Manual: Techniques and Procedures for Implementing, Deactivating, Testing and Evaluating Secure Resource-Sharing ADP Systems;* also see *Industrial Security Manual for Safeguarding Classified Information*, DOD 5200.28M, January 1973 and DOD 5220.22M, April 1970, order from Superintendent of Documents, US Government Printing Office, Washington, DC 20402. These two manuals provide very helpful guidance for non-DOD government and commercial organizations in defining and implementing physical and data processing security programs. Even though the concepts of the DOD classification of information hierarchy are pervasive, the methods, ideas and procedures are valuable in any environment.

45. Chadwick, H. A., "Burning Down the Data Center," *Datamation*, Vol. 21, #10, October 1975, pp. 60-64. A well written article that discusses DP insurance from the point of view of the data processing expert. Complex insurance related terms and concepts are clearly explained. Guidance is given as to what insurance coverage is needed, why various forms should be considered and who can provide insurance services to DP installers.

46. Enger, I. Sador, Guy T. Merriman and Ann L. Bussemy, *Automatic Security Classification Study*, RADC TR 67-472, October 1967. Report of an investigation of the feasibility of using computers to assign the government security classification to textual material. The "correctness" was only 54% but the techniques used did show promise for further research.

47. Federal Fire Council, *Recommended Practices No. 1—Fire Protection for Essential Electronic Equipment*, March 1962, Clearinghouse for Federal Scientific and Technical Information. Discusses practices in dealing with the threat of fire. Is the most thorough and concrete guidance to date.

48. Feistel, H., *Cryptographic Coding for Data Bank Privacy*, IBM Research Report, RC-2827, March 1970, also in *Scientific American* as "Cryptology and Computer Privacy," May 1973. Discusses concepts of cryptography that eventually led to the development of an IBM pilot project and the Federal encryption standard.

49. Fenwick, William A., "Marketing EDP Services: Reviewing the Legal Considerations," *Computers and Automation*, November 1971. A misnomer. The author is really talking about security measures to protect the confidentiality of data.

50. FIPS PUB-39 *Glossary of Terminology for Computer Systems Security*) Federal Information Processing Standards

Task Group 15: Computer Systems Security, National Bureau of Standards, US Department of Commerce, Washington, DC. September, 1975. A glossary of 70 terms relating solely to the concepts of privacy and computer security. The terms were exacted from many sources and refined through the joint efforts of FIPS Task Group 15, which was established in 1975 to develop standards and guidelines in computer systems security. Emphasis is on technical terms that relate to computer security architecture and communications security.

51. Foster, Caxton C., "Data Banks—A Position Paper," *Computers and Automation*, March 1971, p. 28. A summary of what can go wrong (machine failure, logical errors, eavesdropping, wiretapping) and what to do about it.

52. Friedman, T. D., "The Authorization Problem in Shared Files," *IBM Systems Journal* #4, 1970, pp. 258-280. The problem of sharing information yet providing proper authorization is reviewed. A model of a secured file system provides the basis for much current work in the field. Friedman rejects the hierarchial approach to authorization in favor of compartments or categorization of access rights.

53. Gaines, R. Stockton, An Operating System Based on the Concept of a Supervisory Computer," *Communications of the ACM*, Vol. 15, No. 3, March 1972. Concepts of protection are outlined.

54. Girsdansky, M. B., "Cryptology, the Computer, and Data Privacy," *Computers and Automation*, April 1972. Also see *Data Privacy: Cryptology and the Computer at IBM Research*, IBM Research Reports, Vol. 7, #4, 1971. An interesting study on what researchers are doing to devise 'unbreakable' codes and how many classical approaches to encipherment are easily compromised. The paper discusses "Lucifer," a hardware encryption device.

55. Glaser, E. L., "A Brief Description of Privacy Measures in the MULTICS Operating System," *SJCC 1967*, Vol. 30, pp. 303-304. Must reading for the student of protection theory.

56. GMIS, *An Administrative Guideline: Security and Confidentiality for Government Data Centers*, GMIS, December 1973. A report for state and local government members of GMIS that views computer security from an organizational viewpoint, and structures guidance on legislation, administrative control, personnel security, data flow security, physical security, hardware/software protection and confidentiality codes of ethics.

57. Goldstein, Robert C., "The Cost of Privacy, *Datamation*, Vol. 21, #10, October 1975, pp. 65-71, also see PhD dissertation, published by Honeywell Information Systems, Brighton, MA, 1975. Discusses implementation requirements for operators of personnel data systems in order to comply with privacy legislation. Physical security and clerical costs appear to be high-cost categories. Some possibilities for reducing the impact of privacy legislation are outlined.

58. Goode, George E. "Security for Teleprinters and Data Communications," *Data Management*, January 1973. Decribes cryptographic methods for securing communications.

59. Graham, G. Scott and Peter J. Denning, "Protection—Principles and Practice," *1972 Spring Joint Computer Conference*, p. 417, May 1972. Graham and Denning have analyzed most existing systems and find they fit the protection model that is described. The work draws heavily on theories of the "Princeton" school.

60. Graham, Robert M., "Protection in an Information Processing Utility," *CACM*, Vol. 11, #5, May 1968, p. 368. Describes the "rings of protection" in Multics.

61. Guide International, *Data Center Security Guidelines*, Guide Data Center Security Project—GSD 28-070, February 1972. Provides a set of guidelines for implementation and management of security in a data processing operations environment. Developed from a dedicated project at GUIDE, the major IBM user group.

62. GUIDE SHARE, *Data Base Management System Requirements*, Joint GUIDE-SHARE Data Base Requirements Group, November 11, 1970. An important document that outlines idealized requirements for data base management. Security and integrity play a dominant role.

63. Held, Gilbert, "Locking Intruders Out of a Network," *Data Communications*, January-February, 1975, pp. 27-31. The author favors a password scheme for controlling access to network components. Security is gained through use of nonprinting characters. Interesting statistics are presented on compromise possibilities utilizing a minicomputer and repeated attempts to exhaustively enumerate possible password combinations.

64. Healy, R. J., *Emergency and Disaster Planning*, New York, Wiley Press, 1969. An industrial security expert writes on the principles of emergency planning.

65. Hemphill, Charles F., Jr., *Security for Business and Industry*, Homewood, Illinois, Dow Jones, Irwin, Inc. 1971. This book has very little to do with EDP (only one chapter talks about computer room safeguards) but the principles of physical security are worth reading.

66. Hoffman, Lance J., "Computers and Privacy: A Survey," *Computing Surveys*, Vol. 1, #2, June 1969. The "classic" survey on this subject.

67. Hoffman, Lance J., "The Formulary Model for Flexible Privacy and Access Controls," *FJCC*, November 1971, Las Vegas, Nevada. Presents a model for interfacing user access controls and data by means of coded procedure called formularies.

68. Hoffman, Lance J. and W. F. Miller, "Getting a Personal Dossier From a Statistical Data Bank," *Datamation*, May 1970. An interesting example of how to input information by indirect means from innocent files.

133. Winkler, Stanley and Lee Danner, "Data Security in the Computer Communication Environment," *Computer*, Volume 7, No. 23, February 1974, IEEE. Describes security concerns in multi-terminal computer systems. Useful as an introduction to the problems and the nature of network security. Describes a number of possible implementations of controlled access to data.

134. Yourdan, Edward, "Reliability of Real-Time Systems," *Modern Data*, January-June 1972. A six-part series that thoroughly explores data integrity and reliability. Covered are the different concepts of reliability, causes of system failure, examples of failure and approaches to error recovery.

Computer abuse perpetrators and vulnerabilities of computer systems

by DONN B. PARKER
Stanford Research Institute
Menlo Park, California

ABSTRACT

Analysis of computer abuse experience is valuable in threat and risk studies performed to develop appropriate safeguards in computer use. A profile of computer abuse perpetrators has been developed on the basis of interviews with 17 offenders involved in a total of 15 cases. Common characteristics, occupations, and modus operandi are documented and analyzed. Computer systems' and user organizations' vulnerabilities that facilitated perpetrators' actions are also described, based on study of 375 reported cases of abuse. Eight main vulnerable functions and nine main vulnerable functional locations are identified and ranked by incidence of occurrence. Each vulnerability is described by examples in the form of brief case descriptions. Finally, priorities for safeguards are deduced from the results of the study.

INTRODUCTION

Computer abuse research has been conducted over the past five years at Stanford Research Institute, supported in part by the National Science Foundation (Grants GI-37226 and GJ-44313). Computer abuse is defined as any intentional act in which one or more victims suffered or could have suffered a loss, and one or more perpetrators made or could have made a gain.

The assessment of computer abuse and development of a case file—which now contains information on about 375 cases—are now sufficiently advanced to allow analyses that can assist security planners and EDP management. Two basic areas of concern are the sources of threats—the computer abuse perpetrators—and the vulnerabilities that facilitated their acts. With the rubric, "know the enemy to overcome him" in mind, a profile of known perpetrators was developed and documented. The admonition to be aware of the vulnerabilities of victims is the motivation for also identifying and presenting the weaknesses and functional locations of weaknesses among the known, reported cases of computer abuse.

COMPUTER ABUSE PERPETRATORS

An important aim of computer abuse research is determining a typology of known perpetrators as an aid in developing safeguards. Such a typology can be used in reducing the number of possible perpetrators and their potential for doing harm.

Interviews of varying lengths were conducted with seventeen perpetrators. In some cases over 20 hours of interviews were held, involving numerous sessions covering pretrial, criminal trial, presentencing, incarceration, and post incarceration periods. In six cases only brief telephone conversations were held with perpetrators, but information from them was heavily supplemented with facts and opinions of other case participants. No attempt was made to carry out psychological profiling, but obvious characteristics were determined in a gross fashion by interviewers with expertise in computer technology, management, and law. The sample of perpetrators was chosen on the basis of geographic and interview schedule expediency, case notoriety, and technical novelty or frequency of the abuse method. In the future attempts will be made to choose perpetrators so that the growing sample will be more representative of the total file of cases.

Characteristics were collected and synthesized by interviewing perpetrators, and conclusions were based on computer technology management experience of the interviewers. Characteristics of white collar criminals were identified from criminology literature.[1-3] Theories and information from this source include the trust position vulnerability, Robin Hood, and differential association theories; known characteristics of people in EDP occupations such as their ages, skills, occupation-related actions, technical challenge and game playing interests; and characteristics discovered in interviews, such as tendencies to collusion and business and occupational aggressiveness. The characteristics identified are those that a manager of a computer system might recognize among people within the computer environment operating or affected by computer services.

There are ten characteristics of the typology and supporting data based on the sample of 17 perpetrators.

(1) Age—Perpetrators are young. Mean age is 29 years, median age is 25 years, and the range is 18 to 46 years.

(2) Skill Level—Skill level pertaining to the abuse is high, with professional and managerial skills predominant:

Skill Level/Occupation	*Number of Perpetrators*
Low experience technician	1
Technician	3
Low experience professional	1
High experience professional	5
Manager	7

(3) Relation Between Occupation and Abuse—In all cases except one, perpetrators performed their acts while engaged in their occupations. The exception is an individual who, while president of an electronic supply house, posed as a telephone company employee to order the delivery of telephone equipment. Eleven of the perpetrators violated their occupational positions of trust. Six performed their acts without violating occupational trust.

The perpetrators' occupations, associated with types and characteristics of the victims appear in Table I.

A significant range of types of perpetrators and victims is included with consumers, non-EDP employees, EDP employees, managers and staff, and large and small victims in various industries.

(4) Abuse Modi Operandi—The modi operandi were almost equally divided between unauthorized data manipulation during authorized computer use and unauthorized computer use. In eleven cases computers were primarily objects of acts; in five of the cases they provided the environment for the act; and in one case a computer was the instrument of the act. Eight cases involved batch-operated computer systems, five involved time-sharing systems, and four involved transaction systems.

Table II presents a range of perpetrators' technical acts.

Types of losses were: information or property fraud or theft in five cases, financial fraud or theft in ten cases, and unauthorized use of services in two cases. In the last two cases, perpetrators were able to use time-sharing services without paying for them and also took proprietary data, but no loss was sustained by victims of the data theft.

(5) Collusion—Collusion occurred in seven cases. Four of the cases involved only two people; the others involved five, seven and twenty-two people. Collusion was found necessary by the perpetrators either because they did not possess all of the skills, time, or resources necessary for the act, or they needed assistance in converting the act to financial gain. Several of the other perpetrators said they considered obtaining assistance from others but rejected the idea because they felt they should not entice others into wrongdoing.

(6) Personal Gain—For a group of eight of the cases, a total financial gain of $4 million was discov-

TABLE I—Computer Abuse Perpetrators' Occupations and Types of Victims

Perpetrator Occupations	Victims	Number of Perpetrators
Retail consumer	large insurance company	1
Teller	large bank	1
Accountant and computer service company owner	small manufacturing company (one accountant)	1
Time-sharing user	large service, small service, large private system	3
Business programmer	small banks	2
Systems programmer	state agency	1
Data input supervisor	large insurance company	1
Computer operations and systems managers	small bank, large insurance companies	3
Firm presidents	small electronic supply and software house	2
Business manager	large manufacturer	1
Sales manager	large time-sharing service	1

TABLE II—Perpetrators' Technical Methods of Computer Abuse

Number of Cases	Methods
2	Manipulation of data by unauthorized computer program changes.
1	Unauthorized use of an existing program to manipulate data.
3	Compromise or penetration of a time-sharing computer system by legitimate access from an on-line terminal performed by discovering and exploiting a weakness or error in the system controls that protect users or the system.
2	Impersonating an authorized terminal user of a time-sharing computer service by using confidential identification codes to obtain and use proprietary programs and data.
1	Use of a computer as an instrument or tool to plan or control a noncomputer related act.
2	Taking by manual means and/or selling copies of proprietary computer programs without the owner's permission or knowledge.
4	Inputting incorrect data and/or using incorrect output by authorized and correct means but for unauthorized purposes.

ered, with an average gain of $500,000 per case. The range for the 15 cases is $1400 to $1.5 million. Another type of gain was business or employment advantage over competitors through sabotage or espionage (intelligence gathering).

(7) Differential Association—Thirteen perpetrators demonstrated the differential association syndrome: The white collar criminal in his act deviates from accepted practices of his associates only in small ways.

(8) Robin Hood Syndrome—Twelve perpetrators exhibited the Robin Hood syndrome: They differentiate strongly between harming people, which is highly immoral within their standards, and harming organizations, which they can easily rationalize.

(9) Game Playing—Fifteen perpetrators indicated that they considered their acts games pitting their skills against the computer and the victim organization. The games represented challenges to them, and made their lives exciting and filled with danger. Fourteen perpetrators accepted the challenge with considerable aggressive behavior, identified by one perpetrator as the desire to participate in physically dangerous activities such as entering a bull ring or driving a race car.

(10) The dispositions of the perpetrators at this writing follow:

Disposition	*Number of Perpetrators*
Felony conviction	9
Felony charged	1
Lawsuit judgment	1
Charges dropped	1
No sanctions proposed	4
Hired by victim	1

Only one perpetrator, a nineteen-year-old programmer, had a prior conviction—for a misdemeanor of marijuana possession.

(11) Personal Characteristics—Generally the perpetrators were accepted as reliable, honest, bright, highly motivated in their work and most desirable people for a manager to hire. They do not appear special as a class and could not be classed as professional criminals who take pride in their wrongdoing. The greatest fear they reported occurring during their acts was unanticipated detection and exposure of their acts to their families, friends, and coworkers. This was feared more than incarceration. In fact, after sentencing, several said imprisonment was the best solution to the original problem that drove them to their acts. After they were caught, their greatest concern was to minimize the criminality aspects of their cases.

This initial study of perpetrators is enough to suggest the value of a thorough sociological and psychological study as a basis for identifying populations of potential perpetrators in automated crime.

COMPUTER SYSTEM VULNERABILITIES THAT FACILITATE ABUSE

Vulnerabilities to computer abuse must be understood for effective threat and risk analysis and computer security. Many vulnerabilities seem obvious, but the security planner can never be sure he has thought of them all or even the important ones. Two analyses, based on the principal vulnerability found or surmised in each of the 375 recorded cases of computer abuse were made to assist in this activity. The first was based on a breakdown of common functional weaknesses, such as inadequate input/output controls; the second was based on a breakdown of the most common functional and physical locations of vulnerabilities. Tables III(a) and III(b) summarize these vulnerabilities and locations.

FUNCTIONAL VULNERABILITIES

Eight primary functional vulnerabilities emerged from the analysis. They are listed below in order of frequency of occurrence. Each vulnerability is general enough to maintain an acceptable level of confidence in assignment of cases to types of vulnerabilities. This approach was adopted because the amount of information about some cases is limited. Examples from the file that demonstrate the range of acts facilitated by each vulnerability appear in the appendix.

(1) Poor Controls Over Manual Handling of Input/Output Data—This vulnerability was associated with 147 cases. The greatest vulnerability occurs wherever assets are most exposed. Over the past 17 years—the period of reported cases—assets have been most tangible and subject to human acts before entry into computers and after output from computers. Data assets are more accessible outside computers than when they are within them, and programs must be executed to achieve unauthorized access. Controls that are often absent or weak include separation of data handling and conversion tasks, dual control of tasks, document counts, batch total checking, audit trials, protective storage, access restrictions, and labeling.

(2) Weak or Nonexistent Physical Access Controls—This vulnerability to access to computing facilities accounted for 46 cases. Where physical access is the primary vulnerability, nonemployees have gained access to computer facilities, and employees have gained access at unauthorized times and in areas in which they were unauthorized. Perpetrators' motivations have included political, competi-

tive, and financial gain. Financial gain occurred mostly through unauthorized selling of computer services, holding computer centers for extortion purposes, burglary, and larceny. In a number of cases employee disgruntlement has been the motivating factor. In some of these cases disgruntlement stemmed from frustration with various aspects of automated society. Controls that were found to be weak or nonexistent include door access, intrusion alarms, low visibility of assets, identification and establishment of secure perimeters, badge systems, guard and automated monitoring functions (closed circuit television), inspection of transported equipment and supplies, and staff sensitivity to intrusion. A number of the intrusions occurred during nonworking hours when safeguards and staff who might notice intrusions were not present.

Four cases from the case file in which abuse was facilitated by physical access vulnerability involved attacks on computers with firearms; one involved a dispute over national politics; another case was perpetrated by a computer operator frustrated with his job, and the remaining two are presumed to have involved citizens frustrated in dealing with government bureaucracy and computer-based services.

(3) Computer and Terminal Operations Procedures—This vulnerability accounted for 43 cases. Losses resulting from operational procedures weaknesses have resulted from sabotage, espionage, sale of services and data extracted from computer systems, unauthorized use of facilities for personal advantage, and direct financial gain associated with negotiable instruments in operational EDP areas. The controls whose weakness or absence facilitates these kinds of acts include separation of operational staff tasks, dual control over sensitive functions, staff accountability, accounting of resources and services, threat monitoring, close supervision of operating staff, sensitivity briefings of staff, documentation of operational procedures, backup capabilities and resources, and recovery and contingency plans. The most common abuse problem has been the unauthorized use or sale of services and data. The next most common problem is sabotage perpetrated by disgruntled EDP operations staff.

(4) Weaknesses in Business Ethics—Abuse facilitated by this vulnerability accounted for 41 cases. A weakness or breakdown in business ethics can result in computer abuse perpetrated in the name of a business or government organization. The principal act is more related to a company's practices or management decisions rather than to identifiable unauthorized acts of individuals using computers. These practices and decisions result in deception, intimidation, unauthorized use of services or products, financial fraud, espionage, and sabotage in competitive situations. Controls include review of business practices by company boards of directors or other top level management, certified public accountant audits, and effective practices of regulatory and law enforcement agencies.

(5) Weaknesses in the Control of Computer Programs—This vulnerability facilitated 33 cases. Programs are assets subject to abuse. They can also be used as tools in the perpetration of abuse, and are subject to unauthorized changes to perpetrate abusive acts. The latter abuses are the most common. Controls found lacking include labeling programs to identify ownership, formal development methods (including testing and quality assurance), separation of programming responsibilities in large program developments, dual control over sensitive parts of programs, accountability of programmers for the programs they produce, the safe storage of programs and documentation, audit comparisons of operational programs with master copies, formal update and maintenance

TABLE III—Vulnerabilities to Computer Abuse

(Incidence in Reported Cases)

(a) Vulnerable Functions

Function	Number of Cases	Percent of Cases
Manual handling of input/output data	147	41%
Physical access to EDP facilities	46	13
Operations procedures	43	12
Business practices	41	11
Computer programs usage	33	9
Operating systems access and integrity	24	6
Time-sharing service usage	19	5
Magnetic tape storage	9	3
Totals	362*	100%

(b) Vulnerable Locations

			Total	
Functional Locations	Number of Cases	Percent of Cases	Number of Cases	Percent of Cases
Data and report preparation	120	33		
Terminal areas	14	4	134	37
Computer operations	95	26		
Terminal areas	10	3	105	29
Non-EDP	44	13	44	13
Computer systems	7	2		
Terminal systems	33	9	40	11
Programming	27	7	27	7
Magnetic tape storage	12	3	12	3
			362*	100%

* 13 of 375 cases were not amenable to analysis.

procedures, and establishment of ethical concepts of program ownership.

(6) Operating System Access and Integrity Weaknesses—This vulnerability facilitated 24 cases. All of these compromises of computer operating systems that are recorded involve the use of time-sharing services. Compromises are accomplished through discoveries of weaknesses in design or taking advantage of bugs or shortcuts introduced by programmers in the implementation of operating systems. The acts involve intentional searches for weaknesses in operating systems, or the unauthorized exploitation of weaknesses discovered accidentally. Most of the acts have been perpetrated in university-run time-sharing services by students committing vandalism or malicious mischief, or attempting to obtain computer time without charge. Controls that would eliminate weaknesses in operating systems include methods for proving the integrity and security of the design of operating systems, imposing sufficient implementation methods and discipline, proving the integrity of implemented systems relative to complete and consistent specifications, and adopting rigorous maintenance procedures.

(7) Poor Controls Over Access Through Impersonation to Time-Sharing Services—This vulnerability facilitated 19 cases. Unauthorized access through impersonation to time-sharing services can most easily be gained by obtaining secret passwords which are keys for the most common method of protecting users of time-sharing services. Perpetrators learn passwords that are exposed accidentally through carelessness or administrative failures, or obtain them by conning people into revealing their passwords or by guessing obvious combinations of characters and digits. It is suspected that this type of abuse is so common that few victims bother to report cases in recordable form. Control failures include poor administration of passwords, failure to change passwords periodically, failure of users to protect their passwords, poor choices of passwords, absence of threat monitoring or password-use analysis in time-sharing systems, and failure to suppress or obliterate the printing of passwords.

(8) Weaknesses in Magnetic Tape Control—This vulnerability accounts for nine cases. Theft of magnetic tapes, their destruction, and data erasure from them are acts attributed to weaknesses in control of magnetic tapes. Many other cases, identified as operational procedure problems, involved the manipulation of data on tapes and copying. (No cases are known in which magnetic disk packs have been subject to abusive acts.) Controls found lacking include limited access to tape libraries, safe storage of magnetic tapes, the labeling of tape reels, location and reel number accounting, control of degausser equipment, and backup capabilities.

FUNCTIONAL LOCATIONS OF VULNERABILITIES

The functional locations of vulnerabilities were analyzed for the 375 cases. Data and report preparation areas and computer operation facilities—the physical locations with the highest concentration of manual functions—were the most vulnerable locations.

Nine primary functional locations of vulnerabilities emerged from the analysis.

(1) Data and Report Preparation Facilities—These were the locations of 120 cases. Areas included key-to-tape/disk/card data conversion, computer job setup, output control and distribution, data collection, and data transportation. Input and output areas associated with on-line, remote terminals are not included here.

(2) Computer Operations—These were the locations of 95 cases. All functional locations concerned with operating computers in the immediate area or rooms housing central computer systems are included in this category. Detached areas containing peripheral equipment cable-connected to computers and computer hardware maintenance areas or offices are also included. On-line remote terminals (connected by telephone circuits to computers) are not included here.

(3) Areas Without EDP Functions—Forty-four cases occurred in non-EDP locations. Many cases involved business decisions in which the primary abusive act occurred in non-EDP areas such as management, marketing, sales, and business offices.

(4) On-Line Terminal Systems—These were the locations of 33 cases. The vulnerable functional areas are within on-line computer software operating systems where acts occur by execution of programmed instructions such as are generated by terminal commands.

(5) Programming Offices—These were the locations of 27 cases. This includes office areas where programmers produce and store program listings and documentation.

(6) Data Preparation and Output Report Handling Areas for On-Line Terminals—Fourteen cases occurred in these locations. This category includes the same functions identified in (1), data preparation but is associated with on-line terminals rather than computers.

(7) Magnetic Tape Storage Facilities—These were the locations of 12 cases. Areas included in the category are tape libraries and any storage place for tapes containing usable data. This does not include temporary or short-term storage of tapes

in tape-drive mounting areas. The latter are included in categories (2), computer operations, and (1), data preparation.

(8) On-line Terminal Operations Areas—These were the locations of ten cases. This category is the equivalent of (2), computer operations, but is in on-line terminal areas.

(9) Central Processors—These were the locations of seven cases. These functional areas are within computer systems where acts occur in the computer software operating system (not induced from terminals).

SAFEGUARDS AGAINST COMPUTER ABUSE

A computer-dependent organization intent on optimizing resource expenditure for computer security can profitably use the results of this study against known and reported types of computer abuse. In general, priorities for safeguards should be established in the following order:

(1) The most important priority, by far, is safeguarding input/output data from disclosure (taking), modification, and denial of use during manual handling in data preparation and distribution.

(2) Secondly, access to sensitive EDP areas should be strictly limited. Particular attention should be given to access by non-EDP employees and non-operational employees (such as programmers) into any operational areas and to the access of operational employees and vendors' employees into operational areas not directly connected with their work. The dangers are primarily vandalism and sabotage.

(3) Computer and on-line terminal operational safeguards are almost as important as access control. The dangers also derive principally from vandalism and sabotage by disgruntled employees in positions of trust.

(4) Business ethics are next in importance to access and operations safeguards. Lack of ethics is a vulnerability found at the highest levels of management and among EDP managers and staff performing or supporting unethical acts for higher management. Accepted ethical standards are needed throughout the computer field.

(5) The next level of concern should be directed at the control of application and operating system programs, including safeguards against unauthorized modification and use, and proprietary aspects.

(6) The specialized and growing problem of preventing access to time-sharing systems by unauthorized users is of next importance.

(7) Finally, the special problem of protecting magnetic tapes in tape storage areas from vandalism and theft must be addressed.

Physical EDP areas of importance for safeguarding appear to be primarily those where manual, operational functions are performed. They are followed by computer systems, then programming offices, and finally magnetic tape libraries. An interesting conjecture is based on the apparent concentration of abuse in the areas of heaviest manual functions. As technical advances eliminate and reduce the size of manual activities, the incidence of abuse could diminish, independent of the degree of security efforts.

APPENDIX

RANGE OF ACTS PERPETRATED IN EACH VULNERABILITY: EXAMPLES FROM CASE FILE

Vulnerability/Case Number *

Case Abstract

1. Poor Controls over Manual Handling of Input/Output Data

75327

A keypunch operator in Stockholm, Sweden manipulated payroll data to produce 86 false payroll vouchers payable through the Swedish postal system. She cashed the vouchers at small, remote post offices that had either not received the computer listings of valid vouchers, or did not bother to check the listings before cashing the vouchers. She escaped to South America.

75321

A data control clerk in a bank computer center embezzled $7,200. He diverted and stole checks being processed from a correspondent bank. For each check he then wrote a check for the identical amount on his own checking account and then deposited it in a second checking account, also his own. When his own check turned up for processing he destroyed it and substituted the stolen check. Thus, the check he wrote against his own account was never charged against that account.

* The first two digits of case numbers identify year of occurrence. The third indicates the type of loss (1=vandalism; 2=information or property fraud or theft; 3=financial fraud or theft; 4=unauthorized use or sale of services). The last digit or two digits is a sequence.

7524

Three oil company employees are alleged to have conspired to manipulate computer stored data and oil tank gauges to indicate a full delivery had been made to a refinery from tankers when only part of the load went into the tanks. The rest of the oil is alleged to have been delivered to two smaller companies. The acts were discovered when an inventory check revealed a discrepancy between the amount of oil in the tanks and the amount supposed to be in the tanks according to computer-stored records.

2. Weak or Nonexistent Physical Access Controls

72112

An EDP employee or a vendor's maintenance engineer did $590,000 worth of damage to computer memory stacks by attacking them with a pointed instrument, probably a screwdriver.

7219

An unknown person poured acid over telephone wires where they enter a building containing data processing equipment.

7522

Twelve persons, including a computer manufacturer's employee, thought to be engaged in international espionage, were caught while taking computer components, maintenance manuals, magnetic tapes and circuit diagrams from computing facilities in Frankfurt and Karlsruhe, Germany. Financial losses were estimated to be $110,000.

3. Weaknesses in Computer and Terminal Operations Procedures

74313

In a large bank fraud in Germany, computer operators prevented bookkeeping entries by activating system interrupts from the computer console. Invoices were prepared by the system without recording the transactions.

70410

A programmer analyst used his employer's computer under nonchargeable software development usage in conjunction with his personal outside consulting business.

6711

A disgruntled computer operator dropped pieces of metal into an IBM 2740 terminal causing electrical shorts, fires and considerable downtime. The operator was discharged and successfully prosecuted.

7427

A computer printer operator was paid to make an extra carbon copy of competitive bidding reports for industrial espionage purposes. The operator was discharged.

7438

A computer operator printed copies of unemployment checks and deleted the copying record from the file. An auditor discovered the $10,000 fraud in a computer audit run. The employee was convicted and given a suspended sentence and five years' probation.

7415

A computer operator working alone at night carried a hand gun because the computer center was in a high crime area. One night out of frustration with the computer he shot it with his gun.

4. Weaknesses in Business Ethics

7523

A customer charged a computer equipment vendor with fraudulently representing the capacity and capability of a computer system and charged that the full system was never delivered and did not have adequate software.

7539

One company made a loan to another company based on certain collateral. The pledging of the collateral was hidden by the company receiving the loan so that it could be reused for new loans. Computer listings containing fake data describing the collateral were used.

7446

A computer dating service was sued because referrals for dates were so few and inappropriate. The new owner of the dating bureau said that no computer was used at that time although use of a computer was advertised.

73216

A convicted criminal filed an appeal against the U.S.A. claiming he was denied a fair trial by admission of computer-produced statistical summaries from which inferences of guilt were suggested. The appeal was denied.

5. *Weaknesses in the Control of Computer Programs*

75315

The manager of a bank computer center made unauthorized changes to the demand deposit accounting program to credit service charges to his and a friend's accounts rather than to the proper bank income account.

72219

The president of a French software company posed as a professor of computer science on a tour in the United States where he collected many free programs offered from more than 200 computer centers. He returned to France and sold copies of the programs he had collected. He was caught and fined 5,000 francs for the sale of one program. No action was taken concerning all the other programs he was selling.

6542

A systems programmer replaced a computer operating system supervisory module with a new one that allowed him access to the area of storage used for the resident operating system.

6521

Accounting clerks programmed and used a program called "fudge". It was run at the end of each month to change account balances until all column totals balanced correctly.

7439

A programming manager in a savings and loan association changed updates to the savings program to ignore withdrawals from his account. He was convicted after he was caught by auditors when he made a keypunch error in an account number.

72216

A computer specialist in the government taxation commission in a foreign country sold copies of program logic documentation describing the controls and checking on deduction claims in income tax forms.

73212

A 19-year-old girl convinced her boyfriend to steal copies of computer programs from his employer, a service bureau. She then attempted to sell them to customers of the service bureau. She was convicted and received a one-year suspended sentence.

6. *Weaknesses in Operating System Access and Integrity*

6611

Students caused disruption of a time-sharing service when they tested the operating system and found a failure in the exception handling of filled physical disk storage.

7441

A graduate student compromised a time-sharing system to convert his terminal to the functional equivalent of the computer console. He performed this act to convince management of the computer facility of the vulnerability of the time-sharing system.

7343

A student wrote a program masquerading as an operating system. When a user attempted to log in, the masquerading program obtained his account number and then declared the system unavailable. The student used the account numbers discovered in this fashion for his own purposes to obtain computer time without charge.

7. *Poor Controls over Access Through Impersonation to Time-Sharing Services*

7525

A time-sharing user discovered he was being underbid by small amounts in contract negotiations where the data was stored in a time-sharing service computer. He concluded that a recently terminated employee retained knowledge of his password. He had the password changed, and the problem disappeared.

74316

A man was convicted in France of counterfeiting bank cash dispenser credit cards. He impersonated a bank official to obtain the personal identification numbers associated with the cards by calling the card number holders requesting them to report their numbers so that new numbers could be assigned.

6842

High school students found a time-sharing user's passwords on discarded terminal printouts. The students used the passwords to obtain unauthorized services.

7344

An unauthorized user of a commercial time-sharing service was found to have used eight hours of computer time by continuing to use a password assigned him only for demonstration purposes. The password had not been purged as scheduled.

8. Weaknesses in Magnetic Tape Control

74212

A mailing house employee was caught in attempts to sell magnetic tapes containing mailing lists to a competitor of the mailing house.

7511

An EDP employee sabotaged his company by erasing magnetic tapes with a degausser.

6212

An EDP employee in a bank destroyed all dividend accounts for shareholders of a large company by destroying the magnetic tapes containing the data with a sharp instrument.

7216

A tape librarian in an insurance company was fired but given a 30-day notice. During that time she replaced most of the magnetic tapes in the tape library with scratched tapes.

Effective safeguards for computer system integrity

by NORMAN R. NIELSEN, BRIAN RUDER and DAVID H. BRANDIN
Stanford Research Institute
Menlo Park, California

ABSTRACT

This paper reports the findings of a project to identify types of computer system integrity safeguards that would have been effective in preventing, detecting, or mitigating the effects of actual reported incidents of computer system integrity violations. More than 350 cases were analyzed and categorized among one of 26 types of violations and among one or more of 34 types of applicable safeguards. Brief definitions are provided for all categories, and distributions of incidents over the various violation categories and over the applicable safeguards are presented.

The analysis revealed that most safeguards have a surprisingly narrow range of applicability, whether measured by number of cases or by number of violation categories affected. However, much broader violation coverage is possible through use of combinations of small numbers of safeguards. Directions for further research are discussed, including the need to develop measures of violation category importance and to include a consideration of safeguard cost, effectiveness, and operability factors.

INTRODUCTION

The history of computing is marked by periods of specialized concerns, such as those for the development of high level programming languages and time-sharing systems. Currently, there is intense interest in computer security and related topics such as privacy and data confidentiality. A number of research projects have been and are being conducted in such areas as physical security equipment, secure operating system kernels, program certification, data encryption, operations procedures, personal identification, and audit practices. While the developments in all these areas are effective against certain types of problems, no general appraisal has been made of their effectiveness against actual computer security problems.

System integrity is used herein to refer to the related and overlapping concerns of:

- Security (protecting system integrity from compromise)
- Audit (verifying the continued existence of system integrity)
- Recovery (restoring system integrity and operability in the event of the loss of such integrity).

Computer system is broadly defined to encompass not only the computer hardware and software but also the computer facility itself. Thus the operations associated with that facility are included, from the initial capture of input data to the final usage of output information by the user. Within the broad perspective of computer system integrity maintenance, the questions of interest concern:

- The safeguards that the user should implement first
- The areas in which development efforts should be focused
- The directions in which future research should be guided.

This paper reports an effort to identify the types of system integrity safeguards that would have been effective in preventing, detecting, or mitigating the effects of actual reported computer system integrity violations. Although the representativeness of the known cases of system violation relative to the total population of actual violations is unknown, this paper does provide some initial information concerning the types of safeguards applicable to the types of violations that are occurring. The scope of potential threats to computer system integrity is vast; hence if a system integrity maintenance budget is to be allocated meaningfully, attention must be focused on the likely threats and the relevant tools for defending against those threats.

The second section describes the integrity violation information used in this research, the third section the categorizations of violations, and the fourth section the safeguards. The fifth section discusses the relationship of the types of violations being experienced to the various types of safeguards. The directions suggested for further research are indicated in the last section.

CASE FILE OF COMPUTER SYSTEM INTEGRITY VIOLATIONS

The computer abuse case file collected by Donn B. Parker was used as the basis for categorizing both violations and safeguards. This file, described by Parker[1] in 1973, now contains information on more than 350 computer incidents. The cases have been collected over a number of years, with information obtained from newspaper articles and other published reports, from personal contacts, and from a number of in-depth interviews with victims and perpetrators. The information available about an incident ranges from a two-inch newspaper clipping to several hundred pages of transcripts and investigatory notes.

It is suspected that, in the history of computing, there have been far more than 350 cases of system integrity violations. However, most of these incidents, for various reasons, have not been reported and in some cases have been actively suppressed. Hence, small as the 350-case sample may be, it represents the most complete coverage available of the known computer system integrity violations.

Each case in the file was studied, and a one-page summary data sheet was filled out. Exhibit I shows the form that was used for this purpose. The collection of summary sheets then became the primary data base on which the remainder of the investigation was based.

INTEGRITY VIOLATION CATEGORIES

In analyzing the types of system integrity violations against which various types of safeguards might be effective, it is helpful to be able to deal with classes or categories of violations rather than with a long list of specific violations. Accordingly, the violation case file was categorized by type of violation.

Each case was studied and given a brief descriptive label. These labels were then collected, refined, and consolidated to form a tentative set of 26 violation categories. Each case was then re-examined by a different analyst and placed into one of the new categories. Differences in placement between the original assignment and the reassignment were resolved, so that there was consensus over the assignment of each case to one and only one of the violation categories.

It should be noted that the choice of 26 categories is not sacred. The categories simply represent a condensation of the various violations for the convenience of this study. It would have been possible to develop only ten categories or as many as 50 categories, if we had found that helpful.

There is as yet no definitive and universally accepted mechanism for determining the precise violation occurring in a given case. Most cases represent a combination of violations. For example, a person enters a restricted area (e.g., a computer room) without authorization, which can be considered one type of violation. Having gained access, the perpetrator then uses the computer in an unauthorized manner or for an unauthorized purpose, which can be considered a different type of violation. The problem is determining which type of violation was the "real" violation.

As a result of such ambiguities, the assignment of cases to the various violation categories is a subjective process. While the placements we have made may not be suitable for all purposes, the subjective nature of our assignment process does not detract from the value of these data to the study. It must be remembered that the categorization of violations serves only to stimulate the isolation or development of safeguard concepts having practical application to the problems actually being experienced.

After all the cases had been reviewed and categorized, 62 were discarded from further consideration. Most of those discarded cases were eliminated because the available information was too sketchy or so vague that it would have been impossible to identify applicable safeguards. A small number of cases were also eliminated because they closely paralleled other cases for which more extensive information was available.

The distribution of the 293 remaining cases across the 26 violation categories is shown in Table I. A brief definition of each violation category is given in Exhibit II.

It is interesting to note that the two violation categories having the largest number of cases (Direct Change of I/O Data, Adding to I/O Data) refer to activities taking place outside the computer itself. However, lest incorrect conclusions be drawn, it is important to note that the distribution figures represent incidents and not a random sample of the full population of incidents. Thus, the concentration of cases noted above may indicate that a preponderance of violations are of this type or that a greater percentage of the violations in these categories are reported or otherwise become known.

TABLE I—Case Distribution Over Violation Categories

	Number of Cases
1. Application Software Manipulation	29

Total	293

EXHIBIT II—System Integrity Violation Categories

1. Application Software Manipulation—Direct manipulation or change of application programs, in the design, implementation, or maintenance stages.
2. System Software Manipulation—Direct change to or nonstandard use of operating system functions or utilities.
3. Contract Mistakes—Poor contract specifications, permitting integrity violations.
4. Improper Use of Personal Identification—Use of personal identification mechanism (e.g., a badge) by an unauthorized person to obtain information or money.
5. Misuse of System Authorization—An otherwise authorized person performing a legitimate task, but one for which he or she is not authorized.
6. Destruction of Data—Physical or logical destruction of data.
7. Unauthorized Copying of Data—Copying files or other data for personal use or resale without authorization.
8. Misuse of Passwords—Unauthorized use of passwords to gain access to computer system.
9. Direct Change of I/O Data—Alteration of computer input data before its entry into the computer system.
10. Adding to I/O Data—Adding data to the computer input stream or to computer outputs after processing.
11. Personnel Practices—Errors or oversights that result in improper privilege level assignments to staff members.
12. Unauthorized Building Access—Unauthorized building access for theft or vandalism.
13. Violation of Operating Procedures—Authorized persons violating computer room procedures or access controls for theft of hardware supplies or for vandalism.
14. Unauthorized Use of Terminal Area—Unauthorized access to the terminal area or use of terminal equipment in unauthorized ways.
15. Misuse of Communications Equipment—Misuse of communications equipment such as lines, multiplexors, and front-ends but excluding terminals.
16. Management Inaction or Misaction—Failure of management to act or improper action because of lack of understanding of computing.
17. Unauthorized Use of Services—Use of computer services in an unauthorized manner (e.g., without payment).
18. Unethical Behavior—Violation of the "reasonable man" ethical standard.
19. Software Theft—Theft of programs or program documentation.
20. Improper Training—Errors made by personnel receiving inadequate or improper training for their assigned duties.
21. Natural Disasters—Damage arising from earthquake, fire, or explosion, flood, etc.
22. Aura of Computer—Computer used as a "know-all" symbol to cheat or mislead people.
23. Computer Support of Another Crime—Computer used in the planning or in the support of another, possibly non-computer related, crime.
24. Accident—Accidental damage to or destruction of data.
25. Negligence—Destruction of data, supplies, or equipment through negligence of personnel.
26. Miscellaneous—violations that do not fit into any of the above categories.

SAFEGUARD CATEGORIES

In analyzing the types of system integrity violations against which various safeguards might be effective, it is helpful to be able to deal with classes or categories of safeguards rather than with a long list of specific safeguards. In the early stages of analysis, it is more helpful to deal, for example, with a category called "personal identification procedures" than it is to deal with a list of specific safeguards such as "badge with photograph, machine readable badge, handprint, fingerprint, signature, and password." Accordingly, the violation case file was categorized by the types of safeguards that would have been effective in preventing, detecting, or mitigating the effects of those violations.

Each case was studied and given a set of brief descriptive labels. Each label described a safeguard that, had it been applied, would have altered the outcome of the incident. Generally two to four safeguards were identified for each case. These labels were then collected, refined, and consolidated, and a tentative set of safeguard categories was formed.

The safeguard categories were themselves analyzed and organized into a set of four generic categories. Each generic category was re-expanded into a set of carefully defined subcategories. Each case was then re-examined and recategorized using the refined categories. This reassignment of cases resulted in one additional round of refinements before the present 34 subcategories were defined and established.

The four generic categories of safeguards are:

- Management safeguards
- Systems safeguards
- Industrial security safeguards
- Legal and educational safeguards

Figure 1 illustrates the hierarchical organization of the safeguard categories, and Exhibit III provides a brief definition of each. Systems safeguards constitute the principal technical defense against computer system integrity violation. Management safeguards are more conventional and less difficult to implement. Industrial security safeguards are the familiar and well understood "physical security" safeguards. The legal and educational safeguards are essentially longer term measures that apply to society as a whole rather than to the environment of a specific organization.

The determination of helpful safeguards for cases faces subjective problems similar to those encountered in assigning cases to violation categories, although the freedom to specify several safeguards eliminates the problem of specifying the safeguard for multiple violation situations (i.e., a situation in which violation A was committed so as to be able to commit violation B). However, the categorization problem for each specific safeguard proposed still remains, analogous to the categorization problem for each violation. Consider the specification of a test procedure to be used as a safeguard in the installation of operating system modifications. Is such a safeguard more appropriately classified as a management procedure, an operations procedure, or a software interface procedure? Thus, a large degree of subjectivity exists in the selection of applicable safeguard categories for cases.

Table II shows distribution of cases across the various types of safeguards that might have been applicable in defending against the violation that occurred. Note that the total number of applicable safeguards is 738, making an average of 2.5 safeguards for each of the 293 cases. It is interesting to note that the two types of safeguards identified as being applicable to the largest number of cases (Audit Procedures, Data

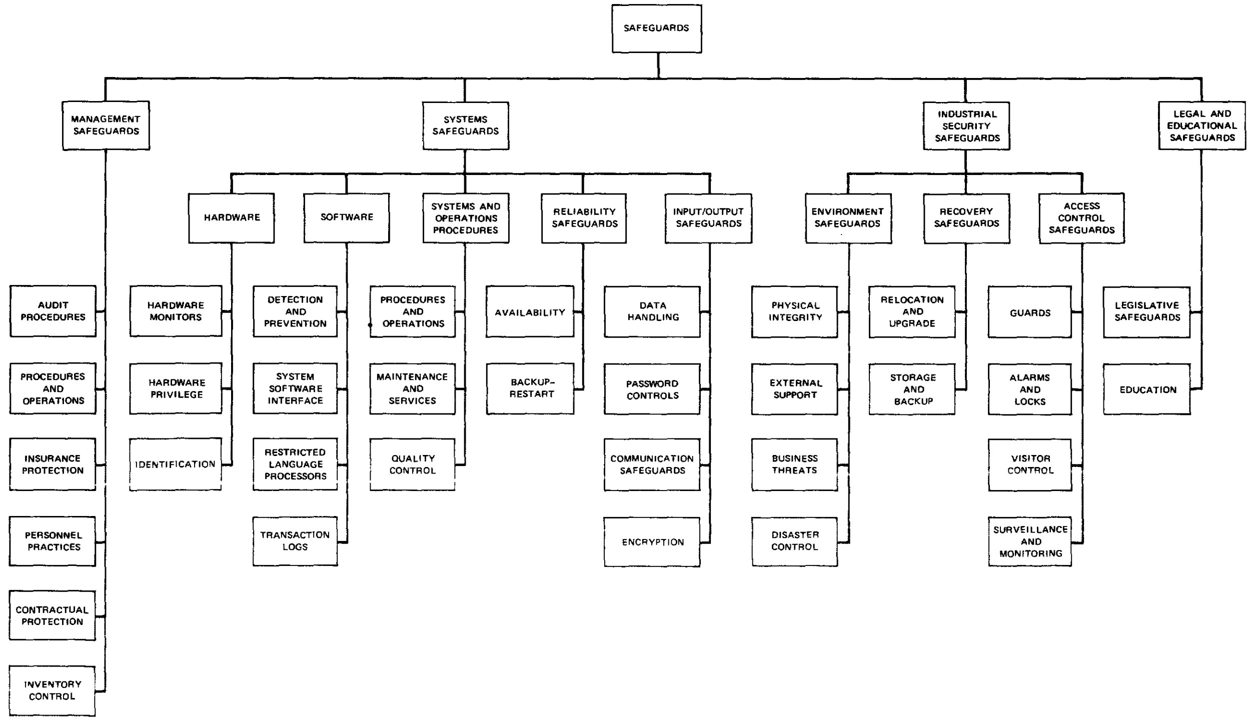

Figure 1—Safeguard schematic

EXHIBIT III—Protective Categories

MANAGEMENT SAFEGUARDS

- Audit—Use of internal and external audits to validate the EDP system.
- Procedures and Operations—Establishment of management procedures that define and enforce operational procedures.
- Insurance Protection—Maintenance of adequate EDP insurance protection.
- Personnel Practices—Investigation of new employees, monitoring of anomalous behavior, and use of effective dismissal techniques.
- Contractual Protection—Use of contracts that address deliverables, specifications, and liabilities.
- Inventory Control—Identification and control of all computational resources and hard copy forms.

SYSTEMS SAFEGUARDS

Hardware

- Hardware Monitors—Use of independent devices for measuring system activity.
- Hardware Privilege—Use of hardware to control access to and use of system resources.
- Identification—Use of hardware devices to identify equipment and people accessing a computer system.

Software

- Detection and Prevention—Use of software to monitor and check program accesses to I/O programs, utilities, and special hardware.
- System Software Interface—Use of software controls to monitor and limit references to operating system components and system utilities.
- Restricted Language Processors—Development and use of families of language processors (and loaders) with increasing levels of privilege.
- Transaction Logs—Use of serialized logs to record transactions, log-ons, I/O, and detected unauthorized accesses.

Systems and Operations Procedures

- Procedures and Operations—Identification of work responsibilities, separation of responsibilities, procedures for handling data, and increased sensitivity to security during abnormal times.
- Maintenance and Services—Use of procedures to ensure timely preventive maintenance and good quality control procedures for software maintenance.
- Quality Control—Use of stringent testing procedures for operating system software and assignment of quality control to separate teams of programmers.

Reliability Safeguards

- Availability—Use of environmental safeguards and architectural configurations that facilitate modular recovery.
- Backup-Restart—Establishment and testing of restart procedures, proper hardware/software backup, and a carefully monitored checkpoint/restart program.

Input/Output Safeguards

- Data Handling—Verification of input data, special handling of extraordinary input, shredding of surplus output, proper storage and backup of data and program files, and limited transmission of output to remote devices.
- Password Controls—Development and enforcement of password procedures, updating of passwords, monitoring of invalid log-ons, and the use of passwords to verify devices and users.
- Communication Safeguards—Establishment of secure communications, hardwired lines, and use of intelligent front-end processors to supplement mainframe coding.
- Encryption—Encryption of sensitive files, including data, password, and accounting files.

INDUSTRIAL SECURITY SAFEGUARDS

Environmental Safeguards

- Physical Integrity—Use of procedures to protect the physical environment of the facility, the use of UPS, and the housing of computing facilities in structurally secure buildings.
- External Support—Establishment of relationships with local police and fire agencies as well as monitoring vendor and other outside personnel in a computing facility.
- Business Threats—Management procedures for anticipating potential threats from competitive and other forces.
- Disaster Control—Establishment of provisions for reacting to natural disasters, e.g., drainage in the event of floods.

Recovery Safeguards

- Relocation and Upgrade—Use of detailed procedures for maintaining system integrity during hardware upgrade or system relocation and comprehensive testing of all system modifications.
- Storage and Backup—Enforcement of operational procedures for storing systems and data backup and documentation in off-site vaults, and the logging of all vault traffic.

Access Control Safeguards

- Guards—Use of building guards to control building access, monitor visitors, and to patrol restricted areas.
- Alarms and Locks—Use of alarms to detect unauthorized entry and locks to limit traffic.
- Visitor Control—Use of proper identification procedures for all persons in the facility, validation of the purpose of all visitors, and investigation of all packages moving in and out of a computing facility.
- Surveillance and Monitoring—Use of surveillance and logging equipment to monitor activities in and around the computing facility.

LEGAL AND EDUCATIONAL SAFEGUARDS

- Legislative Safeguards—Formulation of civil and criminal codes that aid in apprehension and recovery in the event of violations.
- Education—Education of computer practitioners, the public, and law enforcement authorities, curricula developments in protective procedures, and improved professionalism.

Handling) are two areas that are not commonly treated by security research efforts aimed at developing new tools and techniques. It is also interesting that none of the reported violations could have been aided by the application of system availability safeguards. A third observation concerns the large number of cases for which it was judged that some form of procedural development would have been effective, as opposed to some type of hardware or software tool or technique.

Care must be exercised in drawing conclusions from Table II, since the underlying cases do not necessarily represent a random sample of the full population of computer system integrity violations. Thus, the large number of cases for which some type of audit procedure would have been helpful may indicate that a large percentage of the violations actually occurring could have been affected by the application of appropriate audit procedures, or it may only indicate that a large proportion of cases in which audit safeguards were lacking are reported or publicized.

Many interrelationships exist between the safeguard categories depicted in Figure 1. However, these relationships are not shown, since their number is so large as to confuse the categorization. Thus, for example, two well-known interrelationships (between Hardware Monitors and Detection Software and between Quality Control and System Software Interface) are not indicated.

It is interesting to note the pervasiveness of procedural aspects throughout the safeguard categories. It was this multitude of interrelationships that presented one of the biggest problems in attempting to isolate and define unique safeguard subcategories. On the other hand, this pervasiveness of procedural safeguards is in itself a significant finding.

SAFEGUARD APPLICABILITY

As discussed earlier, Table II presents the distribution of violation cases over the various types of safeguards that might have been applicable in defending against those violations. However, in view of the unknown representativeness of the violation frequencies of the available cases, it is important to measure safeguard applicability by means other than simply number of relevant cases.

An important alternative measure relates to the range of types of violations against which a safeguard is applicable. Such a measure provides insight into the types of safeguards that potentially have the greatest impact and that should be given prime attention when planning for system integrity maintenance. Accordingly, the safeguards judged applicable to each case were aggregated by violation category. The number of cases in each violation category for each category of applicable safeguard is presented as a matrix in Table III. Several observations should be made relative to these data.

First, there is a tendency for safeguards to cluster, that is, for the safeguards in a set of subcategories to apply to the same types of violation categories. Second, the range of violation types to which a given type of safeguard applies is fairly restricted. Only two violation categories (Data Handling, Detection and Prevention Software) are applicable to at least 50 percent of the violation categories. However, combinations of categories can increase the range of coverage. For example, nearly 70 percent of the violation categories are covered if all the procedural safeguards are considered together. This finding supports the observation discussed earlier about the pervasiveness of procedural safeguards encountered in the formulation and definition of safeguard categories.

As expected, the industrial security safeguards have a very narrow span of applicability. Nominally, Table III shows that some safeguard from this generic category is applicable to cases from 11 violation categories. However, if violation categories having only one safeguard subcategory applicable to but a single case are eliminated from consideration, then the industrial security safeguards apply to only 5 of the 26 violation categories.

It is possible to obtain greater violation category coverage by combining safeguard subcategories. For example, the two management safeguards, Audit Procedures (11 categories) and Procedures and Operations (8 categories), combine to cover 15 categories. The two systems safeguards, Detection and Prevention (13 categories) and Procedures and Operations (10 categories), combine to cover 15 categories. Even Data Handling, with the broadest coverage of any safeguard (17 categories), can be extended to 20 categories when combined with Password Control (10 categories). These types of combinations are very likely to occur in practice because of the natural relationships between safeguards.

Despite the aforementioned overlap in violation category coverage by the various safeguard subcategories, a surprising finding was the lack of broad applicability of the subcategories within a single violation category. For example, in only 5 of the 11 applicable violation categories does Audit Procedures apply to at least 50 percent of the cases in a category. Data Handling applies to a majority of the cases in

only 9 of its 17 applicable categories, while Detection and Prevention applies to a majority in only 2 of its 13 categories.

This shallowness of coverage supports the findings from Table II showing only two safeguard categories applicable to as many as 35 percent of the violation incidents (Audit Procedures, Data Handling), only two additional categories applicable to as many as 20 percent of the cases (Detection and Prevention, Procedures and Operations—Systems), and only three additional categories applicable to as many as 10 percent of the cases (Password Control, Quality Control, Procedures and Operations—Management).

The research project to date has utilized applicable violation categories as a measure of breadth of safeguard applicability. While this measure has certain advantages over a measure such as number of applicable cases, it also has certain disadvantages. For example, measurement of range by number of applicable violation categories makes an implicit assumption that all violation categories are of equal importance, an assumption unlikely to hold in practice.

Thus, in drawing conclusions about the "most applicable" types of safeguards, it is important to consider the likelihood of violations occurring in a particular category as well as the likely damage that would result from a violation in that category. A set of weights must be developed for the violation categories, based on both risk of occurrence and risk of loss on occurrence, so as to permit safeguard category coverage to be adjusted by the relative importance of each category. Furthermore, safeguard selection must be based on far more than just potential applicability. Cost, effectiveness, operability, and like factors must be considered as well. Extensions into these areas are part of the planned course of the research project.

Nevertheless, the first-cut, coarse approach used thus far is informative and does provide a meaningful base from which to proceed with further work.

Our analyses and the data presented in Table III support many subjective feelings held about effective types of safeguards. Two conjectures that are supported relate to the potential range of application of particular safeguards. (This support is not affected by the uncertainties that exist concerning the representativeness of the cases used relative to the actual population of computer system integrity violations or by the coarse applicability measure used.) First, the data provide no evidence that there is a type of safeguard that is likely to apply to all types of possible system integrity violations. Second, the data provide evidence that there are likely to be few if any instances where a particular type of safeguard will apply to all cases within a given type of violation.

Consequently, from a user's point of view, effort must be directed toward the development of sets or packages of safeguards rather than the development and refinement of single techniques to address one problem area. The breadth of violations encompassed in a single violation category requires that a similar breadth exist in the safeguards applied.

FURTHER RESEARCH

The research conducted thus far and reported herein has focused on the types of computer system integrity safeguards available and on the range of applicability

of these safeguard categories relative to the identified types of computer system integrity violations. It has been an exploratory effort aimed at revealing the types of safeguards that would have been effective in detecting or preventing the actual system integrity violations that have been publicly reported. This work is now being expanded to examine the range of applicability of combinations of safeguards relative to the violations themselves (rather than the categories of violations). The identified safeguards will be categorized according to implementation cost, operational cost, and effectiveness. This should aid in identifying promising research areas and types of tools where further development work would be helpful.

A second phase of the research will be oriented toward the development of an effective collection of detection tools. This set of tools will be designed to address the types of violations not more readily addressed by other categories of safeguards. Emphasis has tended to be placed on the prevention of computer system integrity violations; yet there are many situations where rapid, inexpensive detection of violations (or attempted violations) is more effective from a system standpoint than reliance on stronger but more expensive prevention mechanisms. The research findings with respect to safeguard effectiveness, implementability, operation, and cost will be used as the base for the second phase effort to develop a set of detection tools appropriate for computer system integrity maintenance purposes.

SUMMARY

The coarse analysis of more than 350 incidents of computer system integrity violation revealed a surprisingly narrow range of applicability of particular safeguards over the various types of possible violations. This narrowness was observed both in terms of safeguard applicability to the 26 violation categories and in terms of applicability to the cases within any one category. However, since there are many interrelationships between the 34 safeguard categories, combinations of safeguards are a logical development. The study found that combinations of small numbers of safeguards readily extend the range of violation categories covered.

The study also revealed the desirabiilty of extending the work to consider the relative importance of violation categories, to include consideration of safeguard cost, effectiveness, and operability factors, and to examine combinations of safeguards at the case level rather than at the violation category level.

Interesting sidelights arising from the study were the findings that the two largest violation categories (in terms of number of cases) were ones that apply to activities taking place outside the computer proper and that the two most applicable safeguards (in terms of number of applicable incidents) were ones that are not commonly treated by security research efforts aimed at developing new tools and techniques.

A centralized approach to computer network security*

by FRANK R. HEINRICH and DAVID J. KAUFMAN
System Development Corporation
Santa Monica, California

ABSTRACT

This paper presents an approach to network security at the system design level. Some basic network concepts and major network security threats are outlined. The design approach is described and a brief security analysis is presented. The proposed network structure incorporates data protection devices called network cryptographic devices and a special-purpose processor, the network security center, to control access in the network.

INTRODUCTION

The ever-increasing utilization of computer systems has heightened demand for broader computer service and data management capability. Computer networks are an attempt to meet this demand by organizing many individual computer systems to act as a single, very large system or supracomputer.

The distribution of data processing functions among a set of distinct systems decentralizes the control of data storage and processing. In addition, information must be transmitted between computers and is therefore subject to exposure. These factors complicate the problem of providing a high degree of security assurance in computer networks. Additionally, current emphasis on privacy considerations underlines the need for network security. Thus security must be a major factor in network design.

This paper presents an approach to network security at the system design level. To provide a basis for discussion of this design, a few basic network concepts are first outlined. Some major network security threats are then presented to provide a context for evaluating the system. Finally, the network structure is described and a brief security analysis presented. The proposed network structure incorporates data protection devices called network cryptographic devices and a special purpose processor, the Network Security Center, to control access in the network.

The design in this paper provides a means for centralizing control in computer networks. When global policies toward network access, data storage and processing can be established, this design is quite appropriate. In some instances, however, it may be difficult to develop such global policies. The management at each network site may decide to maintain greater control over local policy and resist centralization. A second approach to computer network security in which control can be more easily distributed, is presented in a companion paper.[1]

BASIC NETWORK·CONCEPTS

In an intercomputer network, a number of computer systems and terminals are linked. The individual computer systems (hosts) and terminals are called network resources. Interconnection of these resources requires functions performed by both hardware and software, but in this section we consider only the logical arrangement of networking functions rather than associating any particular functions with specific hardware devices.

Network resources must be physically interconnected in some manner. That is, facilities must exist to provide data paths between network resources. These facilities, called the communications subnetwork, may take many forms. The communication subnetwork may consist of telecommunications lines, a message switch, or a packet switched network. Regardless of the configuration, however, we will view communications subnetworks as logically equivalent, supplying a means for data to flow from any network resource to any other network resource.

Figure 1 illustrates three layers, or levels, of network functionality. Layer 1 is network resources; layer 2 is connection-oriented functions; and layer 3 is the communications subnet. Network resources can be thought of as *correspondents,* freely exhanging information (i.e., message text) by way of a *carrier* consisting of the connection-oriented functions and the

* The work reported in this paper was supported by the U.S. Department of Commerce, National Bureau of Standards contract #5-35934.

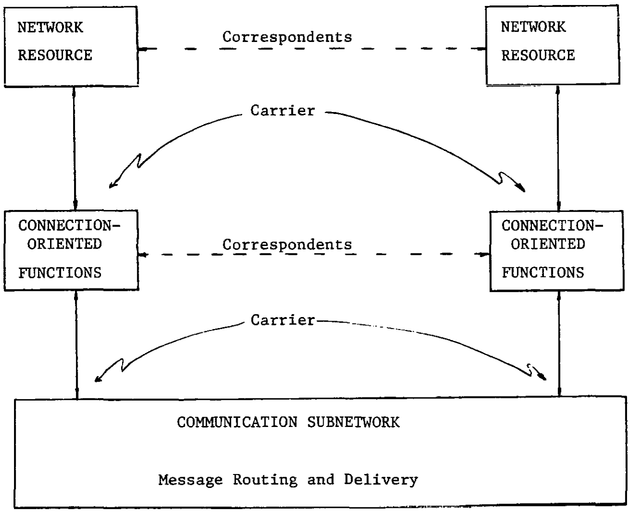

Figure 1—Layers of network functionality

communications subnetwork. The connection-oriented functions at different locations are, in turn, correspondents, exchanging information concerning the state of message pipelines via their carrier, the communications subnetwork. We refer to correspondents as being (logically) above the carriers.

The actual content of the communication between correspondents is not of concern to lower layers (the carrier). Within a carrier, control messages may also be exchanged which are of no concern to higher level correspondents.

Countering the network security threats discussed in the following section will require introduction of additional network functions. These new functions will not alter the logical relationship between the three layers already presented, but will necessitate the addition of a new functional layer.

NETWORK SECURITY THREATS

With privacy statutes being enacted, security vulnerabilities are a serious concern. Yet networks present formidable security problems due to the multi-user, multi-resource, multi-system environment. Physical and procedural controls have proven to be particularly inadequate in such geographically distributed systems. Primary security threats to intercomputer networks are:

1. *Threats to Network Communication*—Network communications are susceptible to several major security threats. Penetrators may tap communication lines or network devices outside of physically secure facilities. Tapping of communications may result in unauthorized exposure of sensitive information or alteration of message text. A penetrator may record legitimate messages and replay them at a later time in order to spoof a network resource. Spoofing could also be accomplished by generation of spurious, but apparently legitimate messages. Misrouting and subsequent misdelivery of messages, either accidentally or maliciously, may result in unauthorized disclosure of sensitive information.

2. *Counterfeit Network Resources*—Network penetrators may be able to utilize counterfeit network resources. A bogus terminal or host computer may be made to appear as a legitimate source or destination of network messages. Without mutual authentication of network resources, uncontrolled use of the network may be obtained by those who would normally not have access to the network.

3. *Forged User Identification*—A penetrator may gain network privileges by forging the identity of a valid user. Of course, this same threat applies to a single computer system. In a network, however, a penetrator may capitalize on a domino effect. A penetrator may use a forged identity to compromise a single host with poor security controls. Other network resources may then be compromised if they, in turn, trust the user's identity as established by the compromised host.

4. *Unauthorized Access by Legitimate Users*—Legitimate network users may gain unauthorized access to host computers, data files, programs, etc. A malicious user may take advantage of unauthorized access to delete or modify data files or programs, or even subvert an entire host computer system. Furthermore, sensitive or private information may be subject to unauthorized browsing.

If each of the host computer systems which make up the intercomputer network were secure when operated separately, the security threats of forged user identification and unauthorized access would be eliminated. Separate network countermeasures for these threats would then be unnecessary. Mechanisms might still be included to relieve each host of the operational burden of implementing identification/authentication mechanisms and to provide a single unified network access protocol increasing user convenience when accessing various network sites. However, no secure general-purpose computer systems exist today. Furthermore, it is doubtful such systems will be widely available for a long time. Thus, network mechanisms must be developed to protect network communications and to avoid increasing compromise threats to hosts because those hosts are linked in a network.

SYSTEM DESCRIPTION

This section presents a system level design of a secure intercomputer network as illustrated in Figure 2. The design incorporates cryptographic devices which

Figure 2—System level design

encipher data (i.e., transform data in order to conceal its meaning) and decipher data (i.e., reverse the encipher process to render data once again intelligible).[2] This transformation is based on a secret parameter called a Key. The cryptographic devices provide an additional layer in the logical structure of the network.

The design also incorporates a new network resource called a Network Security Center (NSC), which is based on Branstad's concept of a Network Agency.[3] Connections between network resources are permitted only when authorized by the NSC, based on stored access control information. This control is enforced by the network cryptographic devices which will form cryptographic links only when instructed by the NSC.

The network shown in Figure 2 contains Network Front Ends (NFEs). An NFE is a processor which implements connection-oriented functions for a set of terminals and hosts. A network, which adheres to the secure design, can be built without NFEs. NFEs do have operational advantages, however, and are being considered for use in many future networks. Thus, we address their role in network security.

An example may clarify the functioning of the NSC and network cryptographic devices.

A user (U) at a terminal, desires access to a process (P) at a distant host (H). Before being connected with H, the user must carry on a dialogue with the NSC. During this dialogue, U must identify himself and supply additional information, such as a password, to authenticate his identity. U then requests access to host H. The NSC verifies the user's identity. If the user's identity is valid, the access request is checked, otherwise access to H is denied. The NSC uses previously stored access control information to determine if U is permitted access to host H. If the access control information indicates that the access request is legitimate, the NSC will initiate establishment of a logical connection between U and H.

The scenario is similar to that of a user attached directly to a host with an access control mechanism. In that sense the network appears to the user as a single large system.

All messages in the User-NSC dialogue are enciphered and deciphered by cryptographic devices attached to the terminal and to the NSC. Each network cryptographic device has the capability of protecting such dialogues with the NSC. Creating a connection between U and H requires that a new key be established in the cryptographic devices at U's terminal and at H. When the cryptographic devices begin to use the new key they can communicate, forming a cryptographic link between U and H. User U may then initiate formation of a message pipeline to host H via the connection-oriented functions. This connection authorization protocol is similar to that described by Branstad.[2,3]

CRYPTOGRAPHIC DEVICES

There are two main types of cryptographic devices utilized in this design. One is the cryptographic device at the NSC called the master cryptographic device. The other type is attached to each of the other network resources, and is called the slave encryption device.

Slave encryption devices can accept new keys from a remote location. If attached to a single terminal, a slave cryptographic device need maintain only one new key. If attached to a host or NFE, a slave cryptographic device must be able to maintain several new keys in order to support each of the multiple logical connections with a distinct key.

The master cryptographic device must be able to encipher and decipher messages to and from each of the slave cryptographic devices. The master cryptographic device manages establishment of new keys at the slave cryptographic devices.

Both the master and slave cryptographic devices distinguish message headers from message text. Headers must remain in the clear so that the communication subnetwork has sufficient control information to route and deliver messages. Only message text will be enciphered and deciphered.

These devices should make use of the National Bureau of Standards (NBS) Data Encryption Algorithm, which has been proposed as a Federal Information Processing Standard.[4] Several characteristics of this algorithm make it well suited for use in network cryptographic devices:

1. The secrecy of the transformation is dependent only on the secrecy of the key, not on the secrecy of the algorithm.
2. The length of the key is 64 bits, eight of which are reserved for parity. Thus there are 2^{56} potential keys. The key is not so short as to make exhaustive search techniques feasible, yet not so long as to make distribution to a remote device difficult.
3. The algorithm is block-oriented; that is, data

is grouped into blocks of 64 bits which may be enciphered and deciphered independently of any other block. As long as the same key is used, position or time synchronization of encryption with decryption is not required.

Due to routing and transmission differences, message transit time through a network is somewhat variable. Messages may arrive at a destination in a different order than they were sent Using the NBS Algorithm, cryptographic devices can be built which do not require position or time synchronization and are independent of the communication subsystem.

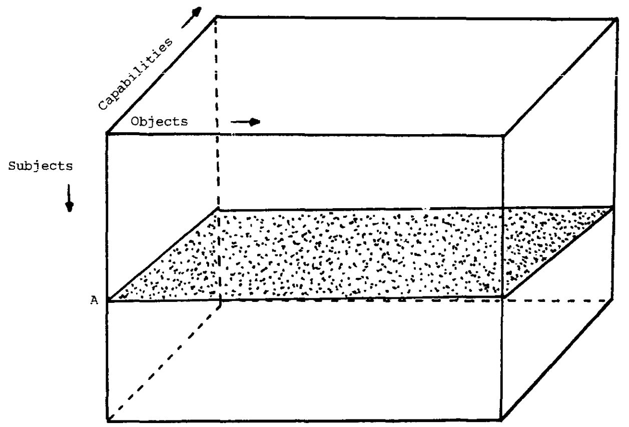
4. When enciphering or deciphering, the change of a single bit in either the key or the input text has an unpredictable effect on the output text. This characteristic has two implications. First, the correct key must be known to make use of (i.e., decipher) enciphered information. Second, alterations to enciphered text cannot produce predictable changes to the corresponding clear text.
5. Analysis of clear/enciphered text pairs does not aid in code-breaking to determine the key used. Penetrators are forced to use impractical exhaustive search techniques for code-breaking.
6. The NBS algorithm is expected to be available as an LSI package. This will provide a low cost, high speed implementation suitable for use in network cryptographic devices.

Network security center

The NSC authenticates the identity of network users and authorizes connections between network resources. When an access request is approved, the NSC must generate a random, distinct encryption key to be distributed to the cryptographic devices at both subject and object. In addition, the NSC will keep audit logs of all access requests, both approved and denied, and will issue appropriate alarms when a suspected penetration attempt is detected.

The NSC must, therefore, maintain a data base which contains sufficient information to verify (authenticate) the identity of users, and sufficient access control information to determine the legitimacy of access requests (access authorization). This data base will not remain static, but will require timely updating. This updating can be accomplished by a security officer at the NSC or by protocols between the NSC and network hosts. Except for authentication of updates, the issues of NSC data base updating are conventional data management system cost and performance tradeoffs and beyond the scope of concern here.

NSC access control information is defined in terms of subjects, objects, and capabilities. A subject is an entity such as a user or a process that can initiate access requests. An object is an entity such as a data file, a process, a host computer system or another network resource that can be the target of access requests. Capabilities are the actions which a subject may perform on an object.



The access control information can be represented by a 3-dimensional space. The shaded plane would contain all information concerning user A.

Figure 3—Access control matrix

A good conceptual model for the access control information is a three-dimensional access matrix[5] as illustrated in Figure 3. On one axis of the matrix are subjects; on another axis are the objects, and on the third axis are the capabilities. Entries in the matrix are boolean values, indicating whether a capability is available to a subject for a given object. This model can accommodate objects to any desired degree of granularity; where granularity refers to the relative size of the subject being controlled. For most systems this matrix is rather sparsely populated, with subjects having access to only a few objects. Thus the actual implementation will use some other more compact and logically equivalent data structure.

Network front ends

A Network Front End (NFE) may interface one or more network resources to the communications subnetwork. The NFE performs the connection-oriented functions on behalf of hosts as well as terminals. The NFE could also provide a user-level command interface for terminals. It is likely that NFEs can reduce the software cost and system overhead normally involved in connecting to networks. A Secure Front End may, in fact, enhance network security, a concept discussed later.

SECURITY ANALYSIS

The system design presented above counters the network security threats. The following discussion analyzes the design approach with respect to the threats presented earlier.

1. *Network Communication Threats*—The characteristics of the NBS data encryption algorithm (and cryptographic devices in general) eliminate many network communication threats. Obviously, line tapping yields encrypted text which cannot be read by a penetrator. Furthermore, alteration of enciphered text can be detected if an error detection field is included in the message. This error check must be enciphered, so that the error check value cannot be predictably altered. Additionally, the check value must be calculated with clear, rather than enciphered, text; otherwise it is possible to alter enciphered text such that the error detection field does not indicate the change. Inclusion of redundancy checks and message sequence numbers within the enciphered portion of the message can prevent undetected message playback or introduction of spurious messages.

The network cryptographic devices used in this design utilize a distinct encryption key for each logical connection between network resources. Therefore, misrouted messages are rendered unintelligible to unauthorized recipients. Currently available "line" cryptographic devices can only be placed on the communication lines, and therefore do not eliminate the threat of misrouting.

Network cryptographic devices with the characteristics required in this design offer greater security assurance than is currently available with existing "line encryption" devices. Although not currently available, network cryptographic devices can be built with current technology.

2. *Counterfeit Network Resources*—The term end-to-end encryption refers to data being enciphered at the source and remaining unintelligible until it is deciphered at its final destination. Network cryptographic devices provide such end-to-end encryption, thereby eliminating the threat of counterfeit network resources. Communication with a bogus network resource is impossible because it would not be attached to a network cryptographic device, or know an appropriate key.

If a network resource, attached to an NFE, is the source or target of network communication, the NFE is responsible for maintaining a proper message pipeline. The NFE must, therefore, guarantee that connections are made with the proper resource. Thus a secure NFE guarantees that the message routing and connection management functions are performed correctly on behalf of attached terminals and hosts.

3. *Forged User Identity*—The NSC requires each user to identify himself and provide information to authenticate that identity. A user's identity is validated before connection to any network resource is permitted. The NSC is a separate tamper-proof mechanism which is not part of a general purpose host computer system. Therefore, the NSC provides a protected environment for the user authentication process, which is less vulnerable than similar mechanisms within a general purpose host.

4. *Unauthorized Access*—The NSC maintains an access control data base that defines all permitted accesses, and must authorize all access requests before a connection between network resource is formed. The NSC is only involved in the initial decision to permit or deny access; an acceptable overhead cost analogous to "opening" a file in most operating systems.

Access requests may specify objects with a varying degree of granularity, but network cryptographic devices can enforce access control only to the granularity of entire network resources. The NSC can, however, pass the results of the access request decision, and any necessary parameters for enforcement, to the host system. The host can then provide the finer granularity of enforcement.

Terminals should not be connected to the network through network hosts. Connection of terminals to the network through general-purpose computer systems needlessly exposes the terminal's communications to security vulnerabilities within the host. Similarly, the hosts are subject to uncontrolled access from the terminals. When terminals are connected directly to the network, on the other hand, all access can be controlled by the NSC. Terminals could therefore either be connected directly to the network with their own cryptographic device (and providing their own connection-oriented functions and message formatting) or be connected to the network through a secure NFE.

SUMMARY AND CONCLUSION

The secure network design outlined here is a centralized management and control philosophy based upon centralized key management. Keys are generated by the NSC and managed by the master cryptographic device. NSC access control decisions are enforced through the use of centralized key management. A companion paper[1] describes an alternative, equally effective approach to network security based upon decentralized key management, and is useful where centralized control is precluded by law, policy, jurisdiction, reliability or practical constraints. In that decentralized approach, all cryptographic devices are identical, but more complex, with each capable of generating keys and relaying keys to other cryptographic devices. The master cryptographic device is eliminated and the NSC is optional.

The network structure described in this paper greatly reduces network security vulnerabilities. The

NSC provides a separate, secure network facility to insure that only legitimate users can access network resources and that only authorized access requests are permitted.

Network cryptographic devices virtually eliminate security threats to network communications and aid in authentication of network resources. Although currently available cryptographic devices do not have the appropriate characteristics, suitable network cryptographic devices can be built with existing technology. Thus, a high degree of cost-effective security assurance can be provided in computer networks with currently available technology.

Computer network cryptography engineering

by HARRISON R. BURRIS
TRW Systems Group, Inc.
Redondo Beach, California

ABSTRACT

A definition of system security and a unified description of encryption methods is presented as background. Alternatives for five major computer network design decisions related to the employment of cryptography with the network are discussed in terms of efficiency (security achieved) and cost.

INTRODUCTION

This paper discusses several design decisions relating to the employment of cryptographic techniques with computer based networks. Cost (hardware purchase prices and effect on performance parameters other than security) and efficiency (security achieved) measures are used for comparisons of alternatives. A definition of security is presented in section two and a method of describing basic types of encryption is presented in section three. The remainder of the paper compares the various network cryptography design alternatives which must be considered in planning efficient secure computer networks.

Given a professionally designed cryptographic algorithm (ignoring considerations of cryptanalytic resistance), the computer network designer should be aware of the impact of decisions concerning the method of employment of the cryptographic techniques upon the overall performance of the system design.

Following the example of Baran,[1] it is assumed that the system attackers are thoroughly familiar with all aspects of the system security design including cryptography and that only the current cryptographic keys are kept secret from the attackers.

There are three possible system security objectives for any computer based system, from single processor to distributed computer network.[2] These are:

Restriction of information to authorized persons.
Protection of system performance (availability and responsiveness).
Restriction of system resources to authorized persons.

One or more of these security objectives may be appropriate to a particular network depending upon the application. Penetration through the network communications system is a high probability threat to all three security objectives and network cryptography is an important system security technique which, depending upon the design decisions made, can either greatly strengthen or weaken the system's threat resistance.

Restriction of information

Restriction of information refers to the objective of preventing unauthorized persons from obtaining the information present in a system. There is nothing as effective as professionally designed cryptography for securing the information content of a communication.

Kahn[4] provides numerous examples of the ease with which "unbreakable" amateur ciphers have been broken by professionals, and restates the maxim that only the skilled cryptanalysts can determine the cryptographic strength of a cipher algorithm. Given professionally designed encryption techniques (hardware or computer algorithms) it is the job of the network engineer to insure that the method of employment does not provide an opportunity to compromise the encryption system.

Protection of system performance

Protection of System Performance refers to all actions taken to prevent system degradation. Degradation of performance is achieved either by causing a system to function with incorrect data so that the outputs are meaningless, or by slowing the system response time until even a correct response is useless. Degradation of performance can be achieved through the communications links by attacking the information being transferred or by monopolizing a sufficient portion of the available communications resources to slow down the system. The manner in which cryptography is employed with a particular network will either reduce the chances of successful attempts at system degradation or may greatly increase the impact of an attack (i.e., it may take much longer to resynchronize an encrypted communications link than one sending clear text).

Degradation of performance is measured as the increase in processing time or computational inaccuracy when the system is under attack over the processing time or computational inaccuracy when the system is operating in a benign environment. This measure should be distinguished from the security cost measured in increased processing time, hardware complexity, or computational inaccuracy of the secure system design over a system performing similar processing but without security capabilities.

An attacker can achieve degradation of performance by attacking the communications network with any combination of four types of attack: (1) Jamming, (2) Playback, (3) Alteration, and (4) Generation. Jamming refers to the introduction of some signal into the communications stream thereby preventing the reception of legitimate transmission. Playback refers to the recording of a legitimate transmission and then reintroduction of the message into the communications stream at some later time. Alteration refers to introducing changes into legitimate transmissions. Generation refers to introducing new messages into the communications stream. Since generation generally implies breaking the cipher before new messages can be produced it will be considered as precluded by the cryptographic algorithms being used in the network.

While cryptography is the principal tool for information protection its contribution to achieving the other security objectives is largely dependent upon the presence of other system security techniques such as Message Sender Identity Verification.[5] Just as a poorly designed encryption algorithm can cause the compromise of information, a poor application of either amateur or professionally designed encryption can greatly increase the impact of an attack aimed at degrading system performance.

Restriction of system resources

Restriction of System Resources refers to the objective of insuring that the system is used only for intended processing, or from another point of view, that each user pays for the system resources used. As for attacks through the communications links (and hence cryptographic design decisions), threats to this security objective are just another form of degradation of performance. From this view, the unauthorized processing load introduced represents the amount of degradation achieved.

ENCRYPTION METHODS

Most digital cryptography has developed as an aspect of digital communications, and this practical rather than theoretical outlook has resulted in digital cryptography being described in terms of a particular logic implementation. The resulting lack of a clear distinction between the cryptographic principles and the logic implementation presents a formidable barrier in assessing the performance (speed and cost) of a particular algorithm compared to other algorithms with similar properties.

The n character message to be encrypted (plaintext) is represented as a character string $P_1,P_2 \ldots, P_n$ and also as a bit string $B_1,B_2 \ldots, B_\alpha$ where $\alpha = n\beta$ and β is the number of bits per character. The n character long encrypted message (cipher text) is represented as a character string $E_1,E_2 \ldots, E_n$ and as a bit string $Y_1,Y_2 \ldots, Y_\alpha$. The different encryption methods (sometimes called privacy transforms[6,7,8,9]) are categorized according to the manner in which plaintext string P is transformed into the encrypted string E.

There are three major categories of enciphering:[4,8] (1) Transposition, (2) Substitution, and (3) Additive Encoding.

(1) *Transposition*—Transposition enciphers a message by reordering the characters of the plaintext. A transposition cipher is decrypted by reordering the encrypted message according to an inverse of the transform used to encrypt the message.

(2) *Substitution*—Substitution enciphers a message by replacing the characters of the plaintext with other characters, perhaps from another alphabet.

(3) *Additive Encoding*—Additive Encoding enciphers a message by combining the bits of the plaintext with the bits of a binary string using the exclusive OR (binary add) function. The encrypted message is decrypted by repeating the exclusive ORing of the encrypted text with the identical binary string.

Transposition

Define a transposition vector, T, of length n such that each value of T controls the transposition of the corresponding character in P into string E according to

$$E_{T_i} \leftarrow P_i \text{ for } 1 \leq i \leq n \text{ and } 1 \leq T_i \leq n \qquad (1)$$

Clearly, $T_i \neq T_j$ is required for $i \neq j$ and $1 \leq i \leq n$ and $1 \leq j \leq n$. The enciphered message is transposed back to the plaintext (decrypted) by the inverse transposition vector, $\overline{T}$, such that

$$P_{\overline{T}_i} \leftarrow E_i \text{ for } 1 \leq i \leq n \qquad (2)$$

where $\overline{T}$ is related to T by $\overline{T}_{T_i} \leftarrow i$ for $i = 1$ to n.

Plaintext messages of length greater than n can be encrypted using a transposition vector T of length n by partitioning P into a series of n long character strings and transposing each separately. The last string of P can be padded to length n with pseudorandom characters without weakening the transposition system.

Substitution

Define the plaintext alphabet, A, as the ordered set of all characters from which characters can be chosen to generate cleartext message strings. Define $\lfloor a \rfloor A$ as the sequence number of character a in the ordered alphabet A.

Define a substitution alphabet, S, such that for every $a \epsilon \{A\}$ there corresponds an $s \epsilon \{S\}$. The correspondence or mapping of A into S is determined by a substitution table F. The substitution table F is defined such that $j = f_i$ indicates a correspondence between A and S such that a_i corresponds to s_j. Table F could in some cases be represented as a function rather than a table which will be done now for brevity. Table I indicates two alphabets A and S whose characters happen to be mutually exclusive.

TABLE I

I	A	S	I	A	S
1	A	S	10	J	2
2	B	T	11	K	3
3	C	U	12	L	4
4	D	V	13	M	5
5	E	W	14	N	6
6	F	X	15	O	7
7	G	Y	16	P	8
8	H	Z	17	Q	9
9	I	1	18	R	0

For an F table defined according to the function $f_i = i$, the correspondence between the alphabets of Table I would be $Y \epsilon S$ corresponds to $G \epsilon A$. For the function $f_i = n+1-i$ with $n = 18$, Table I indicates the correspondence of character $4 \epsilon S$ to $G \epsilon A$.

A plaintext message P is encrypted by substitution on a character by character basis where P_i is encrypted according to

$$E_i \leftarrow S_{f_j} \text{ where } j = \lfloor p_i \rfloor A \qquad (3)$$

The encrypted message string is decrypted using the inverse transform vector F defined so that

$$P_i \leftarrow A_{f_j} \text{ where } j = \lfloor s_i \rfloor S \qquad (4)$$

Substitution ciphers are not explicitly influenced by the length of the plaintext strings.

Substitution ciphers where only one substitution alphabet and one substitution function are defined are called monalphabetic (including $S \equiv A$ except that for this case $f_i \neq i$ is required to avoid an identity transform). Polyalphabetic substitution ciphers[4,10] can be represented as multiple mappings (multiple F's) into a single S, as multiple alphabets controlled by a single F, or as a combination of multiple S's and F's. In order to complicate the cryptanalysis of substitution ciphers, several characters in S are often defined as being equivalent to one character in the plaintext alphabet. These sets of equivalent substitution characters are called homophones.[4]

Additive encoding

An additive encryption system transforms the plaintext bit string B into the enciphered string Y by applying the exclusive OR operation to string B and ciphering string X on a bit by bit basis where

$$Y_i \leftarrow B_i \oplus X_i \text{ for } i = 1 \text{ to } \alpha. \qquad (5)$$

It is the property of the exclusive OR operation that string Y can be decrypted by a repeated application of the transform

$$B_i \leftarrow Y_i \oplus X_i \text{ for } i = 1 \text{ to } \alpha. \qquad (6)$$

Partitioning the encrypted bit string into characters shows a key additive encryption to be equivalent to a polyalphabet substitution.

Plaintext strings longer than the coding string can be encrypted by partitioning the plaintext string into a series of bit strings of length α and encrypting each separately. The last string can be padded (random characters should be used for padding to strengthen the crypto system).

Encryption primitive security considerations

Jamming and Playback are not directed against the cryptographic primitives. For this presentation, generation has been eliminated as a threat (professional cryptographic algorithms), so only alteration remains as an attack directly influenced by the cryptographic primitives embodied in an implementation.

With a transposition cipher the plaintext characters are replicated in the ciphertext string so the attacker can precisely determine the plaintext character that result if a change to a ciphertext character is made. However, since the T vector is unknown, the correct position occupied by each character in the plaintext string cannot be determined. With both substitution and additive ciphers, the exact position of an altered character is known to the attacker but the exact plaintext character represented by each ciphertext character cannot be determined. Numerous highly effective probabilistic attacks can be made against substitution and additive cipher systems.[5] Cryptographic implementations employing multiple transposition and substitution or additive primitives can counter all but brute force alteration attacks since both position and resulting plaintext are unknown.

SYNCHRONIZATION

Synchronization of cryptographic devices is the process by which the encrypter at the sending end and decrypter at the receiving end are kept in step with each other. Three synchronization alternatives exist. The first two are in general use, the third is considered a practical proposal.

(1) *Link Synchronous Encryption*—The term link

synchronous is applied to an employment of cryptographic devices in which a one directional (simplex) point-to-point communications channel is enciphered such that a continuous stream of encrypted characters appear on the communications link and the receiving crypto device (the decrypter) is kept in step with the key of the sending encryption device by counting characters in the received data stream. In order to maintain the continuous character stream when no data is available to be sent, the encrypting end of the link generates a string of pseudorandom padding characters which are switched in and out of the transmission stream as required.

Link synchronous encryption is highly susceptible to degradation of performance attacks, since once the encryption devices are forced out of synchronization (i.e., by jamming) it requires a relatively long period to reestablish the network. Thus, a short duration jamming attack on the part of the attacker can deny use of the communication link for a period much longer than the period of jamming.

Because the communications link is continuously in operation, the network attacker is denied information about the volume and frequency of message traffic. This is called transmission security (TRANSEC).

The costs of this synchronization method are extremely high in terms of encryption equipment and communications resources (radio frequency spectrum or wire lines) required. The upper bound for a fully interconnected n node network is n^2-n links (dedicated frequencies or wire lines) and 2(n^2-n) encryption devices.

(2) *Packet Synchronous*—A packet is a block of characters, which may be either a segment of a message or an entire message, and may or may not be of fixed length. The term packet synchronous will be used to describe methods of synchronization which rely upon the appending of crypto synchronization information to the header of the packet in order to set the decryption device to the appropriate key.

In this mode, packets may be deleted without detection, and playback is possible. These attacks are facilitated by packet synchronization because as long as the synchronization and message text are associated together, both can be sent to a receiver at a later time and still be decrypted correctly. This method does not require the time consuming resynchronization processes of link synchronous systems since each packet carries its own synchronizing information.

Since a network can be established in which each node (and encryption device) recognizes its own address in the packet header, the costs of this method are considerably less than those for link synchronization since dedicated links and encryption devices are no longer required. For an n node network offering fully interconnected routing only n links and n devices are required.

(3) *Clock Synchronous*—Clock synchronous is a term proposed for the following method of encryption synchronization. The use of extremely accurate atomic (Rubidium or Cesium Beam) clocks for achieving synchronization of communications devices has been proven and portable clocks are available.[11] It should be possible to use the same methods to synchronize encryption.

In this mode a clock at each node is used to control the advance of the key. The clock time at which encryption was begun is appended to the message packet and serves as the synchronization information to set the key at the receiving node. If the message is not received within a set time period after encryption, it is rejected. Aside from the reduction of the synchronization bit string (often longer than the data in the packet) to a string just long enough to contain the start time to the required accuracy, the clock synchronous method offers no additional benefits over the packet synchronous mode. An atomic clock is required at each node for the clock synchronous method.

IMPLEMENTATION OF ENCRYPTION DEVICES

Presupposing the cryptographic algorithms are highly resistant to cryptanalysis it is extremely important to insure that the information to be protected is not compromised in some other fashion. It is possible that a circuit failure could result in plaintext being passed through a failed encryption device without detection. It is possible the electromagnetic radiation caused by the encryption device could radiate the plaintext data.[9,12-Ch. 29]

While status indicators or software checks are available to detect the failure of an applique or main processor cryptographic process, these are not nearly as reliable for preventing accidental information release as using an LSI cryptographic device tied to some other critical circuit such as the main processor instruction sequence controller (CPU master clock) so that if the encryption chip failed, the main processor would stop within one instruction!

There are some applications where it is critical that the processing functions be performed even when the security system has failed. In these circumstances, the strong argument for LSI becomes a liability. Bypassing a failed applique is usually accomplished by a switch action or at most replugging a patchboard, bypassing circuits at the LSI or even card level can be a more difficult problem. However, as LSI availability increases, multiple encryption chips could be used with "hot spares" switched in after a failure.

KEYING METHODS

The autokey (or ciphertext autokey) method was developed for use with polyalphabetic substitution ciphers.[4] For a plaintext alphabet of n characters define n substitution functions (and inverse functions)

$F^1,F^2,\ldots F^n$ and $\bar{F}^1,\bar{F}^2,\ldots\bar{F}^n$ each of which specifies a transform of every character in A into S and vice versa. The notation F_j^i is defined for multiple functions where i specifies which substitution function is to be used and j is the input (sequence number) to the function.

Encryption begins by placing an extra plaintext character which indicates the start of the key at the beginning of the plaintext and enciphered strings ($P_0 \equiv E_0$). The plaintext is then enciphered according to

$$E_i \leftarrow S_j \text{ for } j = F^{P_{i-1}}_{\lfloor P_i \rfloor A} \text{ and } i=1 \text{ to } n. \qquad (7)$$

where P_{i-1} determines which substitution function F will be used to transform P_i into E_i. The decryption process is

$$P_i \leftarrow A_j \text{ for } j = \bar{F}^{P_{i-1}}_{\lfloor E_i \rfloor S} \text{ and } i=1 \text{ to } n. \qquad (8)$$

To begin the decryption, recall that $P_0 \equiv E_0$.

It appears practical to extend the autokey strategy to transposition and additive encryption methods. Both of these methods may employ a fixed length transform of n characters at a time. Define a key as a set of transforms for either method with one transform for every possible character in the plaintext alphabet A. Then designate one character position in the n character plaintext string as the position controlling the selection of the transform to be used for encrypting the next n character string. This completely defines an autokeying encryption process. Similar to substitution, decryption is controlled by the key selection character position of the most recently decrypted plaintext string.

Some autokey systems have not been popular for computer network applications because of their tendency to propagate communications errors (or attacker induced changes). A transmission error in one position causes the wrong inverse transform to be selected for decrypting the next character. However, good autokey systems can be devised to be self-synchronizing after an error. Error propagation increases the attacker's leverage for denying the use of the communications resources. However, it makes attacks relying upon the acceptance of an altered message almost impossible. The autokey methods proposed above for transposition and additive systems do not perform as well for detecting alteration, as in many applications it would be unacceptable to wait until receipt of the next message before determining that the system has been penetrated. Even this after-the-fact indication would not be present if the attacker were careful to avoid altering the character position controlling selection of the next key. Error propagation would occur for these transforms only for the case where the key selecting character was in error.

DISTRIBUTION OF KEY MATERIAL

The particular key used with a set of crypto-algorithms is usually changed after a stated period of time (the crypto period). This change makes the playback of previous messages difficult and increases the work of the cryptanalysts since the statistics collected on the previous key must now be repeated. Key material is also changed or updated whenever it is suspected that the previous key has been compromised.

There are two principal alternative methods which can be used to distribute the new keying material: (1) the keys can be transmitted over the network, or (2) the keys can be distributed by an independent distribution system.

Manual key distribution systems require extra storage capability for keys, special handling, such as couriers, and require a relatively long time (manual action) to insert the new key. The strength of this method, which is the standard practice today, is that it requires a physical compromise of the key material in order for the encryption system to be broken during key distribution. Distribution of new key material over the network would have the advantage of changing crypto periods at machine (computer and communications) speeds. However, if the network is used to distribute new keys using an old key, compromise of this key potentially compromises all subsequent keys.

EXTENT OF ENCRYPTION

The network design decision to encrypt all messages (encrypt-all) or to encrypt only messages requiring protection (encrypt-select) must be considered by the network architect. Enciphering equipment is expensive, especially for remote terminals that do not handle information that must be protected. This observation has led to the development of several networks where some nodes are interconnected by encrypted communications and other nodes of the network are interconnected by unencrypted communications.[1,12] Another implementation with similar properties is a network where information requiring protection is sent enciphered (ciphertext) and information not requiring protection is sent unencrypted (cleartext). The advantages of these cleartext/ciphertext systems are that (1) low cost, portable nodes can be used where encryption is not necessary and (2) the network can be easily reconfigured for emergency transmission of priority information even if some encryption devices have failed.

The advantages of encrypt-select designs are transitory at best, since LSI encryption devices should soon eliminate the cost/size/power objections to encryption of even the lowest priority remote terminals. More importantly, the increased complexity in message switching software and encryption status checking hardware in the processors far outweighs the ease of reconfiguration achieved. Once total encryption becomes feasible these bimodal networks will probably cease to exist.

SUMMARY

Several network design considerations involving cryptography were discussed in terms of security and cost. In nearly every case each design alternative traded increased security from one form of attack at the expense of increased susceptibility to another attack. The particular choice of a method therefore is left to the designer depending upon the intended application of the network.

The application of cryptography for data base security

by EHUD GUDES and HARVEY S. KOCH

ABSTRACT

The application of cryptographic transformations for the purpose of enhancing the security in data base systems is discussed. These transformations have been recognized in the past as a valuable protection mechanism but their relation to data base security has not been identified. The major reason is the lack of a suitable data base model for investigating the questions of security and cryptography. A multi-level model of a data base is presented in this paper. This model helps to understand the connection between the data base structure and the cryptographic transformations applied to the data base. It is shown that cryptographic transformations can be applied between the different levels of the data base. Several types of these transformations are identified and the possible ways of using and controlling them are also discussed. The multi-level model can provide a useful framework for further research in the area of cryptography and data base security.

INTRODUCTION

The technical problems associated with providing protection for information in a shared computer environment have received considerable attention in recent years. Petersen and Turn discussed a broad spectrum of these problems in their article on "System Implications of Information Privacy."[14] Subsequently, there have been numerous endeavors attempting to amplify and find reasonable solutions to these problems.[6,7,9,11,12]

Concurrent with the developments in the area of protection has been the very important research in data base systems. This is due principally to the growing size and complexity of existing data bases. Research in data security and research in data base systems have only been combined recently. Most data security models,[7,11] use a unified approach in which all components of the computer system (i.e., objects) are viewed as being on the same level. A data base system is viewed as much more complex than the traditional file system and therefore its security problems are more complicated. In a data base, protection may be required from the file and record level down to the field level. User protection requirements of a data base are more complex than protection of a full file (or segment) and complex protection specifications based on boolean expressions may be needed. A unified approach is, therefore, not suitable for dealing with the security problems in data base systems. Our view is that the security problems of data base systems have to be dealt with separately from the security problems of operating systems. (A similar view is held by Minsky.[13]) However, since a data base system uses the operating system services, the two problems cannot be completely disconnected.

Since we are interested in data base systems, our assumption is that the hardware and the operating system are correct and secure. This is not as strong an assumption as it may seem at first glance. Since we have removed the problems of files and data bases from the operating system domain, the operating system becomes smaller and easier to verify. Clearly, the complexity of the protection problem in the data base system increases.

In this paper we concentrate on the security problems of data base systems. We develop a model of a data base which allows the incorporation of several protection mechanisms. The goal is to define a structural model of a data base in which known protection mechanisms can be applied, and their dependency on the structure of the data base can be understood. In this paper we are interested in one protection mechanism called *cryptographic transformations*. The value of these transformations as a means of protection has been well established[14] and some research was done on their application in file systems.[19] This model will help us to understand where and how to apply these transformations, and how these transformations can be used in conjunction with other protection mechanisms, in a data base system.

CRYPTOGRAPHY AND DATA BASES

Cryptographic transformations have been recognized long ago to be an effective protection mechanism in communication systems. In the past they have been used mainly to protect information which is transferred through communication lines. However, as Peterson and Turn[14] pointed out, they can be used as an effective counter-measure against some of the threats to security which exist in computer systems. Among them are: wiretapping, between lines entry, browsing files, physical acquisition of removable files. Although several other articles mention their existence and suggest their application in computer systems (Skatrud,[18] Van Tassel[20]), not much (public) research has been done in this area. In particular, there is no research on the problems of how to apply cryptographic transformations to permanent sharable data bases as opposed to their application to information transferred through communication lines. We call the first form of cryptography *data base cryptography* as opposed to the more popular form of *communication cryptography.*

There are large differences between the constraints put on communication cryptography (see Shannon[15]) and between those put on data base cryptography. Turn[19] enumerated some of these differences. The major ones are: (a) *The problem of selective retrieval*—because files are usually organized so that selective retrieval of records can be achieved, it is very desirable that enciphering (deciphering) of record *i* will not depend on another record *j*. This constraint prevents the use of the popular Vernam Cipher using a pseudorandom number generator of a very large period. Such a generator would be usually used for enciphering large quantities of data (e.g., the whole file) and would have to include more than one record in the enciphering process.* (b) *The long "life" of the data*—data in data bases usually resides there for relatively long periods. Therefore, the very popular method of changing the cryptographic keys very often cannot be applied, since it will require a complete reprocessing of the data base or a large part of it. (c) *The processing problem*—data in files and data bases is stored for processing purposes. It would be very desirable if we could process the ciphered data in the same way we process the "clear" data. The reasons for this are that the system is more secure if only ciphered data is processed and the overhead of enciphering/deciphering every time we access the data is saved. We would like therefore to design "processable" ciphers. Examples of such ciphers will be given later. It can also be shown that in the case of a "processable" cipher, applying the cryptographic transformation on the data item level only, is not secure enough. Given the constraints above, it is clear that the subject of data base cryptography is strongly connected to the subject of data base organization, representation and accessing. None of the current models of data base systems addresses this problem directly. Furthermore, current data base models are not suitable for answering questions related to data base cryptography.

Very few models of security in data bases mention the use of cryptographic transformations. The CODASYL[3] model provides the ENCODING/DECODING clause on the data item level. However, application on the data item level *only* may not be secure enough. The connection to other protection mechanisms is not clear. Hoffman[9] mentions the SCRAMBLE/UNSCRAMBLE procedures, but does not give any details of their use.

We are then faced with the following questions: (a) To which level should the cryptographic transformations belong? To the physical structure, to the logical structure, or to the mapping between them? (b) Should the Data Base Administrator (DBA) have complete control on the cryptographic transformations? Similarly, should the keys for these transformations be part of the system, e.g., in its Data Definition Language (DDL), or should only the appropriate user have some of the cryptographic keys? (c) Should cryptographic transformations preserve or destroy the structure of the data base and what are the advantages and disadvantages of each case? (d) What is the relation with other protection mechanisms? Should they complement each other and how should it be done? The main goal of this paper is to answer the questions above. However, in order to answer them, we need a *framework—a data base model* in which the security problems and their relation to the data base structure are clearly identified. Such a model will be developed. Before we develop this model, we want to review some of the basic concepts in data security.

BASIC CONCEPTS

Looking at the literature on data security, we find some degree of confusion about the basic concepts. We will use the terms *security, protection* and *access control* interchangeably and assign them the following meaning by McCauley,[12] "The process of determining the authorized users of the data base and of determining which access may be permitted and which would be denied." Graham and Denning[7] made a very important distinction between the *protection specification* and the *protection mechanism* in computer systems. The protection specifications are the translation of management privacy views into exact specifications. The

* Of course, VERNAM cipher can be applied to each record separately, probably using different "seeds" for the pseudorandom number generator, but then its security is far from a "one time" cipher.

protection mechanism is the mechanism to execute correctly the protection specifications and to assure that any *protection violation* of these specifications will be detected.

In different systems there exist different protection mechanisms. Most of these mechanisms are composed of two parts: the *protection procedure* and the *protection data*. The protection data is not to be confused with the protection specification. The protection data is data which is internal to the protection mechanism, for example—passwords in the case of the password protection mechanism or tags in Friedman's model.[5] The protection procedure is analogous to the program or procedure in programming systems and it is the coded form of the protection mechanism algorithm. An important example of such a two part protection mechanism are *cryptographic transformations*. In this case, the transformation algorithm is the protection procedure while the cryptographic keys are the protection data. The analogy to programming systems can be carried further as follows:

Programming Systems	*Data Security*
Procedure	Protection Procedure
Temporary Variables	Protection Data
Input Data	Protection Specifications
Output Data	Protection Decision (i.e., Grant or Deny)

As an example for the use of the concepts above, let us look at the protection mechanism in OS/360 file system.[10] The protection mechanism is a password protection mechanism where a file can be accessed if and only if the right password is given by the user during OPEN. The protection procedure then is part of OPEN. The protection data is the list of passwords. The protection specification is the distribution of passwords between users according to the privacy decisions: which user has access to which file. So passwords here has a double role: as the protection data and as the way to express the protection specifications.

In the next section, we will use the concepts defined here in the discussion of the data base model and its relation to security.

A MULTI-LEVEL STRUCTURED MODEL FOR A DATA BASE

The existence of several data base levels is well recognized in the data base "community." Usually a distinction is made between the logical level (structure) and the physical level (structure). A good discussion of these levels and the mapping between them is given in Sibley & Taylor.[17] In the CODASYL model we can distinguish three levels: the Sub-Schema and Schema levels which define the logical structure and the storage level which defines the physical structure. A four level model known as the entity-set model was suggested by Senko, et al.[1] Another four level model, similar in concept to the one we suggest here, was suggested by Sibley.[16] We could have developed most of our notions in the framework of one of these models, however we preferred to develop our own terminology and structure for two major reasons: First it allows us to stress the security point of view which we are interested in. Secondly, our model differs from other models by its recognition of the existence of *more than one physical level in a data base.* In most data base models only one physical level is recognized and this is usually the secondary storage structure. However in most conventional systems (even with virtual memory), data exists physically in more than one medium and this fact is very important from the security and cryptographic points of view. The main idea in this model is that a *data base is composed of several logical or abstract levels which describe data which physically resides in one or more physical media and therefore have one or more physical structures.*

The existence of these physical media is recognized even in the conceptual model of CODASYL.[3, p. 15] In CODASYL three media are identified:

1. The user-working area
2. The system buffers
3. The secondary storage

Therefore we should have logical schema which describe the data structure in each of these levels. Actually in the CODASYL model the sub-schema describes the data in Physical Level 1 while the schema describes the data in Physical Levels 2 and 3.

A FOUR LEVEL MODEL

In the model that we have developed there are *four logical-abstract levels:*

1. User-logical level
2. System-logical level
3. Access level
4. Storage level (also called structured storage level)

Each of these levels can be composed of several sublevels. Corresponding to each logical level there is a physical level which is connected to a physical medium. We will now concentrate on the description of the logical levels and their relation to security.

The *user-logical* level corresponds to the way a user or a user group sees the data base. It is very similar to CODASYL's Sub-Schema with the exception that we do not have the constraint that the user-logical level must be a subset of the system logical level. On the contrary, it might be useful to have complex transformations between the two levels. Usually there are several user-logical level structures in a data base. The *system-logical* level describes the whole logical structure of the data base. It may correspond to CODASYL's Schema with the difference that indexes, directories, and access paths are not part of the system-logical level (they are part of the Schema in CODASYL.) The *access* level describes the directories, indexes and all possible access paths in the data base. The storage level is the result of applying the access level to a particular physical secondary storage device(s) and describes characteristics which are special for these devices. To each logical level corresponds one or more physical levels according to the number of physical media. An example is shown in Figure 1.

In this example the user logical level describes the data as it appears on the user site. The system logical level gives the interpretation to data which appears in memory. And the access and storage levels give the right interpretations to the data which reside on the secondary storage devices. It is conceivable that in the future the secondary storage hardware will do all the access calculations and therefore no access information has to be in memory or described in the system logical level. The main idea is the existence of more than one physical level corresponding to more than one physical media.

The relation of this model to security is discussed in Gudes.[8] The model is shown to be general and to include other known data base security models[5,12] as special cases. The main idea is the *decentralization* of protection mechanisms by the "spreading" of protection specifications and mechanisms through the different levels of the data base. In this paper we are interested with only one protection mechanism—cryptographic transformations. The model will be used as a framework for the application of cryptographic transformations in a data base. As is shown in the following sections, cryptographic transformations are a subset of the transformations between the physical levels of a data base, which is used for protection.

FORMALISM

In order to understand the relationship between the logical levels of a data base and their corresponding physical levels we need some notation. When one looks on a data base as it is represented on secondary storage one sees a sequence of 0's and 1's. These binary digits make sense only when one knows the right *structure, coding* and *interpretation* of the data. One starts with the simple division to data items and then starts to build the more complex blocks of the structure (repeating groups, records, files). The basic concepts, then, for describing a data base is the concept of the *data item*. A *data item* has the following properties:

interpretation (attribute)—what the data item is
length and what it is used
value for.
representation (coding)
address

We denote data items as: d_i

A common case in data bases is that one data item contains one or more properties of other data items. We give two examples:

Example 1	d_1	d_2
interpretation:	Length of d_2	name
value:	5	SMITH

In this case d_1 contains the property: length of d_2.

Example 2	d_1	d_2
interpretation:	units	distance
value:	0 or 1	100

If $d_1 = 0$ then d_2 is in miles
If $d_1 = 1$ then d_2 is in kilometers

Hence d_1 contains the interpretation of d_2. However we need also the interpretation of d_1 in order to know what d_2 is. The interpretation of d_1 is probably documented in some manual which describes the system.

We see then that a set of data items may have *several levels of interpretation.* Some of them are in the data base itself and some of them are only implicit. Each physical level of the data is just a set of data items, where their interpretation is either in some of the data items themselves, or in the logical description of this level, or documented in some manual. More formally, a physical record j on level i is denoted as PR_j^i where this physical record has the address A_j. This physical record is an ordered tuple of data items

$$PR_j^0 = (d_1{}^i{}_j, d_2{}^i{}_j, \ldots, d_n{}^i{}_j)$$

The address of data item $d_k{}^i{}_j$ is determined by its relative position and the length of all data items before it. These lengths can themselves be other data items or part of the logical description of this physical record. The order of data items within a physical record is then important for finding their addresses. (A physical record here is "continuous" by definition.) The physical data base on level i is the set of physical records on this level

$$PB(i) = \{PR^i_1, PR^i_2, \ldots, PR^i_m\}$$

In reality only part of a physical data base on some level will exist at any time (Except the fourth level—the storage level—in which the whole physical data base exists.)

The definition of physical records is very simple because we believe that the complex structure of the data base is connected to the interpretation we give to these data items. Most of this interpretation is in the logical levels of the data base. In order to describe these logical levels, we need to define more concepts.

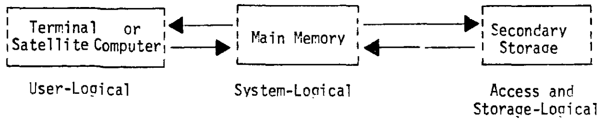

Figure 1—The four levels of a data base

Two data items are called *similar* if they have the same interpretation. A *field* is an abstract concept representing a set of similar data items. A field has no value but usually has a unique name or identifier. We denote field j on level i as F^i_j.

The notation $d_j \sim F_k$ means d_j is a *data item occurrence* of the field F_k. A *logical record* is a set of fields with a unique name or identifier. The order of fields in a logical record is immaterial because each field can be identified by its name. Logical records on level i are denoted as: LR^i_j.

What is the connection between logical records and physical records? Very simple. A physical record is an occurrence of a logical record and a data item is an occurrence of a field!

The logical data base on level i is a set of logical records plus their interpretation which is contained in the corresponding description language DL(i). The logical data base on level i is LDB(i).

$$LDB(i) = \{LR^i_1, LR^i_2, \ldots, LR^i_l\} + DL(i) + \text{some implicit interpretation.}$$

The connection between logical data base level, physical data base level, logical records and physical records is seen in Figure 2.

In order to better understand the concepts above we give two examples for describing structures which are common in data bases.

Example 1: *Repeating Group*

Suppose we have a repeating group which gives information on a person's children. In this example we disregard the level notation. The logical record is:

$$LRC = (F_1, F_2, F_3)$$

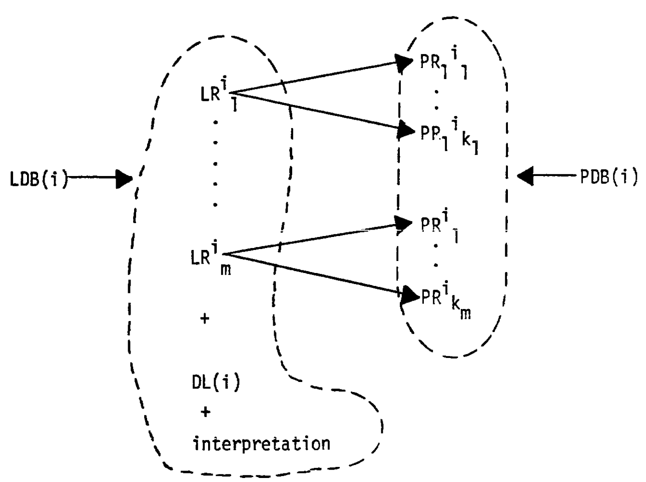

Figure 2—The connection between logical data base level, physical data base level, logical records and physical records

The following interpretation will appear as part of the logical description

LRC—information on children
F_1 —number of children
F_2 —name
F_3 —age

Physical records which are occurrences of this logical record are:

$$PR_1 = \{d_1, d_2, d_3, d_4, d_5\}$$

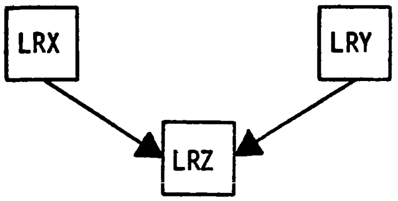
where $d_1 \sim F_1$, $d_2 \sim F_2$, $d_4 \sim F_2$, $d_3 \sim F_3$, $d_5 \sim F_3$ and value $(d_1) = V(d_1) = 2$, $V(d_2) =$ 'AMI', $V(d_3) = 25$, $V(d_4) =$ 'ROMIT', $V(d_5) = 22$ and

$$PR_2 = \{d_1, d_2, d_3, d_4, d_5, d_6, d_7\}$$

where $d_1 \sim F_1$; d_2, d_4, $d_6 \sim F_2$; d_3, d_5, $d_7 \sim F_3$ and $V(d_1) = 3$, $V(d_2) =$ 'SMITH', $V(d_3) = 29$ etc.

Example 2: *Sets*

Suppose we want to describe the structure:



LRX, LRY, and LRX are names for logical records.

$$LRX = \{F^x_1, F^x_2, \ldots, F^x_m, F^x_{m+1}\}$$
$$LRY = \{F_1^y, F_2^y, \ldots, F_n^y, F_{n+1}^y\}$$
$$LRZ = \{F_1^z, F_2^z, \ldots, F_k^z, F_{k+1}^z, F_{k+2}^z\}$$

with the following interpretation

F^x_{m+1}—address of the physical record occurrence LRZ which is the "son" (if there is more than one son, we need another field to specify the number of sons).

F_{m+1}^y—address of son LRZ
F_{k+1}^z—address of LRX parent
F_{k+2}^z—address of LRY parent

We do not show here physical record occurrences of the above logical records. It should be clear now that any structure whether inter or intra record can be represented in this way. The important fact is that the complex structure is part of the logical description while the physical records are no more than ordered tuples of data items.

The user logical level is denoted as U_1 (DB), U_2 (DB), ..., U_k (DB). We denote logical records on Level 1 as: UR_{ij}. Therefore

$$U_i(DB) = \{UR_{i1}, UR_{i2}, \ldots, UR_{in_i}\}$$

We denote a logical record on Level 2 as LR_j. The system logical level is denoted as:

$$S(DB) = \{LR_1, LR_2, \ldots, LR_s\}$$

We do not put any constraints on the transformations between these two levels. For example in the CODASYL model we have the following constraint:

$$\forall UR_{ij}\ \exists LR_k \quad \text{s.t. } UR_{ij} \subseteq LR_k (*)$$

We will allow more complex transformations. In the access level we introduce concept of *access record.* An access record is simply another name for a logical record on Level 3. We denote access record i as AR_i. The access level is then,

$$A(DB) = \{AR_1, AR_2, \ldots, AR_m\}$$

The transformation between the system logical level and the access level is very important and we would like to give some examples of it:

Example 3:

Suppose we have a file—$LR = \{F_1, F_2, \ldots, F_n\}$—and *two indexes.* The first index specifies for each data item occurrence of field F_1 the record(s) which contain this data item. The second index does the same for field F_2. We say that the logical record LR is translated into three *access records:*

$$AR1 = (F_{11}, F_{12})$$
$$AR2 = (F_{21}, F_{22})$$
$$AR3 = (F_{31}, F_{32}, \ldots, F_{3n})$$

where we have the interpretation $F_{11} = F_1, F_{12} =$ address of record containing a specific data item occurrence of F_1. (If there is more than one such record we need another field to specify the number of these records.)

$F_{21} = F_2$, $F_{22} =$ address of record containing a specific data item occurrence of F_2.

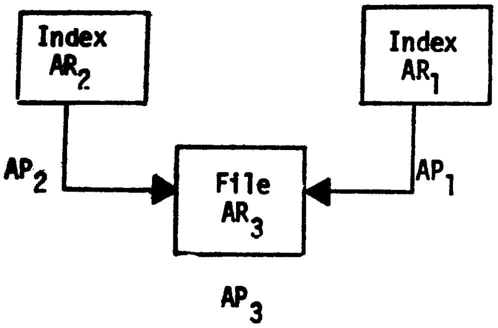
$$F_{31} = F_1,\ F_{32} = F_2, \ldots, F_{3n} = F_n$$

We therefore have three *access paths* to physical occurrences of LR:

$AP_1 =$ access path $1 = (AR_1, AR_3)$

$AP_2 = (AR_2, AR_3)$

$AP_3 = (AR_3)$ which represents a sequential search through the file. The situation is shown below:



With the concepts of access records and access paths, we can present now any structure of directories or indexes.

Example 4—*Inverted File*

$$LR = (F_1, F_2, \ldots, F_n) \text{ (This is also } AR_2)$$
$$AR_1 = (F_{11}, F_{12}, F_{13}, F_{14}) \text{ (directory entry)}$$

with the following interpretation:

$$\text{keyword} = \begin{cases} F_{11} = \text{name of field } F_i \\ F_{12} = \text{value of a data item occurrence on field } F_i \end{cases}$$
$$F_{13} = \text{number of records containing the corresponding keyword.}$$
$$F_{14} = \text{addresses of these records}$$

Notice that F_{13}, F_{14} represent together a repeating group. The possible access paths are

$AP_1 = (AR_1, AR_2)$—using the directory

$AP_2 = (AR_2)$—a sequential search

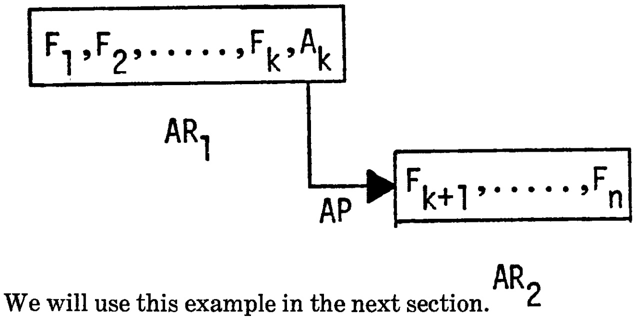
Example 5: *Splitting*

$$LR = (F_1, F_2, \ldots, F_n)$$
$$AR_1 = (F_1, F_2, \ldots, F_k, A_k)$$
$$AR_2 = (F_{k+1}, F_{k+2}, \ldots F_n)$$

A_k is the address of the occurrence of the second half of the same logical record. The *only possible* access path is:

$$AP = (AR_1, AR_2)$$

This situation is shown below:



We will use this example in the next section.

We feel that the concepts of access records and access paths are very significant since they clarify much of the confusion about the question: to which level do indexes and directories belong? We denote the logical records in Level 4 (storage level) as LP_i. The storage level is then:

$$P(DB) = \{LP_1, LP_2, \ldots, LP_p\}$$

In many cases this level is equivalent to the access level, i.e. $LP_i = AR_j$. However it may differ in two important aspects:

1. Control information used by the device such as "gaps" or keys may be added.
2. If cryptographic transformations are used on

(*) The notation $\subseteq$ here is used more by its semantic meaning rather than by its exact mathematical meaning.

this level, they may destroy the whole data item structure. In that case we can speak on another level—Level 5—called *unstructured storage level.*

Until now we discussed mainly the logical abstract levels. As was explained before, the physical records are just occurrences of the corresponding fields. One comment is appropriate at this point. It may be that in reality we will have a smaller number of physical media, and therefore of physical levels, than the number of logical levels. In that case, some of the logical levels are abstract and no corresponding physical level exists. The importance of having these abstract intermediate logical levels is for understanding the structure. For example, it is usually the case that the access level and the storage level correspond to one physical medium—the secondary storage. In this case, the physical records on Level 4 are occurrences of the logical records on Level 4. No physical records on Level 3 exist. The existence of the access records is important because otherwise the transformation $LR_i \rightarrow LP_j$ would be very difficult to understand. *In the case that we have only one physical medium, we come to the traditional view of a data base of several logical levels and one physical level!* So our model contains the traditional view as a special case.

CRYPTOGRAPHIC TRANSFORMATIONS

Now, with the notation defined, we can return to the subject of cryptographic transformations. These transformations can affect both the structure of the data and its coding or representation. The importance of having several physical levels for a data base should now be clear. We can look at the cryptographic transformations as transformations between two consecutive physical levels. *In general, cryptographic transformations are a subset of the set of transformations between the physical levels of the data base, which is used for protection.* Cryptographic transformations can be a powerful protection mechanism. They can be used in two ways:

(1) As part of the standard access control. That is, serving as a protection mechanism for implementing the protection specifications *as they are defined in each level.* In this case the user must know about the existence of these transformations since he probably holds some of the cryptographic keys.

(2) As a *system tool* for protecting against illegal access paths such as: browsing or wire tapping. In this case the cryptographic transformations are completely controlled by the system, they are not connected to a specific protection specification and the user does not have to know about their existence.

Of course, the combination of these two methods can be used. We leave the subject of how to use cryptographic transformations to the next section and concentrate in this section on describing the possible cryptographic transformations between the different physical levels of the data base.

TRANSFORMATIONS BETWEEN PHYSICAL LEVELS

We start with the transformation between the user-logical and the system-logical levels. Clearly, the transformation between the corresponding physical levels is dependent on the transformation between the logical levels. In general, these transformations can be very complex. However, if we want to use system services to process and query on data items and we want the ability of sharing data with other users, the common data item structure has to be preserved. We identify three types of transformations between physical Levels 1 and 2:

Type 1: *Data Item Substitution*

$$d^1_i = f(d^2 j)$$
$$d^2_j = f^{-1}(d^1 i)$$

This is the common substitution transformation which does not destroy the data item structure. Its advantage is its simplicity and the fact that some processing, such as querying, can be done on data items even in their ciphered form. Its disadvantage is that it may not be secure enough. (Because the statistical properties of similar data items may be saved.)

Type 2: *Data Item Expansion*

$$d^2_i = f(d^1_j, d^1_{j+1}, \ldots, d^1_{j+k})$$

A data item in the system logical is expanded to several data items and finer structure on the user logical level. As an example suppose we have the fields: NAME, AGE, SEX on the user logical level, while on the system logical level we have one field: PERSONAL DATA, whose occurrences are a scrambled form of occurrences of the three fields on the user logical level. This transformation can be made more secure than the former one but it has a major disadvantage which is: because the fine structure on the user logical is destroyed a user cannot ask queries, which require processing on the system logical level, about individual fields such as: NAME, AGE, SEX since these fields are not defined in the system logical level.

A third type of transformation is *data item contraction*

$$d^1_i = f(d^2_j, d^2_{j+1}, \ldots, d^2_{j+k})$$

Clearly more complex transformations can be defined between Level 1 and 2. One comment is appropriate at this point. There may be some cryptographic transformations between the two levels that we are not aware of. For example, if Level 1 and Level 2 are far apart and are connected by telephone lines, some enciphering device may be connected to these lines. We are not interested in this kind of enciphering which has nothing to do with the data base structure and as far as the representation of the data in the two levels is concerned does not have any effect. The same comment is true in the case of transformations between other physical levels of the data base.

System Logical⟵- - -⟶Access⟵- - -⟶Storage

We discuss the transformations between these three levels together since we consider the case of one physical medium to both Levels 3 and 4. We identify three types of transformations:

Type 1: *Substitution Oriented*

$$d^2_i=f(d^4_j),\ d^4_j=f^{-1}(d^2_i)$$

The importance of this transformation is that it allows us to define *processable ciphers.* Most of the processing of data items is done on the system logical level (in main memory). So our definition of processable ciphers must be connected to data in Level 2. The advantages of being able to process data in its ciphered form were discussed above. Informally, a processable cipher is a transformation from the system logical level to the storage level which preserves the data item structure and allows the type of operations which are done on the "clear" data to be done on the ciphered data items. Formally, if $d^2_1=f(d^4_1)$ and $d^2_2=f(d^4_2)$ and G is a defined operation on data items in Level 2, then f is processable if and only if:

$$\exists\, G,G' \rightarrow G(d^2_1,d^2_2)=f(G^1(d^4_1,d^4_2))$$

Usually we also require that $G=G^1$. For example, if G is the *compare* operation, then we have

$$d_1{}^4=d_2{}^4 \Leftrightarrow f(d_1{}^4)=f(d_2{}^4) \Leftrightarrow d_1{}^2=d_2{}^2$$

Such a cipher f is called a *retrievable* cipher, since it allows the searching and retrieving of records in their ciphered form. (This is done by comparing the ciphered form of the query to the ciphered content of the record.)

Type 2: *Transposition Oriented*

We have explained before that the order of data items in a physical record is important in order to find their addresses. However, this order may change from one physical record to another. For example, suppose a logical record on Level 4 is: $LP=(F_1,F_2,F_3)$ and following are occurrences of physical records:

$$PR_1=(d_{11},d_{12},d_{13})$$
$$PR_2=(d_{21},d_{22},d_{23})$$
$$PR_3=(d_{31},d_{32},d_{33})$$

Where:

$$\begin{array}{lll} d_{11}\sim F_1, & d_{22}\sim F_1, & d_{33}\sim F_1 \\ d_{12}\sim F_2, & d_{21}\sim F_2, & d_{32}\sim F_2 \\ d_{13}\sim F_3, & d_{23}\sim F_3, & d_{31}\sim F_3 \end{array}$$

That is, the order of data items in a physical record changes from one record to another. Such a transformation is very effective against "browsing" since the starting address of data items is not known to the illegal "browser". Its disadvantages are that it increases the access time of finding a data item, and that another data item has to be added which contains information about the specific order in each record.

Type 3: *Access Oriented*

In this transformation we encipher only the data items which allow the transfer from one access record to another in a specific access path. For example, suppose we use the *splitting* example above. We have

$$LR=(\text{NAME}, F_2, \text{SALARY}, F_4)$$

and

$$AR_1=(\text{NAME}, F_2, A)$$
$$AR_2=(\text{SALARY}, F_4)$$

A—is the address of the second half of an occurrence of LR. If we encipher the field A, then matching the right salary to the right name without deciphering this field is very difficult. The reason is that we have used the notion of *access path* for enciphering. In this case we enciphered the *only existing* access path. This type of transformation can be very effective, since address fields do not have regular statistical properties. (Note also that fields NAME and SALARY do not have to be enciphered.)

COMBINED TRANSFORMATIONS

Shannon[15] has shown the strength of combined cryptographic transformations. The simplest example of a combined transformation is the substitution—transposition transformation. In this case data items are first enciphered by substitution transformation and then transposed by the transposition transformation. It is very difficult now to get the statistical properties of data items in order to "break" the substitution because of the transposition.

Another effective combination is the access-substitution combination. Following are two examples of substitution access combination.

Example 1: *Hashing*

Suppose we have a hashing "file". We have one logical record

$LR=(F_1,F_2,\ldots,F_n)$ and two access records

$AR_1=(F_1)$—F_1 is the hashing field

$AR_2=(F_1,F_2,\ldots,F_n)$

We have two access paths. The legal access path—(AR$_1$,AR$_2$) and the illegal one—(AR$_2$) which is equivalent to a sequential search. Suppose we use the following transformation:

$$k+d \rightarrow \textit{hashing address}+K^1$$

where d$\sim$F$_1$ and K is the cryptographic key. The meaning of this transformation is that as a result of the hashing process we get an address and a key K^1. Key K^1 which is the "residue" of the hashing transformation is used for the substitution transformation of data item d. The illegal path of (AR$_2$) is now very difficult, since in order to guess what the substitution is, we need to go through the legal access path (AR$_1$, AR$_2$) using the hashing algorithm and the cryptographic key K!

Example 2: *Inverted File*

Suppose we have the "file" described above in Example 4. That is

$$LR=(F_1,F_2,\ldots,F_n)$$
$$AR_1=(F_{11},F_{12},F_{13},F_{14})$$
$$AR_2=(F_1,F_2,\ldots,F_n)$$

The two possible access paths are (AR$_1$,AR$_2$) and (AR$_2$). We add to access record AR$_1$ a KEY field. That is

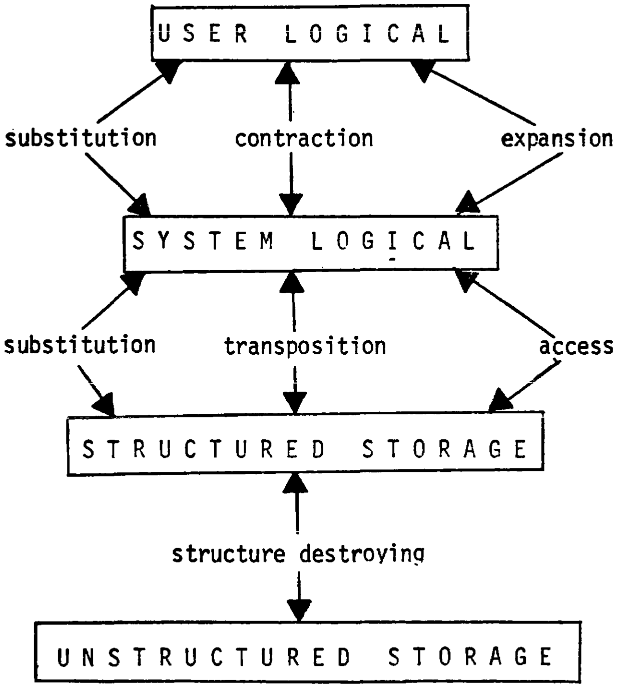
$$AR_1=(F_{11},F_{12},F_{13},F_{14},F_{15})$$

where F$_{15}$ is the key to encipher records with a specific keyword. All records which contain a data item occurrence of Field F$_1$ (=keyword) are enciphered by specific occurrence of field F$_{15}$. Therefore all records which have the same keyword are enciphered by the same substitution key. Again illegal path (AR$_2$) is protected by the fact that for deciphering we need to know which records contain a particular keyword, but this information is contained in the directory only, which is part of the legal access path. (*) Many variations of the combined transformation technique are possible. One possible extension of this is to build the directory as a *tree* where the key for enciphering a node of the tree is contained in its parent node. The subject of the enciphering of search trees is discussed also in Bayer and Metzger.[2]

Storage←- - - - - - →Unstructured Storage

One can think of a general structure destroying transformation which can be used, for example, for backup or data migration purposes. Since usually another physical medium is involved (e.g., magnetic tape) we define another logical and corresponding physical level called: *unstructured storage level.* We do not give any special notation for this level. (It should be straightforward using the examples above.) An example for such transformation is to use a pseudo-random number generator to encipher a complete "file" or a large part of a data base. Such transformation can be made very secure. Its major disadvantage is that complete deciphering is necessary before any access is possible.

We summarize this section with the following schematic diagram of types of cryptographic transformations and their use in the multi-level data base model:



USING CRYPTOGRAPHIC TRANSFORMATIONS

As was pointed out above, there are two ways for implementing cryptographic transformations: (1) as part of the standard protection mechanism according to some protection specifications. These transformations are user oriented (since the protection specifications are user oriented) and the users should know about their existence, since they probably have some of the cryptographic keys, (2) as a system tool to protect against illegal access paths such as "browsing" or "wiretapping". In this case users may not be aware of the existence of these transformations and their keys are under system (or DBA) control.

The actual implementation of the two methods depends on the data base structure and on the way the protection specifications and mechanism are spread out through the different levels of the data base.

(*) The case where a record contains two keywords or can be accessed by more than one access path can be further researched based on McCauley.[12]

SYSTEM CONTROLLED TRANSFORMATIONS

The following transformations are examples for system controlled transformations (method 2 above)

(1) The transformation between the unstructured storage and the structured storage levels are always system controlled.
(2) Combined transformations such as substitution-transposition or substitution—access can be system controlled for protecting against the illegal access path or browsing (e.g., in case of "stealing" a physical secondary storage device). In this case the cryptographic keys for these transformations have to be *internal* to the data management or access control methods.
(3) Substitution oriented transformations, including processable ciphers under system control, can be used to protect against wiretapping or against dumping of main memory. Again, the keys for these transformations are either internal to the processing primitives of the query language or are part of the DDL for Level 2, but they must be protected by standard access control methods.

We see then that system controlled transformations are easy to implement and quite simple to control. They are controlled by the DBA and he can change the cryptographic keys at any time. They are very effective against illegal access paths such as: "browsing" or "wiretapping" but they must be complemented by standard access control methods for protection of the cryptographic keys. This method, of using both system controlled cryptographic transformations and standard protection mechanisms (e.g., passwords) such that each mechanism protects the "weak" areas of the other, can be very effective provided that adequate administrative security exists so that the probability of compromising both mechanisms is low.

USER CONTROLLED TRANSFORMATIONS

The situation with user controlled transformations is more complex, and the main reason is the existence of sharing and overlapping protection specifications. Clearly, if every user has access to a unique part of the data base, then this part can be enciphered by a unique key and only the appropriate user has the right key. But this case is unreal since the main purpose of a data base is *sharing data.* McCauley[12] has suggested a way to *partition* a data base using *security atoms.* The security atoms are data base dependent and not protection specification dependent! Every user has access to a set of security atoms according to the protection specifications. A way to use cryptography in this model will be to encipher each security atom with a unique key and distribute the keys between users according to the protection specification. (Somewhat similar to the passwords mechanism.)

Another possible use of user controlled cryptography is based upon the fact that the only "clear" data which is sent to the user is the data that he should have legal access to. (The fact that he gets a lot of "garbage" may discourage him from issuing illegal queries.) The main advantage of user controlled transformations versus system controlled transformations is concerned with the problem of *key placement.* In the system controlled case, the cryptographic keys must reside at all times in the system and therefore must be protected by the standard protection mechanisms. In the user controlled case there is the possibility that only the user(s) will have some of the cryptographic keys to their authorized data. These keys do not reside in the system except at the actual time the user is accessing his data. In this case even the DBA cannot "decipher" the user's data since he does not have the right key. This is certainly in accordance with the "need to know" concept, i.e., that the DBA does not have to know the content of every data item in the data base. Such a system, where only the authorized user has the cryptographic key was implemented by IBM[4] using the LUCIFER system to protect a "secure field." There are two disadvantages to this method. The first is the possibility of penetration of illegal cryptographic keys. Since the right key is not stored in the system, some checking algorithm (e.g., check digit) must be used. The probability that an illegal key will not be detected by the checking algorithm is not zero and its results in case of updating can be disastrous! The second disadvantage is that it is very hard to control the "user controlled transformations" case. For example, close cooperation between users which share the same data is needed if the cryptographic keys are to be changed. Also, close cooperation is needed between users and the DBA in some cases of error recovery and data base reorganization.

We note that cryptographic transformations which are controlled by the system are easier to implement but since the keys must reside within the system, they may be less secure. User controlled transformations allow the possibility that only the user will have the right cryptographic key, and therefore provide more security, but they require data base partitioning and probably a large number of keys, and therefore present quite a serious control problem.

FURTHER RESEARCH

The model presented in this paper is used as a *framework* for further research in the area of cryptography and data base security. This research is reported in Gudes.[8] The main areas of this further research are: (1) a detailed investigation into the problem of how to design an authorization scheme which is based on user controlled cryptographic transformations. Several types of protection specifications such as: compartmentalized, hierarchical or data dependent are discussed and several cryptographic schemes are suggested for their implementation, (2) research into the problem of *evaluating* the security of data base enciphering. A "security measure" for data base enciphering is suggested and is computed for several types of ciphers, (3) an experiment using a simple file system is being performed. The goal of this experiment is to gain insight on the amount of security provided by the different ciphers and the overhead associated with them. The results of these areas of the research will be reported in future papers.

SUMMARY

In this paper we have investigated the problem of applying cryptographic transformations for enhancing the security of data base systems. These transformations have been recognized in the past as a valuable protection mechanism but their relation to data base security has not been identified. The major reason was the lack of a suitable data base model with which the problems related to security and cryptography can be analyzed. Such a model is developed in this paper. This is a multi-level model of a data base which helps us to understand the connection between the data base structure and the cryptographic transformations applied to the data base. We have identified several general types of cryptographic transformations, and have shown the two major ways in which they can be used: as system controlled transformations, or as user controlled transformations. More research is being conducted on the problem of designing a secure system based on cryptography and on the cost-effectiveness of the application of cryptographic transformations in a data base system.

Multiuser cryptographic techniques*

by WHITFIELD DIFFIE and MARTIN E. HELLMAN
Stanford University
Stanford, California

ABSTRACT

This paper deals with new problems which arise in the application of cryptography to computer communication systems with large numbers of users. Foremost among these is the key distribution problem. We suggest two techniques for dealing with this problem. The first employs current technology and requires subversion of several separate key distribution nodes to compromise the system's security. Its disadvantage is a high overhead for single message connections. The second technique is still in the conceptual phase, but promises to eliminate completely the need for a secure key distribution channel, by making the sender's keying information public. It is also shown how such a public key cryptosystem would allow the development of an authentication system which generates an unforgeable, message dependent digital signature.

INTRODUCTION

In a computer network with a large number of users, cryptography is often essential for protecting stored or transmitted data. While this application closely resembles the age old use of cryptography to protect military and diplomatic communications, there are several important differences which require new protocols and new types of cryptosystems. This paper addresses the multiuser aspect of computer networks and presents ways to preserve privacy of communication despite the large number of user connections which are possible.

In a system with n users there are n^2-n pairs who may wish to hold private conversations. The straightforward way to achieve this is to give each pair of users a key in common which they share with no one else. Each user will then have n-1 keys, one for communicating with each other user. Unfortunately, the cost of distributing these keys is prohibitive. A new user must send keys to all other users. Unfortunately, the network cannot be used for this purpose, and an external secure channel is required. This procedure is comparable to requiring each new telephone subscriber to send a registered letter to everyone else in the phonebook.

Military communications suffer less from this problem for several reasons. Among these are the limitations imposed by the chain of command and the fact that stations change allegiance infrequently. In a computer network designed for business communication, on the other hand, users will regard each other as friends on one matter and as opponents on another. Firms A and B may cooperate on one venture in competition with C, while simultaneously, A and C compete with B on a different endeavor. A must therefore use different keys for communicating with B and C.

One approach to this problem is to assume that the users trust the network. Each user remembers only one key which is used to communicate with a local node. From there the message is relayed from node to node, each of which decrypts it, then reencrypts it in a different key for the next leg of its journey. This process is known as link encryption.[1] When the message reaches the network node closest to its destination, it is sent on to the addressee encrypted in a key shared only by the addressee and that node.

Although this technique requires each user to remember only one key, it has the disadvantage that a message is compromised if any one of the nodes in its path is subverted. In this paper we examine two other ways of allowing secure communication between any pair of users without assuming the integrity of all nodes in the network and without requiring the users to distribute or store large numbers of keys.

The first technique requires no new technology, but imposes a complex initial connection protocol. This is the subject of the second section of this paper. We call the second technique public key cryptography, since most of the secrecy traditionally required for the keys has been removed. This is discussed in section three and represents a radical departure from past cryptographic practices. While it requires further work before it becomes implementable, its simplicity of operation makes it extremely attractive. If a suc-

* This work was supported by the National Science Foundation under NSF Grant ENG 10173.

cessful implementation can be developed it should find wide use in both military and civilian applications.

The fourth section shows how public key cryptography can be used to provide a time and message dependent digital signature which cannot be forged even when past signatures have been seen. This is an example of the general problem of authentication discussed in greater detail in Reference 2, which provides a more general perspective in which public key cryptography can be viewed.

A PROTFCTIVE PROTOCOL

As indicated earlier, a message protected by link encryption will be compromised if any node in the path it follows from the sender to the receiver is subverted. In this section we describe a protocol which guarantees to protect the message unless a large number of nodes are compromised. While many variations are possible, the basic technique is as follows.

A small number m of the network's nodes will function as "key distribution nodes." Each user has m keys, one for communicating with each of these m nodes. These keys vary from user to user, so while each user must remember only m keys, each of the key distribution nodes remembers n, one for each user of the net. When users A and B wish to establish a secure connection they contact the m key distribution nodes and receive one randomly chosen key from each. These keys are sent in encrypted form using the keys which the users share with the respective nodes. Upon receiving these keys, the conversants each compute the exclusive or of the m keys received to obtain a single key which is then used to secure a private conversation. None of the nodes involved can violate this privacy individually. Only if all m nodes are compromised will the security of this connection fail.

It might be objected that any key distribution node acting alone can prevent all communication by mischievously sending out different keys to each of the parties, thus bringing network operations to a halt. The users, however, can easily protect themselves against this threat. If communication using the composite key fails, its use as a key is abandoned, and the components are exchanged one by one, in clear, for comparison. If any key fails to agree, the node which issued it is blacklisted. Finally, on conclusion of this process, the users repeat the request for keys to the nodes which passed the previous test.

Alternatively, the component keys can be compared by the use of one way functions[2,3,5] without ever being transmitted in clear. Loosely speaking, a function f is called a one-way function if it is easy to compute in the forward direction, but given any output, it is computationally infeasible to find an input which produces it. In referring to a task as computationally infeasible, we have in mind that it cannot be done in fewer than a finite but astronomical number of operations, say 2↑100. For practical purposes, this is equivalent to being incomputable. As shown in Reference 2, a one way function can easily be obtained from a secure cryptosystem.

If communication fails using the composite key, the users send the images of the individual keys under a public one-way function. If the image received does not agree with that computed by applying f to the key, the node which issued it is guilty of compromise. Since the valid keys have not been publicly revealed in this process, there is no need to request new ones from the uncompromised nodes. Instead the invalid ones are omitted and the remainder xored.

To sum up, this technique requires each user to remember m keys and each key distribution node to remember n keys. Unless all m key distribution nodes are subverted, any two users can establish a private link through use of a set-up protocol usually requiring 2m exchanges (more are required if a key distribution node has been subverted). The next section describes a concept which eliminates much of this overhead and does not require the user to trust any node. This new concept, if successfully implemented, will make the technique described above obsolete.

PUBLIC KEY CRYPTOGRAPHY

In this section we propose that it is possible to eliminate most of the secrecy surrounding the key used in a communication, and yet to preserve the secrecy of the communication. This is accomplished by giving each user a pair of keys E and D. E is an enciphering key and is public information. D is the corresponding deciphering key, and while this must be kept secret, it need never be communicated, eliminating the need for a secure key distribution channel. Although D is determined by E, it is infeasible to compute D from E.

For reasons of security, generation of this E-D pair is best done at the user's terminal which is assumed to have some computational power. The user then keeps the deciphering key D secret but makes the enciphering key E public by placing it in a central file along with his name and address. Anyone can then encrypt a message and send it to the user, but only the intended receiver can decipher it. Public key cryptosystems can therefore be regarded as multiple access ciphers.

By regularly checking the file of enciphering keys the user can guard against any attempt to alter it surreptitiously. Any such mischief is reported and settled by other authentication means, such as personal appearance.

The crucial feature of a public key system is that it is relatively easy to generate an E-D pair, preferably automatically through a publicly available transformation from a random bit string to E-D, and yet it is computationally infeasible to compute D from E.

At present we have neither a proof that public key systems exist, nor a demonstration system. We hope to have a demonstration E-D pair in the near future, and expect that if the demonstration pair successfully resists attack then we will be able to design an algorithm for automatically generating E-D pairs of a similar kind. In the meantime, the following reasoning is given to help dispel any doubts the reader may have.

A suggestive example is to let the cryptogram, represented as a binary n-vector c equal E m; where m is the message also represented as a binary n-vector, and E is an arbitrary n-by-n invertible matrix. Letting D=E↑-1 we have m=D c. Thus both enciphering and deciphering are easily accomplished with about n↑2 operations. Calculation of D from E, however, involves a matrix inversion which is a harder problem. And it is at least conceptually simpler to obtain an arbitrary pair of inverse matrices than it is to invert a given matrix. Start with the identity matrix I and do elementary row and column operations to obtain an arbitrary invertible matrix E. Then starting with I do the inverses of these same elementary operations in reverse order, to obtain D=E↑-1. The sequence of elementary operations could easily be generated from a random bit string.

Unfortunately, matrix inversion takes only about n↑3 operations even without knowledge of the sequence of elementary operations. The ratio of "cryptanalytic" time (i.e., computing D from E) to enciphering or deciphering time is thus at most n. To obtain ratios of 10↑6 or greater would thus require enormous block sizes. Also, it does not appear that knowledge of the elementary operations used to obtain E from I greatly reduces the time for computing D. And, since there is no round-off error in binary arithmetic numerical stability is of no consequence in the matrix inversion. In spite of its lack of practical utility, this matrix oriented example is still useful for clarifying the relationships necessary in a public key system.

A more practical direction uses the observation that we are really seeking a pair of easily computed inverse algorithms E and D, but that D must be hard to infer from E. This is not as impossible as it may sound. Anyone who has tried to determine what operation is accomplished by someone else's machine language program knows that E itself (i.e., what E does) can be hard to infer from E (i.e., a listing of E). If the program were to be made purposefully confusing through addition of unneeded variables, statements and outputs, then determining an inverse algorithm could be made very difficult indeed. Of course, E must be complicated enough to prevent its identification from input-output pairs.

Another idea appears more promising. Suppose we start with a schematic of a 100 bit input, 100 bit output circuit which merely is a set of 100 wires implementing the identity mapping. Select 4 points in the circuit at random, break these wires, and insert AND, OR and NOT gates which implement a randomly chosen 4 bit to 4 bit invertible mapping (a 4 bit S box in Feistel's notation).[4] Then repeat this insertion operation approximately 100 times to obtain an enciphering circuit E. Knowing the sequence of operations which led to the final E circuit allows one to easily design an inverse circuit D. If however the gates are now randomly moved around on the schematic of E to hide their associations into S boxes, an opponent would have great difficulty in reconstructing the simple description of E in terms of S boxes, and therefore would have great difficulty in constructing a simple version of D. His task could be further complicated by using reduction techniques (e.g. Carnaugh maps) or expansion techniques (e.g. $\sim(AB) = \sim A$ or $\sim B$, or expressing a logical variable in terms of previous variables), and by adding additional, unneeded S boxes and outputs.

For ease of exposition, we have described the implementation of a specific key in hardware. In practice, a special purpose simulator is obviously of most interest. The hardware description is also valuable in exemplifying a generally useful idea. To build a good public key cryptosystem one needs easily inverted elementary building blocks and a general framework for describing the concatenation of these elementary blocks. Here the elementary building blocks are S boxes and the general framework is the schematic diagram. The general framework must also hide the sequence of elementary building blocks so that no one other than the designer can easily implement the sequence of inverse elementary operations. Examination will show that the matrix example had a similar structure, except there the general class of transformations obtainable was too small.

While the above arguments only provide plausibility as opposed to proof, we hope they will stimulate additional work on this promising area of research.

PUBLIC KEY AUTHENTICATION

The purpose of a cryptographic system is to prevent the unauthorized extraction of information from a public (i.e., insecure) channel. The dual problem of authentication is to prevent unauthorized injection of messages into a public channel.

In conventional paper oriented business transactions, signatures provide a generally accepted level of authentication. As electronic communication replaces mail service the need for a digital signature will be strongly felt.

Various types of authentication are now possible,[2] but the development of public key cryptosystems would allow an entirely new dimension.

Currently, most message authentication consists of appending an authenticator pattern, known only to the transmitter and intended receiver, to each message and encrypting the combination. This protects against an eavesdropper being able to forge new, properly authenticated messages unless he has also stolen the key being used. There is no protection against such an eavesdropping thief or against the threat of dispute. That is, the transmitter may transmit a properly authenticated message, later deny this action, and falsely blame the receiver for taking unauthorized action. Or, conversely, the receiver may take unauthorized action, forge a message to itself and then falsely blame the transmitter for these actions. For example, a dishonest stockbroker may try to cover up unauthorized buying and selling for personal gain by forging orders from clients. Or a client may disclaim an order, actually authorized by him, but which is later seen to cause a loss. We will introduce concepts which would allow the receiver to easily verify the authenticity of a message, but which prevent him from generating apparently authenticated messages, thereby protecting against both the threat of eavesdropping thieves and the threat of dispute. Note that these techniques thus provide stronger protection than signatures, voiceprints, etc. which can be forged once seen and are not message dependent.

To obtain an unforgeable digital signature from a public key cryptosystem, the protocol would be as follows: Assume user A wishes to send a message M to user B. The transformed message C=EbDa(M) is sent, where Eb represents the transformation effected by use of B's public enciphering key and Da represents the transformation effected by use of A's secret deciphering key. Upon receipt of C, user B operates first with his secret operation Db and then with the public operation Ea thereby obtaining EaDb(C) =EaDbEbDa (M) =M. No one else can extract M because of the need to know Db. By saving the intermediate result Db(C) =Da(M) user B (and only user B) can prove that he received the specific message M from user A. There must be some structure to the message (e.g., it could include a date and time field) to prevent injection of random bit patterns for C, with the hope that the resultant decoded "message", EaDb(C), might cause random mischief such as deletion of files.

Note that since there is no need for a secure channel for distribution of authentication information, we have a public key authentication system. This system protects against, "eavesdropping thieves" and against a dispute as to whether or not an action taken by the receiver was authorized by the transmitter. Similarly, a public key cryptosystem can be used to protect against the other type of dispute in which the transmitter A claims to have issued an order which was not carried out by the receiver B. The transmitter requests that the receiver B send EaDb(M) as a receipt for the message M. By operating on this receipt with his secret operation Da, the transmitter obtains Db (M), which could only have been generated by the receiver B. Only user A can generate this receipt since it requires knowledge of Da.

While the above discussion centered on message authentication it also applies to user authentication. The implicit message becomes "I am user X and the time is T." Inclusion of the time field prevents an eavesdropper from using old authentication signals to pose as someone else. For reasons noted in Reference 2, such a system deserves to be called a one-way IFF system.

We thus see that public key cryptosystems developed for ensuring the privacy of communications, could also be used to ensure their authenticity. They could therefore be used to fill the need for a digital equivalent of a signature. This need is currently a major barrier to the use of electronic mail for business communications, and provides additional motivation for study of public key cryptosystems.

ACKNOWLEDGMENT

The authors wish to thank Leslie Lamport of Massachusetts Computer Associates for several valuable discussions. In particular, the technique described in Section 2 was discovered during one of these conversations.

Cryptography using modular software elements*

by HERBERT S. BRIGHT and RICHARD L. ENISON
Computation Planning, Inc.
Bethesda, Maryland

ABSTRACT

Protection of information within a computer/communication system can be provided through reversible cryptographic transformation of the information itself into a form that can be returned to usable form only through use of control information known as "key."

It is not necessary, in order to achieve access control, that the encryption algorithms, random number generator, or system organization be kept secret; in fact, a basic requirement of modern cryptographic technology is that it must be effective although a would-be penetrator is assumed to have full access to all of that information and the facilities and competence to apply it. Only the key can be assumed to be, and must be, physically secure.

The building-block approach outlined makes use of pre-programmed software elements for providing all specialized algorithms, including the Proposed Federal Data Encryption Standard (DES), together with necessary nonnumeric generalized support routines for use with application programs written in conventional procedural higher languages (FORTRAN, COBOL, etc.). Both Strong Algorithm and Long Key methods can be used as required by security-level-vs-cost tradeoff considerations.

This method is useful in conjunction with specialized hardware; for testing of programs and hardware; in some cases instead of hardware; and can support multiple-level security applications.

The entire scheme, including the Tausworthe-Lewis-Payne bitwise linear recurrence modulo 2 quasirandom number generator, is based irrespective of hardware type on a standardized 64-bit data element.

INTRODUCTION

In spite of appropriate bars and locks on parts of a system: If the information it handles is in a form that can be understood, used, or damaged by unauthorized persons without such access being immediately evident to management, the information is vulnerable.

Loss of management control over sensitive information or operations is then prevented only by the integrity of system controls.

Unauthorized access may be for improper or malevolent purpose or—much more probably—may occur by accident; but in any case it is ultimately management's responsibility to avoid errors and omissions in planning that can lead to such vulnerability.

In the course of physical and logical configuration planning, management has some choices of "appropriate bars and locks" in hardware/software installation.

Protection of the information itself, through privacy transformation using cryptographic technology, provides an additional level of management control that can be relatively low in cost and high in effectiveness.

Elementary applications of cryptographic protection can include:

- User authentication (off-line)
- Terminal authentication (on-line)**
- Data link protection
- Network protection
- File access protection

The basic concept of modern cryptographic protection for information is that access to it can be limited to only those properly authorized to make such access, merely by protecting an information key.

This paper will outline a method by which preprogrammed software elements can be combined in modular fashion to provide a broad range of cryptographic transformation capabilities.

CRYPTOGRAPHY CONCEPTS

Cryptographic transformation of discrete data elements consists of applying deterministic modification processes that prevent the data from being recognized or used, or modified without such modification becom-

* This work was done in connection with software product development.

** An advanced two-way authentication scheme is outlined in Reference 1.

ing obvious. This paper will be limited to reversible crypto processes (i.e., those which are capable of subsequently reversing the encryption (i.e., "decrypting")) in order to recover the original text.

Basic ideas

Figure 1 defines the nomenclature and shows schematically the relationship between input data (known as Plaintext or Cleartext); the encrypted data (known as Cipher or Ciphertext); the data used to control encryption and decryption (known as Key); and the encrypt/decrypt operations.

A system using the arrangement of elements shown in Figure 1, constituting the simplest and most basic implementation of cryptography, is known by the term "Electronic Code Book" or ECB. Many writers distinguish between encoding (conversion of message elements to different form using a substitution process) and enciphering (transforming message elements using an algorithmic process). Enciphering transformations include both resequencing and in-sequence conversion.

Shannon, whose basic 1949 work[2] is fundamental to much subsequent work and is the foundation for the work reported in the present paper, distinguished between

- "Concealment Systems," also known as Steganography, in which the very existence of sensitive information is concealed;
- "Privacy Systems," in which the physical form of information is transformed and reconverted by special equipment assumed to be not possessed by unauthorized users; and
- " 'True' Secrecy Systems," in which the information is modified only logically, and unauthorized persons can be assumed to be aware of its existence and to have any equipment needed to decrypt it into Plaintext form.

We will consider only what Shannon called True Secrecy Systems: We assume that the algorithm(s) used for data transformation, and all necessary system information, are completely public and that only the key information is physically secure; viz., that a key is known only to authorized persons who are authorized to access the information that is to be protected by cryptographic transformation. This assumption is consistent with the National Bureau of Standards' Draft Guidelines[3] in which D. K. Branstad established the basic assumptions underlying development and use of the Proposed (U.S.) Federal Data Encryption Standard (DES).

Shannon showed that effective cryptographic transformation processes can be implemented using either algorithmic complexity or key length for achieving strength: He showed that what he called "product systems," consisting of a combination of simpler cryptographic processes, form a linear associative algebra with a unit element, thus permitting techniques to be concatenated without losing the required deterministic nature of the resulting process.

The NBS Proposed DES[4] is an example of a Shannon Product System, consisting of an algorithm using bitwise permutation, addition mod 2, and substitution in each 64-bit data block in a highly complex sequence, involving multiple iterations through parts of the process, under control of a 64-bit Key (56 data bits plus 8 parity bits). Its basic character is outlined in gross schematic form in Figure 2, which is taken from Branstad.[3]

Shannon represented all simple substitution processes in the form of character set arithmetic (for En-

Figure 2—Schematic flowchart of DES algorithm

glish alphabetic sets, arithmetic base 26); the Vernam system[5] used bit-by-bit addition modulo 2.

A simple monoalphabetic substitution process, known as a Caesar System (perhaps first introduced to some readers in the form of the Little Orphan Annie Secret Code Wheel), can be represented by

$$y_i = x_i + u$$

where u is a constant and the y_i are the elements of a substitution encoding scheme.

It may be seen by inspection that a Caesar-encoded alphabetic message can be solved by the method of exhaustion, writing it 26 times and choosing one that seems to follow the required language syntax and semantic requirements. Such* processes have not been used by military people since Biblical times.

Vigenère systems[2] use a constantly-changing alphabetic substitution process, stepped synchronously with the message being transformed.

If a single transformation process is stepped to the next sequential substitution using a recirculating transformation representation (initially implemented as a paper tape loop, thus called a "single loop Vigenère system") the transformation can be represented by the sequence

$$a_o, a_1, \ldots, a_\mu$$

A system in which two recirculation transformations are synchronously cascaded can be represented by

$$a_o, a_1, \ldots, a_\mu$$
$$b_o, b_1, \ldots, b_\gamma$$

It is customary to choose μ and γ to be relatively prime.

Tuckerman[6] demonstrated that a general solution to n-loop Vigenère systems could be provided by statistical methods, and showed fully-developed breakings of single- and double-loop Vigenère systems, using real examples.

Shannon proved that a single-loop Vigenère system with infinite "loop" length is unbreakable. Such a scheme is known as "single use code." It requires that the key be at least as long as the message and that the key be kept physically secure.

The significance of the previous paragraph is that the simple Addition Modulo 2 or Exclusive Or algorithm, which is its own inverse, can be used for both encryption and decryption providing that an infinite-length key or an acceptable substitute therefor can be provided and maintained secure. We will use Shannon's designation of such a system as Vernam.

As originally published[5] the Vernam system applied bit-by-bit add-mod-2 (reversible) transformation of a binary message without changing its length.

It may be seen that a similar transformation, also reversible, can be applied through use of sequential logic by merging random noise with the plaintext information to form cipher that will be increased in length by the amount of noise inserted. Subsequent decryption will extract the binary key information and return the cipher to the original plaintext content and length.

Both bitwise operations (Vernam) and sequential logic schemes (merge) depend for their cryptographic strength on the quality of the random number stream used as the Long Key.

The long key information can be retained as physically secure, or can be generated from seed by using a short actual key to start an appropriate random number generator. A third choice is to generate random blocks of key data that can be randomly sequenced to form a pseudo-long-key binary stream. The decision between these implementation approaches should be made in consideration of the required technical performance (in the security sense) and economics of each problem situation.

In the remainder of this paper we will consider only encryption schemes that can be sufficiently strong so that they are economically infeasible to break. We will categorize them into the two broad groups implied in the above discussion:

- Those depending for their strength upon the complexity and effectiveness of a known algorithm, using a nominal-length key, will be called *strong algorithm* systems.
- Those depending for their strength upon the nonpredictability (i.e., the random-bit quality) of a long key, used with relatively trivial algorithms, will be called *long key* systems.

Strong algorithm

Much of the substantive content of the classic Shannon paper[2] and others[7,8] culminating in current algorithm developments has led to what Shannon called Product Systems. Because it has been broadly published and scrutinized, and because current indications are that it satisfies the basic requirements of strength, use of short key, and generality, we suggest that the NBS Proposed DES Algorithm[4] is an appropriate archetype for Strong Algorithm schemes. Its use will be assumed in this section, with the understanding that it could be replaced by a different strong algorithm if such replacement is appropriate.

Proposed Data Encryption Standard (DES)

The National Bureau of Standards (NBS) has selected and published[4] a Proposed Federal Data Encryption Standard. The announcement includes the statement that:

"Data may be protected against unauthorized dis-

* Martin[7] described as a particularly poor example of encryption a method that has been suggested for use with Selectric® typewriter terminals: use scrambled positions for the characters on the type element, and physically secure this removable alphabet.

closure by generating a random key and issuing it to the authorized users of the data. The cipher that has been produced by performing the steps of the encryption algorithm on data using a particular key can only be returned to the original data by use of the decryption algorithm using the identical key. Unauthorized recipients of the cipher who may have the algorithm but who do not have this key cannot derive the original data. A standard algorithm based on a user-generated key thus provides a basis for compatible cryptographic protection of computer data while preventing unauthorized use of the data in cipher form." (The Proposed Standard also states that "Only hardware implementations of the algorithm . . . will be considered as complying with the standard.")

Several manufacturers are developing LSI-chip-based hardware for implementation of the DES algorithm. We are not aware that any of this hardware has been released for sale as of the date of submission of this paper; however, we assume that such release will occur shortly after official confirmation of the Federal Standard.

We have developed exact software Emulators of the DES algorithm for several kinds of hardware, for use as a part of a generalized nonnumeric software element support package. The emulators maintain, and select from, preprocessed key pools. Other parts of the package provide capabilities for data preparation, manipulation, parity bit setting in randomly generated keys, and testing (including optional checking of key parity bits), for use with source programs written in higher procedural languages such as FORTRAN and COBOL.

We anticipate that the special-purpose DES hardware will be much faster in data throughput than the general-purpose versions of the software. The hardware must, of course, be dedicated to particular system functions and consequently cannot be used for general testing and other auxiliary functions without interrupting on-line availability.

NBS has developed two sets of test data for validating implementations of the algorithm:

- What we have called Test A is a set of 24 64-bit key/data pairs designed to demonstrate the power of the algorithm by showing the large effects on cipher of small changes in either datum or key, and the behavior of the encryption process on a variety of bit patterns.
- What we have called Test B is a set of 19 key/data pairs generated as pseudorandom numbers and chosen because the corresponding 19 encryptions reference at least once all of the 512 entries in the "S-box" substitution cipher tables. These 19 pairs were found experimentally by NBS and independently confirmed by us. Correct execution of Test B (in which all cipher produced correspond to presumably correct cipher from a different implementation, and in which all of the S-box table entries are referenced at least once) provides a high order of confidence in the correctness of encryption for any values of key/data.

Result of exercising one of the DES Emulators executing 15 examples from A and B, as described above, is given in Figure 3. In this test output the column headed "CIPHER(ENCRYPTED)" gives the result of machine encryption; the column headed "DECRYPTION OF CIPHER" gives the result of the machine decryption of the machine-produced cipher to recover the original plaintext. All keys and data are shown in hexadecimal notation to correspond with NBS examples.

For all key/data pairs of Tests A and B, the Emulators give results identical to those given by NBS.

From Test A (the first 12 rows of Figure 3), it may be seen that change of a single bit value or a 1-bit shift of a subpattern position within datum or key provides essentially complete change of encrypt/decrypt results. This requires complete accuracy of transmission; conversely, the process can thus be used to display with great sensitivity even slight errors in data entry or transmission.

To show this effect, we repeated Example A9 with the 5th and 6th data digits interchanged (BC becomes CB). Note that the resulting cipher (for Example A25) shows no evident resemblance to the cipher for A9.

Example A26 is a demonstration of the odd-parity check (optional under the Proposed Standard); it consists of Example A10 modified by giving the first eight key bits even parity.

The general-distribution versions of the DES Emulators use medium-speed, medium-space techniques. NCRYPT/DCRYPT requires less than 9000 bytes on 360/370 or 2200 words on 1108. Execution speed is over 100 encrypts or decrypts per second with machines in the 370/155 or 1108 class.

It may be seen that the strong-algorithm process, if executed entirely by software, will be economical for fairly small data volumes but will be costly for large-volume applications (such as, e.g., encrypting all but control elements of continuous high-speed data streams or sizable data bases). For large-scale applications, the long-key methods outlined in the next section (after either a time delay for about a million machine instructions executed in initial (from seed) startup of the high-performance random number generator provided, or time to load a 1042-word restart table) operate orders of magnitude faster than the Emulator.

Applications of the software DES emulator include:

- Testing of application ideas and methods before hardware is available;
- Debugging and production testing of programs independently of on-line hardware;

- Bidirectional authentication procedures (See, e.g., Reference 1).

Long-key systems

Any long-key system depends upon the use of a key stream that must be assumed to be physically secure. The key stream can be provided in two basic ways:

(a) It can be generated from "seed" (i.e., a key unique to that key stream) in a fully-deterministic process when used for either encryption or decryption or both; or

(b) It can be generated, stored, copied as may be required, and played back from the stored form when and where needed.

In case (a), decryption of a particular ciphertext data stream requires that a key-stream generator (software or hardware) identical to that used in encryption of that stream must be available at the time and place of key stream entry for decryption.

Physical security must be provided for the key to be used: in case (b), this will require security of tape or diskpack; in case (a), only the seed need be kept secure. Obviously, physical and geographical considerations will affect the generate-or-playback choice.

An important consideration is that long messages would be in hazard from even trivial communication or other hardware errors; loss of absolute synchronization would generate chaos, effectively preventing recovery of plaintext beyond the point at which, say, a one-bit loss occurred.

The very vulnerability of ciphertext, as noted here, provides a potentially useful and highly sensitive detection scheme: even small errors in ciphertext transmission will result in gross and obvious format and other changes in decrypted output.

Use of message blocking (we have chosen 64 bits as the standard block length corresponding to DES practice[3,4]), and careful block numbering and accounting, prevents loss of more than a single block for a single small error and provides an audit trail for recovery.

As noted in References 3 and 4, validity of the encryption process as secure in and of itself, depending only upon key security, requires that the system not depend upon secrecy of an algorithm or of hardware/software configuration.

With either of the long-key methods discussed below, in order to maximize security and integrity of the encryption process, "leakage" of key stream control information elements should be inhibited in spite of the simplicity of the actual encryption algorithms. Thus, it is desirable that the appearance of cyclic or unchanging (i.e., transparent) bit patterns in plaintext (see, e.g., the all-zeroes and alternate-ones data of Examples A10 and A13 of Figure 6) be suppressed by compression or other means.

Long-key generation from seed

One effective means of key stream generation is a process that produces uniformly distributed random numbers. The process used here is a computer program quasirandom number stream generator of the

Tausworthe-Lewis-Payne bitwise linear recurrence modulo 2 type, of which the developmental background and characteristics are outlined in the Appendix.

Chaitin[9] expressed proof that a truly random string cannot be specified by an information string shorter than itself. It may be inferred that a perfect single-use code cannot have its key stream generated from a short seed expanded by any program of limited complexity.

We believe, however, that despite its finite complexity a publicly known quasirandom number stream generator of long period and good statistical performance, such as that described in the Appendix, when operating on a secret seed, can produce a sufficiently close approximation to a random key stream so that the fundamental objective of the present paper is met: the resulting encryption will be economically infeasible to break.

Figure 4 shows schematically the process by which the quasirandom number generator produces a 64-bit-block key stream starting from a 64-bit (or less) seed, continually accessing a recirculating seed matrix of about a thousand words as outlined in the Appendix.

Initial startup of the generator from a seed requires a half million machine instructions to be executed, after which the process proceeds at a speed corresponding to only a dozen machine instructions executed per number generated.

Restart of the process can be accomplished readily through reloading of the recirculating seed matrix. Backwards re-generation from a previous checkpoint, as is required for some system problems, offers no difficulties; the generator can operate in either direction. Pre-iteration count is a user-controlled parameter.

For encryption purposes this Tausworthe-Lewis-Payne generator offers the advantage that a large amount of information (521 64-bit blocks) would be needed to initiate or restart a quasirandom string. There is no explicit way of identifying the initially-used element of the generated string, other than knowing the actual seed and the starting iteration count. The fact that both seed and period are of great length permits both Vernam and merge/extract encipherments to have considerable cryptographic strength.

On a 360/65, after restart (time to load the current seed string matrix) or startup (2.3 seconds for a pre-iteration count of 20,000p), the generation of 64-bit unsigned quasirandom integers takes 24.1 milliseconds per thousand numbers.

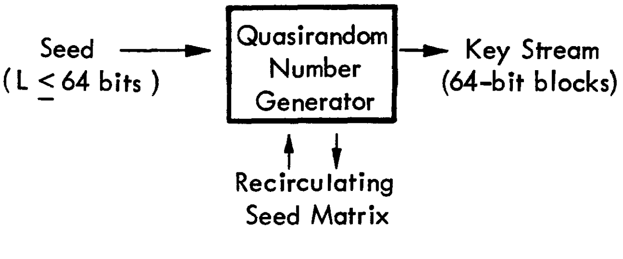

Figure 4—Long-key generation from seed

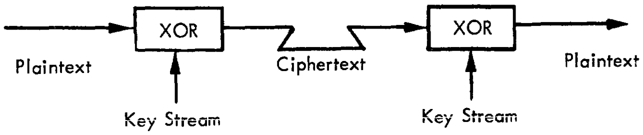

Figure 5—Long-key Vernam (bitwise) logic

The period of this Tausworthe-Lewis-Payne type generator is essentially infinite (viz., $2^{521}-1$). Its gross performance has been checked in dimensionality up to 8-distributivity. Small changes in seed cause large changes in generated key stream.

Long-key Vernam (bitwise)

The classical Vernam single-use-code concept, implemented explicitly, is shown schematically in Figure 5.

As noted previously, this scheme[11] does not change message length.

The building-block approach uses prefabricated software elements for executing the encryption and control logic and for data preparation and testing.

A Vernam test is shown in Figure 6. This test uses as plaintext input data, read from cards, the 15 examples used in Figure 3 above to test the DES Emulator, consisting of 13 examples of NBS "Tests A and B" plus slight modifications of two of the Test A examples. The key stream was generated by the TLP quasirandom number generator from the 64-bit seed 012357BD14905694. Speed of this encryption or decryption on a 360/65 is one 64-bit block per 12.3 microseconds.

Long-key sequential logic

The capability for controlled merging and extracting of noise into and from binary information streams has several potential uses and should be considered in a comprehensive encryption plan:

- Provide a high level of cryptographic protection when used with a long quasirandom number control stream and appropriately generated noise data;
- Provide an intermediate level of cryptographic protection when used with shorter or recycling control stream and a noise data stream of any length;
- Suppress redundancy or cyclic patterns in plaintext or in ciphertext, for the purpose of raising the cryptographic strength of DES or Vernam-type high-level cryptography systems; and
- Permit, in combination with the DES and/or Vernam techniques, the implementation of multiple-level cryptography systems of controllable

Figure 6—Vernam encryption/decryption results

complexity and with controllable strength/cost tradeoff at each level.

The encryption and decryption processes can be controlled from fixed mask (MASK=constant); lists or tables of masks (MASK=array variable); or from a recycling or open-ended mask stream, with corresponding levels of complexity and security.

Use of a constant merge control mask produces weak cipher that has recognizable patterns, especially when used with simple bit pattern plaintext and examined in binary form; a variable mask produces higher-grade cipher.

A sequential logic test is shown in Figure 8. In this case a constant quasirandom 64-bit key (actually one of the generated keys, chosen because it happens to contain exactly 32 one-bits and 32 zero-bits, generated from the same seed used in the Vernam test above) is used as the control mask for noise (the same 15 generated quasirandom keys) to be merged with plaintext to form a kind of cipher. This mask, because of the 50/50 one/zero mask ratio, produces cipher just twice the length of the plaintext. The two sequential 64-bit cipher blocks produced from each plaintext block are shown together in the double column headed CIPHER (ENCRYPTED). The decrypted plaintext, recovered by extraction of the noise stream under control of the same mask, is shown in the right-hand column labeled DECRYPTION OF CIPHER.

The requirements for bitwise testing and processing make this sequential process slower than the Vernam process.

PROGRAM PROTECTION

The protection of proprietary programs from unauthorized use, copying, or alteration is a largely unexploited area of application of cryptography that offers fascinating opportunities for strategy and counter-strategy development.

Protection technology for file and system access, as outlined previously, provides the basic mechanisms for program transformation, detection of alteration, and audit trail development.

A basic decision that must be made at the outset of development of a program protection method is whether personnel and organizations having some level of authorization for system software maintenance are to be considered part of the world against which protection (from errors and omissions as well as malfeasance) is sought. If the answer is yes, the problem set escalates in difficulty and reasonable bounds on the protection objectives must be established.

APPENDIX

Background for a 64-bit quasirandom number string generator

The "mid-squares" random number generators used by pioneers Von Neumann and others in the late 1940s rapidly degenerated (to zeroes or cycles of short period) when used for long string generation. Like physical (e.g., electronic noise) generators, they were

Figure 8—Sequential encryption/decryption: Tests A and B

unsuitable for many modern computing purposes. They were largely displaced by generators (programs) of many designs using congruential methods.

Generators of one type, suggested by Lehmer[30] in 1951 and known as "linear congruential", can be described by the recursive formula

$$x_{i+1} \equiv ax_i + c \pmod{m}$$

where $\{x_i\}$ is the sequence generated. The parameters are the seed (x_0), the multiplier (a), the additive constant (c) and the modulus (m). This is called the multiplicative congruential method when $c=0$, and the mixed congruential method when $c \neq 0$. The x_i's are integers from 0 to $m-1$. A large value of m is needed to avoid trivial sequences with small period. For example, if $m=2$, the sequence is either a constant or an alternating 0, 1, 0, 1, ... Uniform numbers between 0 to 1 are obtained by $u_i = \frac{x_i}{m}$.

Generators of a second type, known as "additive congruential," can be described by

$$x_i \equiv x_{i-q} + x_{i-p} \pmod{m}.$$

Both are special cases of the general linear congruential method:

$$x_i \equiv a_1x_{i-1} + a_2x_{i-2} + \ldots . + a_px_{i-p} + c \pmod{m}.$$

The additive method has properties sufficiently different from the linear as to make it worth studying separately. A large modulus is not needed to ensure a long period; arbitrarily long period sequences can be generated with $m=2$, provided judicious choices are made for p and q.

Both linear and additive methods are described in Knuth Volume 2.[10] Knuth observes that a good sequence of random numbers can be obtained by the additive congruential method, or more generally, by

$$x_i \equiv a_1x_{i-1} + \ldots + a_kx_{i-k} \pmod{m}$$

provided that m is prime and the polynomial $x^k - a_1x^{k-1} - \ldots - a_k$ is primitive modulo m. Such generators with $m=2$ were proposed by Tausworthe[29] in 1965 and are referred to as linear recurrence modulo 2. In this case, the a_i's are 0 or 1; we may write

$$x_i \equiv x_{i-q_1} + \ldots + x_{i-q_r} \pmod{2}$$

and the polynomial becomes $x^{q_r} + \ldots + x^{q_1} + 1$ (note $-1 \equiv 1 \pmod{2}$)). In the simplest case, $r=2$ and the polynomial is a trinomial of the form $x^p + x^q + 1$. Such a generator is simple to implement on many modern electronic computers: addition modulo 2 is provided as the machine operation Exclusive Or.

An additive congruential generator not of this type was implemented by Carroll and McLelland[11] using suggestions made by Green, Smith, and Klem.[12]

Green, Smith and Klem showed that such a generator did not produce a very random sequence; Knuth rejected the Tausworthe generator as a poor source of random strings of bits; however, strings of consecutive bits from a Tausworthe sequence do not yield poor results when larger and more carefully chosen values of p and q are used than those tested by Knuth, and the string sequence can be further improved by using a technique recently proposed by Lewis and Payne.[13]

Statistical tests and criteria

Many tests for a would-be random number generator have been proposed and used. Several tests are described by Knuth:

(1) Equidistribution or Frequency Test: One counts the number of times a member of the sequence falls into a given interval. The number should be approximately the same for intervals of the same length if the sequence is uniform.

(2) Serial Test: This is a higher-dimensional version of the equidistribution test. One counts the num-

ber of times a k-tuple $(x_{ki}, x_{ki+1}, \ldots, x_{ki+k-1})$ of members of the sequence falls into a given k-dimensional cell. If this test is passed, the sequence is said to be k-distributed. It is not practical to divide the coordinate axes into too many subintervals when k is large, say, $k>3$. Other tests of k-distributivity are:

(2a) Poker Test: One considers groups of k members of the sequence and counts the number of distinct values represented in each group.

(2b) Maximum [Minimum] of k: One plots the distribution of the function max [min] $(x_{ki}, \ldots, x_{ki+k-1})$.

(2c) Sum of k: This is similar to tests described by Knuth. The same tests can be made for any function of k numbers, provided one can calculate an expected distribution for the function. This test is explicitly mentioned by MacLaren and Marsaglia[14] as well as by Lewis and Payne, who refer to it as the Yules Test. Several authors use $\sum_{1}^{k} x_i^2$, which is commonly called "the d^2 test".

(3) Gap Test: One plots the distribution of gaps in the sequence of various lengths, i.e., consecutive members $x_i, x_{i+1}, \ldots, x_{i+r}$, such that all members fall into a given interval, while the immediately preceding and succeeding members do not. A special case is where the interval is the set of numbers above (or below) the mean, in which case it is called the Runs Above (Below) the Mean Test.

(4) Runs Test: One plots the distribution of maximal ascending (descending) runs of various lengths. This test (now called the Runs Up/Runs Down Tests) was mentioned by Moshman[15] in the first random number generator paper ever published in an ACM serial.

(5) Coupon Collector's Test: One chooses a suitably small integer d and divides the universe into d intervals. Then each member of the sequence falls into one such interval. One plots the distribution of runs of various lengths required to have all d intervals represented.

(6) Permutation Test: One studies the order relations between the members of the sequence in groups of k. Each of the k! possible orders should occur about equally often. If the universe is large, the probability of equality is small; otherwise, equal members may be disregarded.

(7) Serial Correlation Test: One computes the correlation coefficient between consecutive members of the sequence. This gives the serial correlation for lag 1. Similarly, one may get the serial correlation for lag k by computing the correlation coefficient between x_i and x_{i+k}. This is to show that the members of the sequence are independent.

Other tests have been proposed and used. Lewis and Payne[13] ran a Conditional Bit Test, which tested the independence of each bit in a string from the others, as well as a Fourier Transform Test, also used by Coveyou and McPherson[16] in 1967 and by Lewis, Goodman and Miller.[17] The latter was facilitated by the Fast Fourier Transform algorithm introduced by Cooley and Tukey.[18]

All of the pre-Tausworthe papers referenced here proposed some sort of linear congruential generator. Those who subjected their generators to exhaustive tests admitted that some of the tests failed. Some only ran the simplest tests (e.g., equidistribution and serial test for pairs), and passed; however, in typical cases the same generators were later shown to fail some other test. The generators differed mainly in the choice of such parameters as multiplier, additive constant, and modulus. The modulus was usually the largest number that could be represented on some machine (most often 2^{35}), or a prime less than that number. The present problem required a 64-bit random number generator, which none of the above papers considered. Many authors seemed to choose various parameters arbitrarily and pick the ones that passed the most tests, although in some cases broad guidelines were given (but, in general, were not shown to be useful). One formula giving an approximation to the serial correlation of a linear congruential sequence was published by Coveyou.[19] In certain cases his approximation was a poor one, but Greenberger[20] corrected this flaw by adding another term. Some theoretical and empirical work by Marsaglia [21] in 1968 showed that all linear congruential generators suffered from poor higher-dimensional distributions. There was then little hope of producing one generator that passed all tests.

A paper by Martin-Löf[22] showed, using methods of recursive function theory, that there was a universal test for uniform random number sequences and that almost all sequences (in the sense of measure theory) passed it. Although this paper is quite abstract and not of much practical use in constructing a good random number generator, it did provide some hope that it could be done.

Knuth mentioned a property that seems to come close to the concept of a universal test, namely, complete equidistributivity, or ∞-distributivity: If a sequence is k-distributed, it is r-distributed for $r<k$. A sequence ∞-distributed if it is k-distributed for all k.

A sequence that is ∞-distributed passes all the other tests we have considered. Such a sequence was constructed by Knuth,[23] but, as he observed, his sequence is not of much use in machine generation of random numbers because it takes too long to converge to the desired properties. It was formed by starting with a short 1-distributed sequence, followed by a slightly longer 2-distributed sequence, etc.

The papers after Tausworthe's own paper that describe Tausworthe sequences show increasingly good results: it seems that such sequences can be constructed to pass more of the tests than the linear congruential generators. Whittlesey[24] showed that linear congruential generators that had passed other tests failed some autocorrelation tests he performed with lags from 1 to 50. These tests are related to the serial correlation test.

The Tausworthe sequence passed Whittlesey's test; in fact, it can be shown to pass these and many other tests on purely theoretical grounds. We found such analytical support to be lacking in the papers proposing linear congruential generators. Tootill, Robinson and Adams[25] showed that a Tausworthe sequence had good Runs Up and Down properties, and Tootill, Robinson and Eagle[26] showed that a Tausworthe sequence they generated was indistinguishable, by empirical tests, from one that was ∞-distributed.

It appears to be consensual among recent authors that, in generating a Tausworthe sequence, it is best to use a trinomial x^p+x^q+1 whose degree p is such that 2^p-1 is relatively prime to various parameters of the tests. Also, better results are obtained if decimation is used, which means that one does not pick consecutive groups of bits from the sequence but rather spaces them out; and the amount of spacing should be relatively prime to 2^p-1.

One would expect the best results from a Tausworthe generator if the degree p were such that 2^p-1 were itself a prime number. Such primes are called Mersenne primes, and p is called a Mersenne exponent. A table of primitive trinomials whose degree is a Mersenne exponent was published by Zierler.[33] It included the 23 then known Mersenne exponents, which form a consecutive set, the largest of which is 11213. The largest one having a primitive trinomial is 9689.

The most promising generator we have found seems to be the one described by Lewis and Payne.[13] They use a technique that appears to be superior to decimation: to generate r-bit numbers, each of the r bits is chosen from a different part of the same Tausworthe sequence with a constant gap between bits. Lewis and Payne suggest that a gap of at least 100p should be sufficient. They also suggest that the sequence will be k-distributed for $k \leq rp$.

Our Tausworthe-Lewis-Payne (TLP) generator uses the trinomial $x^{521}+x^{32}+1$ to generate 64-bit numbers that are 8-distributed and have good k-distributivity for $k>8$. The period of the sequence is $2^{521}-1$.

The degree-521 TLP generator requires 521 bits (not all zero) to start, which must somehow be expanded from the initial 64-bit seed. If these 521 bits are "not very random", the next few members of the sequence will also have this weakness; however, Lewis and Payne suggest that about 5000p (here, 2.6 million) bit-iterations of a Tausworthe generator should suppress such non-randomness. Our initial statistical tests appear to confirm that suggestion if iteration count is increased to 20,000p. We have considered but not implemented use of the primitive trinomial $x^{89}+x^{38}+1$ with the TLP method for generating the seed string. This two-level TLP may reduce the number of iterations required.

We have used the prefix "quasi-" which, according to Webster's 3ID, means "seemingly, almost" together with the word "random" to identify effective generators. Most authors have used the prefix "pseudo-" which, per Webster, connotes "false, sham, feigned, fake, counterfeit, spurious". Subsequent test results have shown, alas, that "pseudo" was often an appropriate descriptor. It is hoped that the performance of the generator described here will prove, on further testing, to have justified our use of the term "quasi-random number generator".

We gratefully acknowledge discussions on applicability of congruential methods with Juncosa,[28] whose work was used by many subsequent authors, and on primitive trinomials with Tausworthe,[29] whose basic concept underlies the most promising current developments.

Analysis of secret functions with application to computer cryptography

by INGEMAR INGEMARSSON
Linköping University
Linköping, Sweden

ABSTRACT

In computer cryptography we cannot avoid that data and the corresponding encrypted data can be read by an outside observer. The information contained in these observations may be used to decrypt parts of encrypted data or ultimately to identify the key in the cryptographic transformation. In this paper we have analyzed this situation using the concepts of information theory. The result shows that in most cases it is theoretically possible for an outside observer to identify the key after very few observations. As this must be avoided we have to rely on computational complexity in the process of deriving the key. This is achieved by using one-way functions which are practically impossible to invert.

INTRODUCTION

Computer cryptography differs from communication cryptography in two respects: (i) A particular set of data is used more than once and by several users. (ii) Data are processed by the computer. These two differences impose restrictions on the type of cryptologic transformations suitable for use in an electronic data processing (EDP) system. In this paper we will focus our attention on the problems caused by property (i) above.

Communication cryptography was analyzed by Shannon 1949.[1] His model includes an information source (a stochastic process) with known statistics. The information from the source is encrypted and then observed by an outside observer. The goal of the observer is to derive the original information and/or identify the encryption transformation. Our approach is somewhat different. When several users have access to the same data, the encryption transformation for the particular set of data is preferably fixed, at least for some time. In an EDP system it is also realistic to assume that a set of data and the corresponding cryptogram is known to an outside observer. The observer may use this knowledge to facilitate decryption of other cryptograms, encrypted with the same transformation. He may also ultimately be able to identify the encryption transformation. We want to investigate his chances to work in these directions. A related problem, from the legitimate user's point of view, is: How do we avoid that an outside observer gets the ability to decrypt stored cryptograms? Our approach originates in information theory. The encryption or decryption transformation (or algorithm) may be regarded as a set of known functions of the input variable. The function is chosen by the key which is unknown. From the beginning an outside observer does not know which function is actually realized. To him each function has the same probability.

When he observes the input and the corresponding output he receives some information about the actual function. The number of possible functions is decreased. To what extent does this help the observer if he wants to estimate the output corresponding to another input? We may formulate the question more precisely this way: Before the observation the uncertainty, measured as entropy, is H_0 bits. If no information as how to estimate other outputs is conveyed by the first observation, then the uncertainty remains unchanged. The entropy connected with the second observation is still H_0. It may sound as a good design objective to keep the uncertainty (the entropy) unchanged after several observations. Unfortunately this is limited by one of the main results of this paper.

$$\sum_{i=0}^{\infty} H_i = \log M \qquad (1)$$

Here H_i is the entropy after i observations and M is the number of encryption or decryption transformations, i.e., the number of keys. As is seen from equation (1) the requirement that the entropy should remain constant must be limited to a finite (and perhaps low!) number of observations. After that the entropy is zero, i.e., the observer knows exactly which function is actually chosen, i.e., he knows the key!

If we want to avoid this fallacy the sequence of entropies

$$\{H_i\}_{i=0}^{\infty}$$

must decrease. This means that the difficulty of the observer to estimate outputs for given inputs is decreasing with the number of observations! Obviously we have to compromise to obtain reasonable protection of the key and reasonable low chance to estimate the outputs.

However, when typical figures are put in the equations the result is most unsatisfying for the designer. If the model is accurate, it is too easy to break the system. The way out of this dilemma is of course to build a system for which this model cannot be used. The main point here is that we have not taken into account the computational problem involved in estimating the output for a given input starting from the knowledge from several observations. Hence the theory shows that we have to rely on computational complexity when designing computer cryptographic systems. The complexity requirement is preferably formulated in terms of *one-way functions.* Such a function is easy to compute but its inverse is not computable in a reasonable amount of time.

SECRET FUNCTIONS

We want to implement a secret function, i.e., a function which is not completely known to an outside observer. Such is the case for example in cryptology and in access control systems. The input variable x is supposed to be discrete and takes only a limited number of values. The output variable y is a function of x.

$$y=f_\alpha(x) \qquad (2)$$

where α is a fixed but unknown parameter in the range.

$$\alpha=1,\ldots,M \qquad (3)$$

Starting from scratch, an outside observer does not know α, but knows the set of functions f:

$$\{f_\alpha\}_{\alpha=1}^{M} \qquad (4)$$

The problem is now: How does the knowledge of a number of pairs (x,y), satisfying (2), affect the uncertainty about the parameter α? The range of possible α obviously cannot increase if the observer gets to know one more pair (x,y). The problem of the designer of the secret function seems to be maximizing the remaining number of possible α. We will see that this is not good advice. H leads to low uncertainty about y, given x. A better formulation of the problem is therefore: How does the knowledge of a number of pairs (x,y), satisfying (2), affect the uncertainty of y given x?

STRUCTURE OF THE SYSTEM

We may divide the system into a known part, containing the functions (4) and an unknown part containing the parameter α.

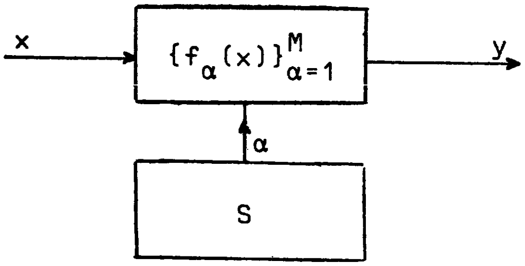

Figure 1—Structure of the secret function

S may be visualized as a store or memory, capable to store the M possible values of α. Hence the capacity, C, of the store must be:

$$C={}^2\log M \text{ bits} \qquad (5)$$

Figure 1 also reflects the structure of the implemented system. The block containing the function f(x) is supposed to be known, while S is a secure memory.

α is regarded as the outcome of stochastic variable A with

$$P[A=\alpha]=1/M \quad \text{for } 1\leq\alpha\leq M \qquad (6)$$

The output is then a stochastic variable Y. n pairs (x,y), satisfying (2), are known to the observer. The uncertainty in Y for a given x is measured as the conditional entropy:

$$H_n\equiv H(Y|Y_1,..Y_n)\equiv$$
$$-\sum_{y}\sum_{y_1}\ldots\sum_{y_n} P(y,y_1,..y_n).{}^2\log P(y|y_1,..y_n) \qquad (7)$$

Note that this entropy is a function of $x,x_1,\ldots x_n$. All entropies are nonnegative. The maximum of H_0 occurs when the possible outcomes of Y are equally likely.

$$\max H_0={}^2\log q \quad \text{when } P(y)=\frac{1}{q} \qquad (8)$$

where q is the number of possible values for the output variable y. If Y is conditionally independent on previous observations $Y_1\ldots Y_n$ then

$$H_n(x)=H_0(x) \text{ as } P(y|y_1,..y_n)=P(y) \qquad (9)$$

Note that H is still a function of x. If we sum H_n over n we obtain the following result:

$$\sum_{n=0}^{N} H_n=-\sum_{y}\cdot\cdot\sum_{y_n} P(y,y_1,..y_n).{}^2\log P(y,y_1..y_n) \qquad (10)$$

If we make N large enough only one or none of the M functions will pass through a given set of points $(x,y),(x_1,y_1),\ldots(x_n,y_n)$. Thus equation (10) reduces to:

$$\lim_{N\to\infty}\sum_{n=0}^{N} H_n=-\sum_{i=1}^{M}\frac{1}{M}{}^2\log\frac{1}{M}=-{}^2\log\frac{1}{M}={}^2\log M \qquad (11)$$

where we have used the probability in equation (6). Finally we combine equations (5) and (11) to:

$$\boxed{\sum_{n=0}^{\infty} H_n = C} \qquad (12)$$

In words: The sum of the entropies at each observation in a sequence of observations equals the capacity (in bits) of the key space. In practice C is the number of bits in the binary key.

Example

In a computer cryptographic system the input, output and key are binary numbers.

In the algorithm proposed by NBS as federal standard,[2] for example, k is 64 bits. (Actually lower because of redundancy in the key.) The output is also a 64-bit word.

Thus the maximum entropy (max H_0 according to (8)) is 64 bits. If H_0 really is 64 bits, then from (12) $H_1, H_2 ..$ is zero. Hence all information about the transformation is given in the first observation. The future outcomes are perfectly predictable:

Now suppose that H_0 is lower than 64 bits. Suppose that we want the system to withstand 8 (eight!) observations before the outside observer can identify the key. Then from (12):

$$\sum_{n=0}^{7} H_n = 64 \text{ bits}$$

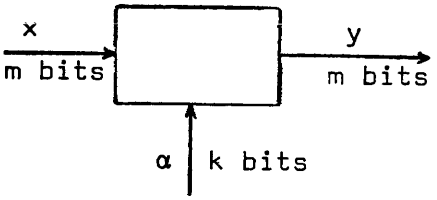

Figure 2—Computer cryptographic transformation

and thus the average of $H_0, .. , H_n$ is 8 bits. With this low entropy it takes only 256 trials (at most!) to make a correct guess of the output for a given input;

The situation is indeed disappointing, from the theoretical point of view!

ONE-WAY FUNCTIONS

We have as yet made no indication as how to compute the estimates of the output or the key from our observations. As we have seen from the above example it may be possible to predict the output and to identify the key after just a few observations. This must be avoided, of course. The only way to stop any effort in this direction is to make it practically impossible to perform the calculations which are theoretically possible.

We refer to Figure 2. The function:

$$y = f(\alpha, x)$$

is calculated by the encryption unit and must be easy to perform. Also:

$$x = f^{-1}(\alpha, y)$$

has to be performed by the decryption unit. On the other hand we have to design the system so that the function

$$\alpha = g(x, y)$$

is practically impossible to compute. This is an example of a one-way function. The algorithm proposed by NBS[2] does indeed have this property. To my knowledge it has successfully resisted every attempt to compute the key, given the input and output.

A secure, national system for electronic funds transfer

by D. KAUFMAN and K. AUERBACH
System Development Corporation
Santa Monica, California

ABSTRACT

This paper presents guidelines for development of a secure national network for electronic funds transfer. Six security principles are developed. These principles, together with certain important networking notions, are utilized to evolve a system level design of a secure localized system for electronic funds transfer. This design is then further defined in order to address the various problems involved when local systems are linked to form a national network. It is concluded that national standards are needed in order to prevent proliferation of incompatible local systems.

INTRODUCTION

As the computerization of bank functions continues its rapid advance, electronic funds transfer is becoming a reality. Independently developed local systems are evolving—but the emergence of a system national in scope is inevitable. Unless planning for security and for operation on a national scale begins now, development of an efficient and secure future system may be impossible.

We believe that a secure, national network for electronic funds transfer (EFTS) can be built with currently available technology. We do not suggest that the monumental task of interconnecting all the various financial institutions in the United States be undertaken, rather we contend that pilot EFTS networks being planned today could and should provide a high degree of security assurance. Furthermore, these pilot systems *could* be built so that as they inevitably grow, proliferate, and interconnect, they can be linked together to form a national network without major impact on either local system structure or local system security and privacy.

EFTS SECURITY PRINCIPLES

As a basis for this discussion of EFTS security principles, several basic assumptions must be made about EFTS schemata. These include:

1. All funds transfer transactions are initiated by a cardholder (possibly assisted by a teller or a merchant) at any of a variety of Point of Sale or Automated Teller devices. These devices are commonly referred to as Remote Service Units (RSUs). Although other transactions not involving a transfer of funds may be handled by an EFTS system, they are not addressed in this discussion to avoid distraction from the major issues addressed.
2. Each bank card has imprinted or recorded on it a personal account number (PAN), institution identification information, and other data such as the expiration date of the card. A cardholder initiating a transaction must supply a value not on the card. This value is called a Personal Identification Number (PIN). The PIN was conceived as an aid in verifying the identity of the user of the card (i.e., the PIN is a password).
3. All funds transfer transactions must be authorized. An authorization, or transaction approval, is based upon a verification of the cardholder's identity and an examination of his account. If the cardholder has supplied the appropriate PIN and if his balance or credit limit is sufficient to allow the transaction, then an authorization is generated. A Host Processing Center (HPC), the computer facility of a financial institution, will typically authorize transactions.
4. Financial institutions may require that the EFTS network provide backup support for the HPC authorization function. For instance, the network may have to provide an alternate site to perform transaction authorizations when the primary HPC is down. Similarly, the EFTS network may be required to log all transactions. These assumptions must be considered in the development of any EFTS network design.

Security Principle #1: The PIN should be known only by the cardholder

It is important to realize that the PIN is potentially a powerful tool for providing EFTS security, and apparently the only currently viable means for positive identification of the cardholder.

The authentication process is important since cards can easily fall into the wrong hands. Cards can, of course, be stolen or lost. Furthermore, any card which can be easily produced can also be easily forged. Electronic funds transfer will provide a powerful incentive to illegally produce and distribute fraudulent bank cards. The identity of cardholders must, therefore, be authenticated.

The PIN, therefore, plays a critical role in EFTS security, and PIN distribution must be carefully controlled. It has been suggested that PINs be stored at the computing facility of the cardholder's financial institution. It may also be desired to store PINs at the network's backup sites. Unfortunately, the greater the distribution of the PIN, the greater is the risk of illegitimate PIN acquisition. For example, if PINs are stored at the bank, they are potentially exposed to dishonest bank employees. And more distressing, if PINs are stored at a backup site, they are potentially exposed to personnel who may not even be under the control of the cardholder's bank.

Only the cardholder need know the PIN if, at the time of issue and within the network, it is transformed by a one-way process to create a unique new value, and if only the transformed version is used to authenticate cardholders. The new value could then be used for cardholder authentication, but the original PIN could not be determined from this new value. Thus, neither the HPC nor the backup sites have access to the original PIN. PIN transformation is discussed in more detail in the system level design portion of this paper.

Security Principle #2: There should be no way to derive the PIN from information on the card

The importance of PIN security to EFTS security is recognized in both the banking and the security communities. Oddly enough, however, many PIN schemes currently being discussed are based upon the notion of deriving the PIN from the information on the card (and primarily from the PAN). Such schemes do reduce the need for PIN storage in the system since PINs can simply be derived when needed, but such schemes risk PIN exposure.

Schemes in which the PIN can be derived from information on the card are inherently weak. Once the algorithm used to convert card information into PINs becomes exposed, any person who obtains the card must be assumed to have obtained the PIN as well. This observation has two important implications in generated PIN systems. First, the secrecy of the PIN depends entirely upon the secrecy of the algorithm used to generate the PIN. Second, the incentive for theft of an algorithm is high, since that algorithm is utilized to generate all PINs for a particular institution's cards. The means for determining such algorithms exists. The algorithms may be exposed by bank personnel who, by the nature of their jobs have access to it, or given sufficient cards with known PINs, it may be possible to synthesize the algorithm. Once the means of deriving PINs is known, production of apparently valid but unauthorized cards is a simple matter. The system level design section of this paper will describe a method of PIN verification which does not require that the PIN be derivable from information on the card.

A rough analogy may be drawn to the security problem of telephone credit accounts. Credit identification numbers are based on the account holder's telephone number, and the time lag between the development of new methods of deriving credit card numbers and the fraudulent use of them has always been short indeed. The potential rewards of defrauding an EFTS system are incalculably greater.

Security Principle #3: Exposure of PINs should be minimized during a transaction

This principle stresses once again the importance of the PIN in EFTS security. A transaction will involve many devices and probably more than one financial institution. PINs should, therefore, be transformed or otherwise protected at the earliest possible stage in the transaction.

Security Principle #4: Sensitive or private transaction data should not be subject to unauthorized exposure

During the course of a transaction, sensitive data passes through a variety of devices and may be transmitted over public communications lines. Not all EFTS devices may be "trustworthy." Communications lines can be easily tapped. Obviously any sensitive data such as the PIN should not be exposed unnecessarily. Furthermore, because privacy statutes are likely to be enacted in the near future, the network must exercise strict control over all personal information involved in transactions. The PAN, for example, may be regarded as private information and not all devices will need to have access to the PAN.

Security Principle #5: Transaction data should not be subject to unauthorized alteration

As transaction processing is performed, alteration of certain data could result in authorization of otherwise illegitimate transactions. For example, transactions may be diverted to the wrong institution or the amount of the transaction might be changed during a transaction, fooling the HPC into authorizing an improper transfer. Protection via an encrypted error detection field is a simple technique to prevent such unauthorized alteration. This technique is detailed later in this paper.

Security Principle #6: All transaction requests and transaction authorizations should be authenticated at their destination

RSUs, where all transaction requests originate, and HPCs, where processing of transactions occur, may be physically remote from one another. However, each must act on information received from the other. It is essential that the identity of the source of information be authenticated by the receiver of the information. An HPC must know that the request it receives actually comes from an RSU and not an outside source, such as a penetrator tapping onto the line. An RSU must know that a transaction authorization actually came from the appropriate HPC. Otherwise a physical transfer of funds or merchandise may occur when the necessary authorization was denied or simply did not take place.

An example will illustrate this point. A grocer rings up a bill for a customer's purchase. The customer wishes to use his card to pay the bill, and wishes to receive an additional $50.00 cash. The grocer enters the transaction request on his RSU and the customer inserts his card and enters his PIN. When the grocer receives an authorization on his RSU, he accepts the transfer as payment and gives the customer $50.00 in cash. A penetrator could have injected a false authorization message somewhere along the line. The grocer would then assume that his account has been credited in the amount of the cash disbursement plus the cost of the groceries, but the "authorization" is fraudulent and the grocer has been cheated. A direct, positive identification of the source of messages in the system must be incorporated to prevent such fraud.

SYSTEM LEVEL DESIGN

The six security principles may now be combined with basic intercomputer network concepts to formulate a general design for a local EFTS system. The following paragraphs describe a design that has the potential to provide a high degree of security assurance.

The design incorporates cryptographic devices. These devices encipher data (i.e., transform data in order to conceal its meaning) and decipher data (i.e., reverse the encipher process in order to render data once again intelligible). Proper use of cryptographic techniques can greatly enhance network security. However, in order to simplify presentation of the design, the system is first presented and analyzed without cryptographic devices. The cryptographic devices are then introduced and discussed in detail. It is important to note, though, that security is an integral part of the entire design.

An EFTS system configuration without cryptographic devices is illustrated in Figure 1. This structure includes four major types of devices or processors.

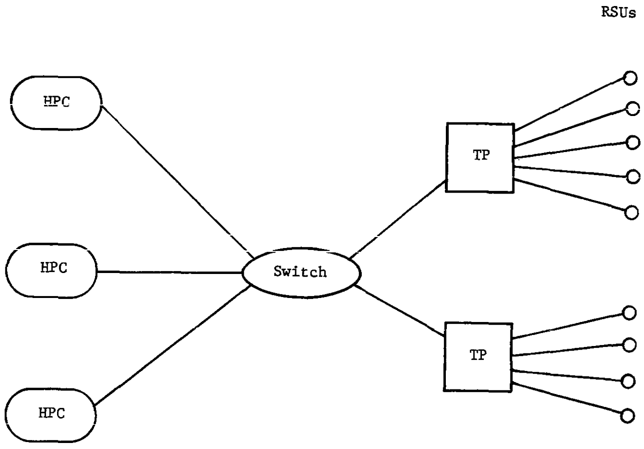

Figure 1—Local EFTS Network (without Cryptographic devices)

Two of these, RSUs and HPCs, were discussed previously. A third type of device, the transaction processor (TP), interfaces RSUs to the rest of the EFTS system, manages funds transfer requests initiated at RSUs, and performs the one-way PIN transformations. The fourth device type, the switch, interconnects HPCs and TPs.

An example (see Figure 2) may help to clarify the function of these devices and the relationship between them. Using the example of the customer at a grocery store, we will assume that the customer maintains his card account at institution X and that the grocer maintains his account at institution Y. The customer desires to use his card to pay his grocery bill of $35.00 and wishes to receive an additional $50.00 cash. The customer inserts his card into the RSU and enters his PIN. The grocer enters a request for a transfer of $85.00 (i.e., $35.00 for the groceries plus $50.00 for the cash the grocer will give the customer) from the customer's card account to the merchant's account. The RSU collects all this information and forwards it to the TP.

The transaction request is then received by the transaction processor. The TP isolates the customer's PIN from the transaction request and derives two new values, PIN′ and PIN″, by performing two successive transformations on the PIN. PIN″ is compared with a set of digits, called cryptographic check digits (CCDs), recorded on the customer's card. If PIN″ is not equal to the CCDs, the PIN is invalid. The funds transfer would not occur and a transaction denial would be sent to the grocer at the RSU. In this example we will assume that the CCDs and PIN″ are equivalent and that transaction processing continues.

The TP then sends a debit request message destined for HPC X, the computer facility of the institution at

RSU	TP	HPC X	HPC Y
1. Grocer enters transaction 2. Customer inserts card into RSU and enters his PIN 3. Transaction data is forwarded to TP	4. Transaction data is received from RSU 5. PIN' and PIN'' are generated 6. PIN'' is checked against CCDs 7. PIN'' check succeeds (If check fails, transaction is aborted at this point.) 8. Debit Approval Message is created and sent to HPC X	9. Debit Request Message is received from TP 10. PIN' is checked 11. PIN' check succeeds (If check fails, rejection is sent to TP and transaction is aborted at this point.) 12. Customer's account balance is checked for sufficiency. (If check fails, rejection is sent to TP and transaction is aborted at this point.)	
	15. Debit Approval Message is received from HPC X 16. Credit Message is created and sent to HPC Y,Transaction Approval Message is created and sent to RSU.	13. Customer's account balance is found sufficient and $85.00 (i.e., the transaction amount] is deducted. 14. Debit Approval Message is created and sent to TP.	
17'. Transaction Approval is received from TP 18'. Customer receives groceries and $50.00 in cash			17. Credit Message is received from TP 18. Grocer's account is credited with $85.00

Figure 2—An EFTS transaction

which the customer has his account. The debit message is addressed to HPC X and transmitted via the switch. It should be noted that the customer's PIN is not transmitted, instead PIN′ is sent along with additional transaction information.

Upon receiving the debit request, HPC X verifies that PIN′ correlates properly with the customer's PAN and that the customer's account balance is sufficient to cover the $85.00 request. If either test were to fail, the debit request would be denied and a debit refusal sent to the TP.

Assuming the debit is approved, HPC X records the debit request, reduces the customer's account balance by $85.00, addresses a debit authorization to the TP and transmits the authorization via the switch.

The TP sends two messages upon receiving the debit authorization. One message is sent to the grocer's RSU, indicating to the grocer that the funds transfer has been approved. The second message is a credit message sent to the HPC Y via the switch. At this point the transaction is completed.

The transaction scenario outlined above demonstrates some basic functions of an EFTS system. Several simplifying assumptions were made to clarify the presentation. Neither backup support for HPCs nor cryptographic devices were included, and logging of transaction data for auditing and accounting was not discussed. Furthermore, message acknowledgments and retransmissions were ignored. Each time a network message is transmitted, an explicit acknowledgment is expected. If an acknowledgment is not received promptly, the message should be retransmitted. Throughout this design presentation we will assume that an acknowledgment/retransmission mechanism exists where appropriate.

In the subsequent, detailed discussion of the local EFTS design, the issues of HPC backup, logging and auditing will be considered. The security of the EFTS system will be analyzed after the full presentation of the system level design.

The switch

The switch interconnects HPCs and TPs. The exact nature of the switch is of no concern here—any switch which is capable of carrying messages to a specified destination in a timely manner is acceptable. In a centralized system the switch may consist of a single message switching computer. On the other hand, the switch may consist of a geographically distributed network of message or packet switching mini-computers. The term "distributed networks" as used in this paper means those networks where messages, or pieces of messages—packets—are carried from source to destination by being relayed from one switching computer to another until the destination is reached. Currently such distributed networks can relay a message across the United States in less than one-half second.

The distributed approach (which is used in the ARPANET) offers many advantages over the centralized approach. Distributed networks have the potential to provide alternate message pathways when one of the switching centers fails. When a centralized switch fails, the entire EFTS system halts. Distributed approaches, besides having a great potential for reliability, may be designed to adaptively route traffic through the various communications paths in order to reduce communications delays.

Unfortunately, distributed systems are not necessarily the most cost effective approach for a local EFTS system. Distributed systems generally require a much higher initial investment than centralized systems. It should be noted, though, that either a centralized or a distributed switch can be incorporated into a local EFTS system without impacting other system components.

Host processing centers

Each HPC is the computer facility for a specific financial institution and as such is subject to the particular policies of that institution. A large and varied population of HPCs now exists. The manner in which accounts are maintained and PINs are handled will undoubtedly vary.

Each HPC must adhere to the message formats and protocols developed for the local EFTS system. All communication between HPCs and TPs must conform to these standards. For instance, HPCs will receive only transformed PINs. The precise manner in which transaction messages are generated, transaction data interpreted, and transformed PINs verified can be determined by each institution.

Functions may be desired in the EFTS system other than those illustrated in the simple transaction scenario presented above. For example, a facility to back up HPCs or to log data on all transactions is likely to be included in most EFTS system requirements. In this EFTS system design these functions are provided by one or more special-purpose HPCs (see Figure 3). The switch need not distinguish between such special-function HPCs and transaction HPCs.

Only TPs and HPCs need to recognize the functions of these special HPCs. It is expected that a TP would transmit a message to the logging HPC at the start and end of each transaction. Similarly, the debit and credit HPCs would transmit log messages to the logging HPC each time they either authorize or refuse a request.

Whenever a primary HPC is not operating, it is expected that TPs would interact with a backup HPC. The backup HPC would partially determine the validity of debit requests based upon information collected from HPCs when they are operating. Transaction information would be stored at the backup HPC until the primary HPC is again operating.

Transaction processor

The TP manages all transactions in the EFTS system. The TP interprets each transaction request received from an RSU. A set of actions is associated with each type of transaction. These actions include a sequence of messages to be sent to HPCs and the RSU initiating the request.

The TP must determine to whom the various transaction messages should be sent. Thus the TP must maintain tables indicating where messages should be routed.

The TP manipulates PINs. Upon receiving a transaction request, the TP creates two transformed PINs, PIN′ and PIN″. Both transformations should be PIN

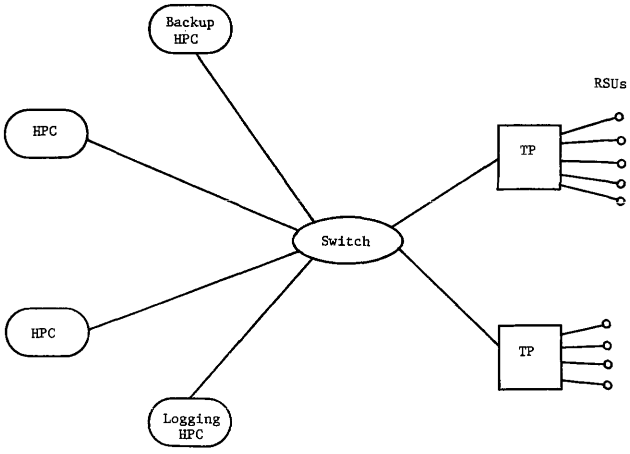

Figure 3—Local EFTS network with special-purpose HPCs

dependent (i.e., they should vary with the value of the PIN) and should be resistant to attempts to determine original PINs from transformed values.

Transformations of this type can be performed in many ways. One such technique employs the NBS standard algorithm for data encryption. This algorithm has two inputs, a text string and a key. The output is a scrambled version of the input text string. The algorithm has the desirable property that even if both a sample input text string and the output are known, the key can only be determined by testing all 76×10^{15} possible keys. (This protects future cyphers from sophisticated penetration attacks.)

The transformation process is illustrated in Figure 4. In this method the PAN is the first text input to the NBS algorithm and the PIN is the key input. The output of the first application of the algorithm is PIN.′ PIN′ is then input to the algorithm as the text and a predetermined but secret value is input as the key. The resulting output is PIN″. Thus both PIN′ and the "secret value" must be known to determine PIN″ and both the PIN and the PAN must be known to determine PIN′. The important security implications of this approach are discussed later.

Cryptographic devices

Two types of cryptographic devices are included in the EFTS system design. These devices are referred to as Network Cryptographic Devices (NCDs) and Serial Cryptographic Devices (SCDs). An EFTS network incorporating cryptographic devices is illustrated in Figures 5 and 6.

The National Bureau of Standards (NBS) Data Encryption Algorithm should be utilized in the SCDs and NCDs. The algorithm has many desirable features for use in such devices (see Reference 1). Furthermore, it is rapidly being accepted as a standard for use in EFTS networks.

SCDs are similar to standard cryptographic devices now available. An SCD protects a single telecommunications line. Multiplexed SCDs can simultaneously handle several such lines. NCDs, on the other hand, are quite unlike anything now produced. NCDs maintain a fully interconnected network. By using a unique key, each NCD can protect the communications path to any other NCD in the network. This technique is described in the following section. It is assumed that an automatic key update mechanism in the NCDs and SCDs changes keys after a given amount of use.

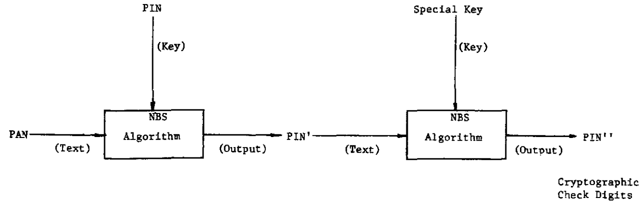

Figure 4—PIN transformation using National Bureau of Standards data encryption algorithm

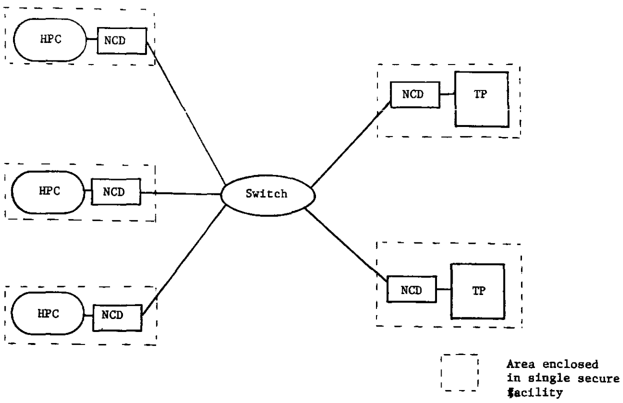

Figure 5—Portion of EFTS network with cryptographic devices

EFTS SYSTEM SECURITY ANALYSIS

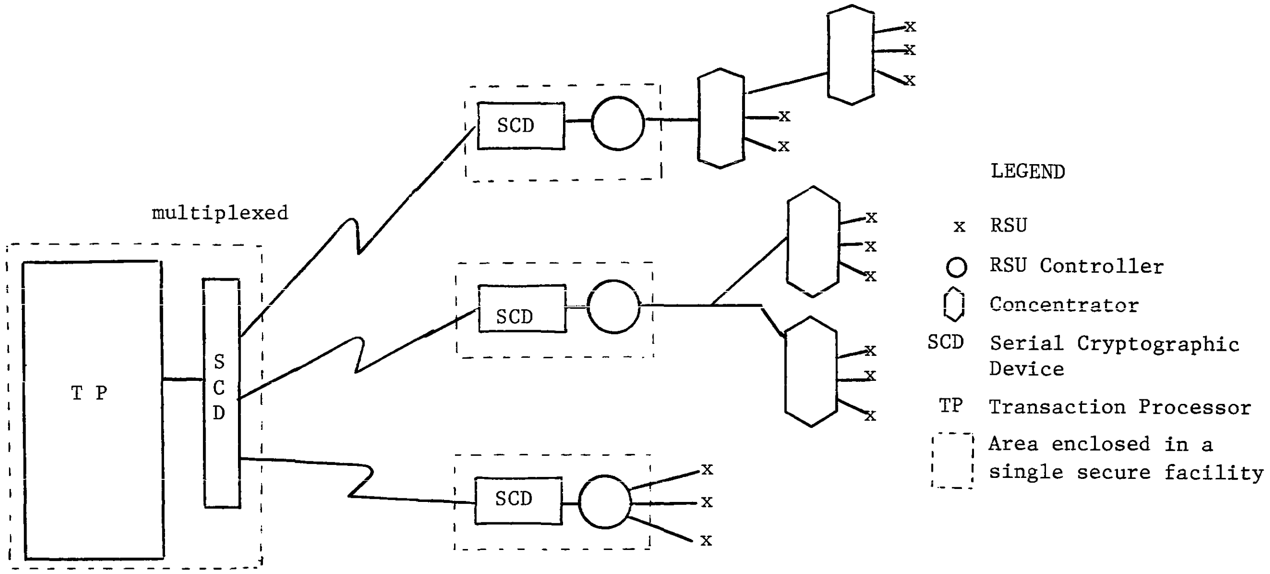
The EFTS system described above should provide substantial security assurance. The following few paragraphs analyze the system's security based upon the six EFTS security principles previously presented.

Security Principle #1: The PIN should be known only by the cardholder

In the system presented above, the PIN is not stored anywhere in the system. All processing beyond the TP is based upon transformed versions of the PIN. HPCs perform authorization checks on transformed PINs only and it is virtually impossible to derive the actual PIN from the transformed PIN.

Security Principle #2: There should be no way to derive the PIN from information on the card

This principle can simply be restated as a system requirement. There is certainly no need in the system presented in this paper to generate PINs from information on the card. The use of cryptographic check digits derived *from* the PIN illustrates that the PIN can be verified without being implicitly exposed on the card.



As shown above, RSUs are not directly connected to TPs or SCDs. RSUs are directly connected to an RSU controller. Several RSUs may be attached to a single controller. This may be accomplished by concentrators, multidrop lines, etc. Communications security between RSU controllers and RSUs is, of necessity, the responsibility of the RSU manufacturer.

Figure 6—Transaction processor—RSU portion of EFTS network

Security Principle #3: Exposure of PINs should be minimized during a transmission

PINs entered at RSUs are in the clear until enciphered by SCDs. PINs are again exposed in TPs. Thereafter, PINs are discarded and only transformed PINS are utilized.

If PINs were transformed at the RSU, only transformed PINs would appear in the network. Unfortunately, many RSUs already exist and none perform the transformation described in the system design. Exposure of the PIN can be reduced further if new RSUs adopt the transformation design proposed herein.

Security Principle #4: Sensitive or private transaction data should not be subject to unauthorized exposure

When data is enciphered, it is considered safe from exposure. Thus, sensitive or private transaction data is safe as it flows between SCDs and as it flows between NCDs. There is, however, a potential weak link between RSUs and their controller. Because RSUs and RSU controllers are built to operate as an integrated unit, the burden of providing communication security between these devices must fall on the manufacturers. Manufacturers should be required to provide this security.

Data is necessarily in clear (non-enciphered) form while in RSUs, RSU controllers, TPs, and HPCs. Consequently these devices will require procedural and physical protection.

Security Principle #5: Transaction data should not be subject to unauthorized alteration

Cryptographic techniques can be used in conjunction with error detection techniques to prevent unauthorized alteration of transaction data. An error detection field is calculated on each message and appended to the message before it is enciphered. Encipherment of data based on the National Bureau of Standards encryption algorithm makes it virtually impossible to alter enciphered data with predictable impact on the data once it is deciphered. Thus, when a message is deciphered and the error detection field recalculated and compared to the value in the message, it is extremely unlikely that any changes made to the enciphered message will not be detected. This technique does not directly prevent unauthorized alteration. It does, however, eliminate any threat due to such alteration since virtually all unauthorized changes to messages can be easily detected. If encipherment is coupled with a procedure for retransmitting messages, incentive for altering data without authorization is eliminated. Thus, SCDs and NCDs combined with appropriate protection of the RSU-RSU controller link prevent unauthorized alteration of transaction data.

Security Principle #6: All transaction requests and transaction authorizations should be authenticated at their destination

NCDs are utilized in this design to authenticate the source of HPC and TP messages. Encipherment and decipherment of messages by NCDs is based upon secret values called keys. An NCD cannot decipher a message unless it knows the key used to encipher the message.

Each NCD will maintain a unique key for communicating with each of the other NCDs in the system. Thus, if TP_1 attached to NCD_1 sends a message to HPC_2 attached to NCD_2, the key used by NCD_1 to encipher the message is known only by NCD_1 and NCD_2. When NCD_2 receives the message, NCD_2 can be assured that the message came from NCD_1. The source of the message which arrives at HPC_2 must therefore be TP_1.

Similarly, SCDs will maintain pairwise-unique keys. This technique provides a means for mutual authentication of TPs and RSU controllers. RSU controllers should be required to have a mechanism for authenticating messages sent between RSU controllers and RSUs. However, RSU to RSU-controller communications are the domain of the manufacturers of these devices.

In this system PINs are known only by cardholders and during a transaction are in the clear only in the TP. A transaction can only be initiated at an RSU since the various cryptographic devices prevent unauthorized insertion of messages into the system. Thus the PIN must be known to initiate a transaction and only a legitimate cardholder can initiate a transaction.

A NATIONAL SYSTEM

The local EFTS system previously described conforms to the six EFTS security principles. That system would provide a high degree of security assurance. By linking several of these local systems it is possible to create a secure national EFTS network. Such a national EFTS network design is illustrated in Figures 7 and 8.

Three major components—a nationwide message switching network, gateways, and NCDs—are needed to link the local systems. The nationwide message switching network carries messages between the local systems. NCDs (like NCDs in the local system) protect messages which flow through the nationwide message switching network. Gateways interface local EFTS systems to the message switching network.

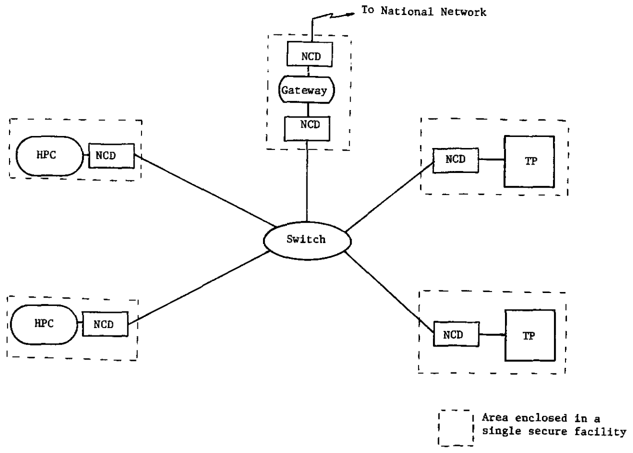


Figure 7—Local EFTS system attached to national network

An example may clarify the function of these internetwork devices. We will assume that TP_1 finds it necessary to send a debit request to HPC_2. We further assume that TP_1 and HPC_2 are not in the same local system.

TP_1, recognizing that HPC_2 is not local, generates a debit request message addressed to HPC_2. That request is enclosed in a message addressed to a local gateway, G_3. The message is transmitted, via the local switch, to G_3. G_3 receives the message and extracts the debit request. The gateway inspects the debit request to determine which local system contains HPC_2. G_3 then encloses the debit request in an inter-

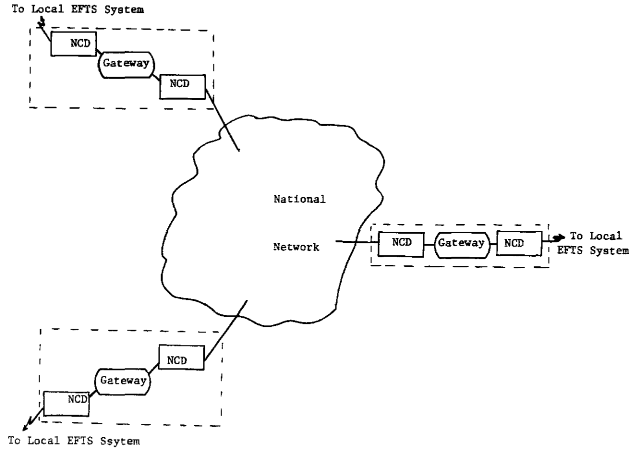

Figure 8—A national EFTS network

network message. The internetwork message is addressed to a gateway, G_4, which is part of the same local system as HPC_2.

The internetwork message, cryptographically protected by NCDs, is routed by the nationwide message switching system to G_4. G_4 receives the internetwork message and extracts the debit request. G_4 then routes the debit request to HPC_2 via the local switch. The resulting debit authorization or denial follows the reverse path from HPC_2 to TP_1.

The national network

Like the local system's switch, the nationwide message switching network may take many forms. Any network capable of carrying messages between gateways in a timely manner is acceptable. The national networks will span large distances and, when compared to local switches, will carry a relatively light EFTS message load. Hence, a distributed shared, public network seems appropriate. Because NCDs protect messages sent through the national network, it is possible to utilize a commercial, value-added network.

Gateways.

A TP views a gateway as a special HPC which represents all HPCs not found in the local system. An HPC views a gateway as a special TP.

The national system design presented above assumed that the local systems to be linked were identical. Unfortunately, such standardization is unlikely. Where little commonality exists between local systems, a national system will be effectively precluded. If the only differences are message formats, gateways can be used to translate the message formats utilized by different local systems. It cannot be stated too strongly—a national EFTS system requires standardization of at least transaction protocols and message information content.

To simplify the format translation task, all messages travelling through the national network will conform to a single, standard protocol and format. If a local system does not conform to the national standard, the gateway to that system must translate messages to and from the national standard. In this way neither HPCs nor TPs are impacted by the differences between the local system and the national system. However, it must be reiterated that gateways can only reformat messages. In all other respects (protocol and information content) local messages must conform to the national standard. The more the local system resembles the national standard, the less complex the gateway becomes.

Security analysis of the national system

The extent to which the national system design adheres to the six EFTS security principles is presented in a two part analysis. First, the protection of the PIN is examined. Second, the protection of transaction communications is examined.

A national network can be built in which all PINs are handled in the same manner as described earlier whether the transaction occurs totally within the local system or whether other local systems are involved. If the national network is built in that way, security principles #1, #2, and #3 are satisfied by the national system design just as they were in the local system design. If, in some local systems a non-standard PIN transformation is used, or if the PIN is not transformed at all, PINs may be exposed. Furthermore, nonstandard PIN handling mechanisms may require ad hoc processing in gateways. Such ad hoc mechanisms would increase cost and decrease security, integrity, and reliability.

The extent to which EFTS security principles #4, #5, and #6 are followed depends entirely upon the local systems. If a local system is built according to the design presented in this paper, then messages are not subject to unauthorized alteration or exposure until they enter a local system not adhering to the security principles. This result occurs because the NCDs of the national system protect against unauthorized exposure and alteration of messages sent between gateways. Furthermore, because the NCDs of the national network prevent misdelivery, a gateway may trust that a message it receives actually originated in the remote local network from which that message appears to have come. If both the source and destination local systems adhere to the security principles, then mutual authentication of the ultimate source and destination of a message is possible.

CONCLUSION

Security must be an integral part of any EFTS system design. Adherence to the six EFTS security principles will provide a high degree of system security. Through the proper use of the NBS algorithm, a system for local electronic funds transfer can be built which conforms to these guidelines for handling PINs and transaction data. Although the devices to implement such systems may not be currently available, the technology to build these devices does exist.

National systems for electronic funds transfer can be created by linking local systems. It is necessary, however, that the local systems be designed to operate as part of a national system—effective and secure after-the-fact linking of heterogeneous local systems may be virtually impossible. National standards *must* be developed to permit interconnection of local systems and to insure a high level of security.

Design considerations for electronic funds transfer switch system development

by JOSEPH P. MAZZETTI
Technology Management Incorporated
Washington, D.C.

ABSTRACT

This paper reviews the EFTS switch concept and outlines some of the major design considerations involved in its implementation. The EFTS switch permits financial institutions to share customer terminal devices (for example, point-of-sale terminals in a supermarket) by transmitting messages generated at the terminal to the financial institutions holding the customer (and merchant) account. The switch, in addition to message routing, must maintain information for settlement among the financial institutions involved, and generate accounting, audit trial and operational reports. Specifically addressed in the paper are: the financial transactions and terminal devices involved; switch message processing and accounting functions; hardware, software, and network components and alternatives; and security and backup considerations. The material presented is based on EFTS project work performed by Technology Management Incorporated (TMI) for the Federal Home Loan Bank System.

INTRODUCTION

An Electronic Funds Transfer System involving shared terminals *—for example, financial institutions sharing point-of-sale devices in a supermarket or an automated teller machine in a shopping center—requires a computerized switch to route messages from a given device to the computer system (host computer) servicing a particular financial institution. A typical switch configuration servicing two institutions is shown in Figure 1. In addition to message routing, the EFTS switch is designed to generate information for interinstitutional settlement and to maintain accounting and audit trials.

The EFTS switch design emphasizes throughput performance while at the same time providing a high degree of message protection and system integrity. Further, a switch must be capable of handling a multiplicity of host computers with different operating characteristics, have the capability of dealing with varied terminal types, and communicate with other switch networks.

The EFTS switch will be a key element in the future of Electronic Funds Transfer because neither the public nor the merchant community will tolerate a profusion of competing terminals and because of the higher costs associated with independent facilities. The technology for switch development is well within the current state-of-the-art; what remains is the application of that technology to real-world situations. Further, a number of alternative switch and network design approaches exist providing EFTS planners in a given area the ability to configure the switch(es) which best meets the geographical, demographic, and market demand characteristics of that area.

This paper treats basic switch concepts and outlines

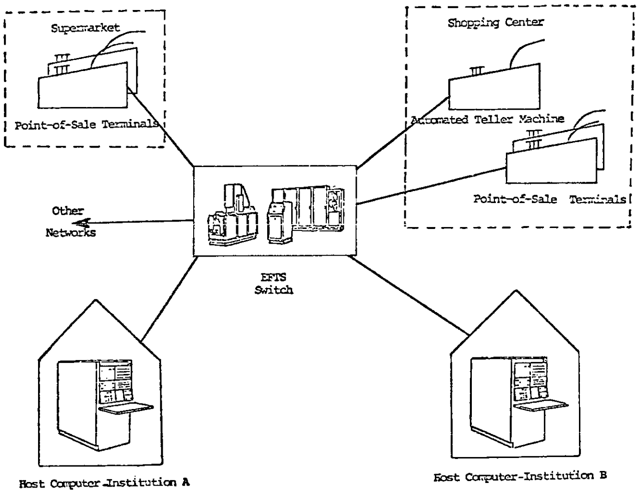

Figure 1—EFTS switch overview

* Commonly called Customer Bank Communications Terminals (CBCTs) by commercial banks or Remote Service Units (RSUs) by thrift institutions.

the major design considerations involved in switch development. It is based on EFTS project work performed by Technology Management Incorporated (TMI) for the Federal Home Loan Bank System.

OPERATIONAL CONCEPT

A range of plastic card transactions initiated by depositors will be processed by the switch, including:

- *cash withdrawal*—direct withdrawal from a checking or savings account;
- *check cashing/guarantee*—placing a "hold" on the customer's account in the amount of the transaction;
- *deposit*—placing funds on deposit to a customer's account;
- *funds transfer*—transfer of funds from one account to another;
- *payments*—direct submission of cash or check for loan payment (e.g., mortgage loan); and
- *balance inquiry*—determining the existing balance in an account.

Other switch-based services could include: interface with Automatic Clearing Houses (ACH); interconnection with Credit and Debit card networks; possible linkage with the FEDWIRE, BANKWIRE, and other networks; and other depositor-based services.

These transactions are generated from several types of terminal devices as shown in Figure 2, including automated teller machines and merchant-operated terminals. The automated teller machines (ATMs) dispense cash, accept deposits, accept payments, and transfer funds between customer accounts, and are activated by a combination of a plastic card and push buttons. They typically limit the total number of withdrawals a customer can make through controls built into the system (on-line operations) and on the customer's plastic card (off-line operations). The merchant-operated terminals are those devices normally operated by merchant personnel in a business establishment such as a supermarket or retail store. They are of two general types:

- point-of-sale terminals used to collect sales, inventory, and other data about a sales transaction in addition to performing some financial transactions. These include: Electronic Cash Registers (ECR) and Point-of-Sale (POS) terminals; and
- terminals located in a business establishment for the sole purpose of performing financial transactions (deposits, withdrawals, etc.). These are often called point-of-business terminals.

These terminals usually include the following components: plastic card, magnetic stripe reader; numeric keyboard and function keys; display; printer or imprinter; journal tape unit (ECR); and usually a terminal controller to service multiple devices.

The flow of data for a typical transaction is shown in Figure 3. In this example, a customer makes a cash withdrawal at a supermarket; the customer's and merchant's accounts are maintained at different financial institutions.

The customer submits his plastic card to the financial service window at the supermarket. The clerk enters the customer's plastic card along with merchant data (either by a second plastic card or key entry). The customer enters his Personal Identification Number (PIN) through a separate numeric key pad. The transaction data is then transmitted to the switch

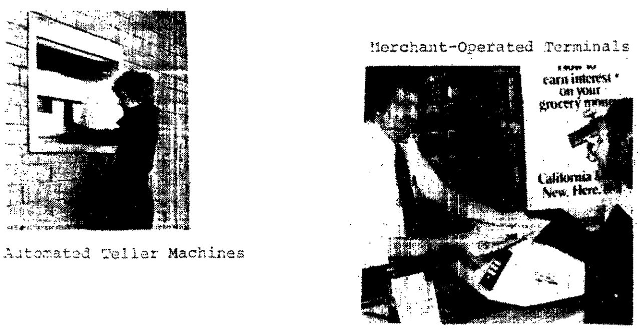

Figure 2—Terminal device types

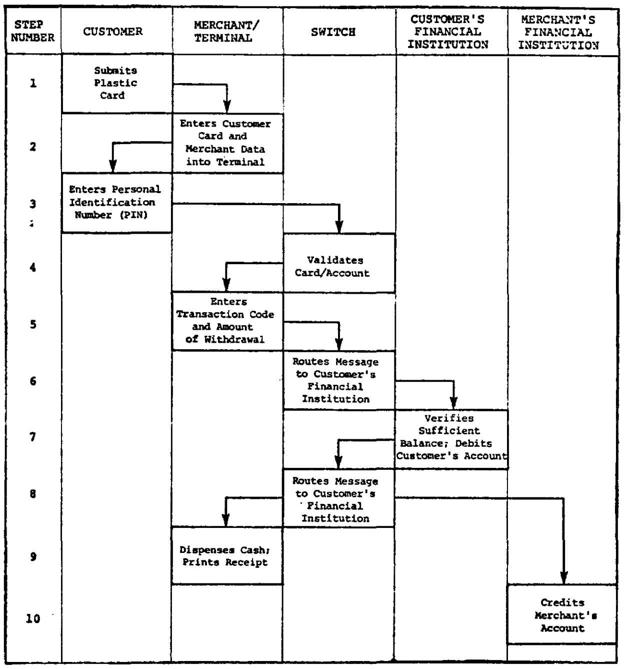


STEP NUMBER	CUSTOMER	MERCHANT/ TERMINAL	SWITCH	CUSTOMER'S FINANCIAL INSTITUTION	MERCHANT'S FINANCIAL INSTITUTION
1	Submits Plastic Card				
2		Enters Customer Card and Merchant Data into Terminal			
3	Enters Personal Identification Number (PIN)				
4			Validates Card/Account		
5		Enters Transaction Code and Amount of Withdrawal			
6			Routes Message to Customer's Financial Institution		
7				Verifies Sufficient Balance; Debits Customer's Account	
8			Routes Message to Customer's Financial Institution		
9		Dispenses Cash; Prints Receipt			
10					Credits Merchant's Account

Figure 3—Transaction data flow-cash withdrawal

where card and account validation and security is performed through algorithmic procedures and reference to a negative file containing stolen or counterfeit card information. Assuming the validation checks are passed, an acknowledgement is sent back to the terminal. The clerk enters the transaction code and the amount, and the message is then transmitted to the switch. The switch routes the message to the customer's financial institution processor which verifies that a sufficient balance exists to cover the withdrawal and debits the customer's account. A positive acknowledgement of the action is sent to the switch which, in turn, transmits the acknowledgement to the terminal (where a receipt is printed) and also transmits a message to the merchant's financial institution processor where the merchant's account is credited.

The processing performed in each of these steps in the case of a cash withdrawal transaction may vary in alternative switch designs, depending on the division of functions between the switch and financial institution processors.

MAJOR DESIGN CONSIDERATIONS

This section describes in some detail the major design considerations involved in EFTS switch development, including: switch functions, hardware and software components, network alternatives for terminal support and degree of centralization, backup, security, and message standardization.

Switch functions

The EFTS switch must be designed with maximum emphasis on throughput performance (i.e., low message residency time as in an inquiry/response communications network) and also on the ability to provide a high level of system integrity and message protection as can be found in a store-and-forward message processing system. General switch design considerations include:

- ability to support the processing of plastic card-based financial transactions described above;
- ability to provide interconnection with a variety of host processors and terminal devices;
- modular system architecture to accommodate evolutionary transaction volume growth so that no major structural changes are required as greater levels of volume are reached;
- flexible hardware and software design to permit new terminal devices to be added in the future; and
- a high degree of system reliability.

The specific functions to be performed by the switch are listed in Figure 4 and discussed below.

- MESSAGE PROCESSING
- SETTLEMENT
- REPORT GENERATION
- AUDIT TRAIL MAINTENANCE

Figure 4—Switch functions

Message processing

The elements of common processing for each transaction message include:

- *message receipt*—receipt of messages transmitted from terminals and terminal subsystems (i.e., controllers and concentrators), host processors, and other switches;
- *message validation*—verification of the format and content of the message received;
- *account verification and security*—verification of customer and merchant account numbers;
- *message logging*—writing of all messages processed by the switch to a historical file (usually magnetic tape) for audit trail purposes;
- *settlement*—posting accounting data to an interinstitutional settlement file;
- *message reformatting*—reformatting of message as necessary to achieve the appropriate terminal/host processor interface; and
- *routing*—directing the output message to the appropriate endpoint.

Settlement

The settlement process provides for transferring funds between financial institutions to cover the value of interinstitutional transactions originated by the customers of those institutions. This is normally accomplished by moving the funds between the clearing accounts held by a common financial intermediary such as a Federal Reserve Bank or a commercial bank.

Settlement can be handled in a number of ways, depending primarily on the relationship between the entity that operates the switch facility and the financial intermediary which holds the clearing accounts. If the switch is operated by the financial intermediary which holds the clearing accounts, a continuous clearing process can be implemented. This allows instantaneous clearing, and each transfer can be applied, as it occurs, to the clearing accounts of both the sending and receiving institutions. Periodic cutoffs could provide for reporting, reconciliation, and analysis.

In circumstances where continuous settlement is impractical or impossible, batch settlement can be used. This involves the accumulation of transaction data between cutoffs for subsequent posting to a clearing account. A single settlement entry can then be made for each participating institution. That entry represents the net of all deposits and withdrawals initiated by that institution's cardholders through its own terminals.

Regardless of the settlement process used, the switch operation will have to provide detailed transaction reports to enable the participating institutions to reconcile their settlement accounts.

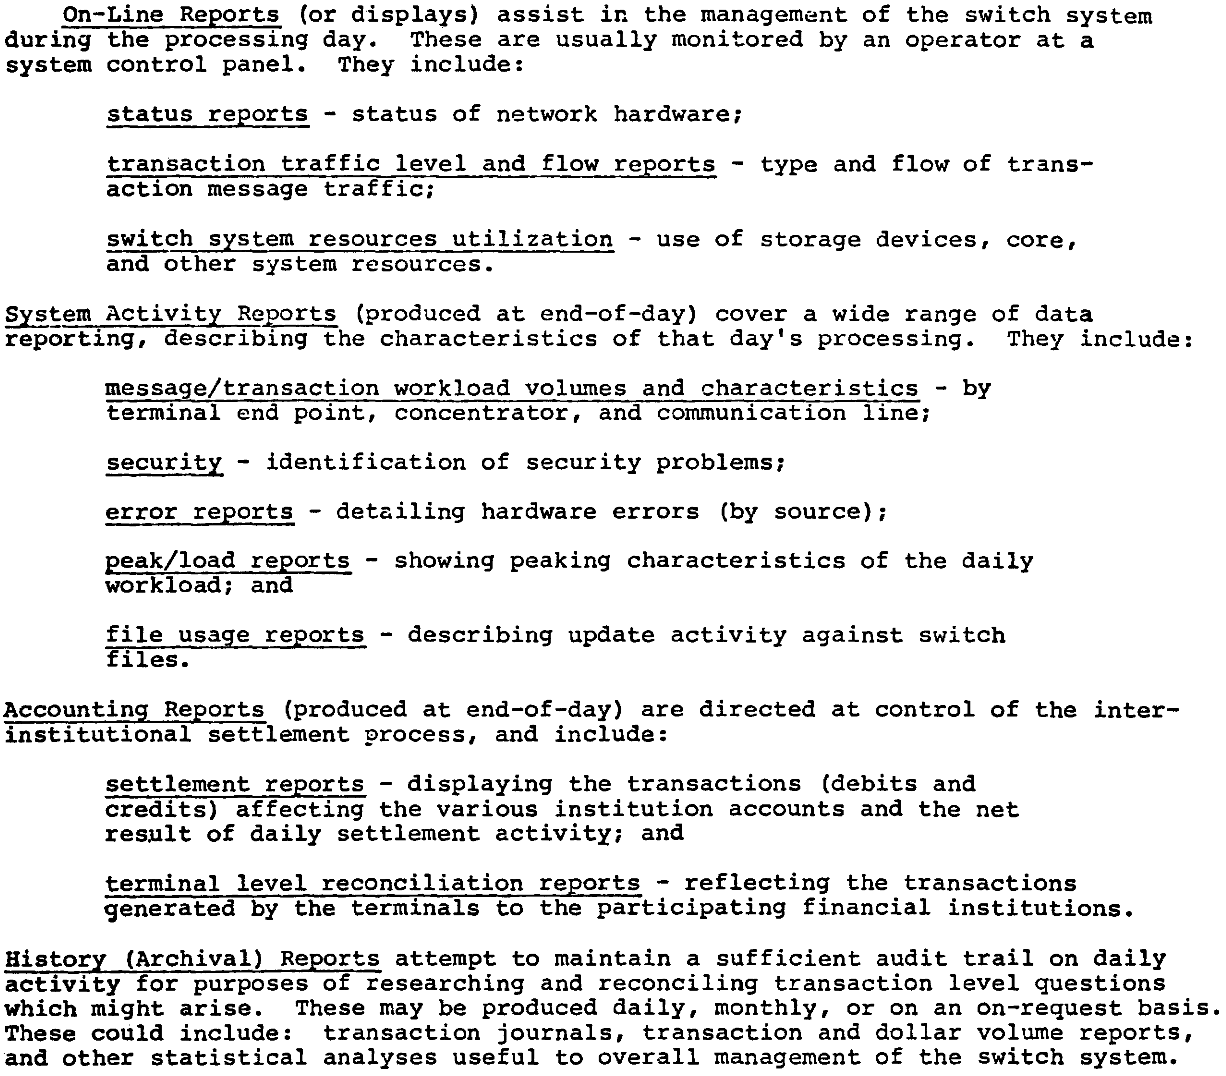
In addition to accomplishing the settlement function, the switch should provide on-line availability of net position data (among institutions) which is a continually updated balance or a beginning balance and net debits and credits. Warning levels can be established at which an institution would be notified of a need to transfer additional funds into the clearing account.

Report generation

The switch must provide data for the production of reports of four types: on-line reports, system activity reports, accounting reports, and history reports. Definitions of these reports are given in Figure 5.

Audit trail maintenance

In order to ensure the ability to restore system operation following an outage, identify patterns of terminal or network use for possible security violations, and assist in reconciliation of switch/host processor/ter-



On-Line Reports (or displays) assist in the management of the switch system during the processing day. These are usually monitored by an operator at a system control panel. They include:

status reports - status of network hardware;

transaction traffic level and flow reports - type and flow of transaction message traffic;

switch system resources utilization - use of storage devices, core, and other system resources.

System Activity Reports (produced at end-of-day) cover a wide range of data reporting, describing the characteristics of that day's processing. They include:

message/transaction workload volumes and characteristics - by terminal end point, concentrator, and communication line;

security - identification of security problems;

error reports - detailing hardware errors (by source);

peak/load reports - showing peaking characteristics of the daily workload; and

file usage reports - describing update activity against switch files.

Accounting Reports (produced at end-of-day) are directed at control of the inter-institutional settlement process, and include:

settlement reports - displaying the transactions (debits and credits) affecting the various institution accounts and the net result of daily settlement activity; and

terminal level reconciliation reports - reflecting the transactions generated by the terminals to the participating financial institutions.

History (Archival) Reports attempt to maintain a sufficient audit trail on daily activity for purposes of researching and reconciling transaction level questions which might arise. These may be produced daily, monthly, or on an on-request basis. These could include: transaction journals, transaction and dollar volume reports, and other statistical analyses useful to overall management of the switch system.

Figure 5—Switch reports

minal interactions, an audit trail must be maintained of each transaction processed by the switch.

All messages received by the switch must be recorded on magnetic tape or some other suitable device. The tape record should include—in addition to the incoming data—a time and date stamp, a sequential reference number, and the identification of the line and terminal or other device from which the data originated. In addition, the record should contain information relating to the disposition of the transaction, such as routing, format revisions, and error codes.

These transaction records will have to be retained for a period of time commensurate with the need for reprocessing, trouble-shooting, and analysis relating to system integrity and security matters.

The hardcopy could be in the form of microfilm, microfiche, printed listings, or another suitable media.

Hardware and software components

The major hardware and software components required for EFTS switch operation are described below. The mix of components will differ for each switch installation based on functions to be performed, transaction workload and performance requirements.

Hardware components will include:

- *Processors*—Several classes of computers could feasibly be used in the switch configuration, including microprocessors, minicomputers, and medium-scale processors. The medium-scale processors would have the capability to perform other financial processing functions, together with the switch functions (integrated switch). For purposes of switch reliability, multiple processors are suggested.
- *Processor Memory*—The range of processor memory sizes will vary according to the class of processor used and the functions to be performed by the switch.
- *Communications Adapters*—These are utilized for communications line control and multiplexing.
- *Input/Output Controllers and Peripheral Devices*—The specific components necessary for switch configurations include:
    - tape drives—for transaction audit log and interfacing with other outside systems;
    - disk—for program storage, switch file residence, and working storage for message processing operations;
    - printer—for production of accounting and activity reports;
    - system console—display-type device for monitoring system operations; and
    - communication "front-ends"—for network control and message handling.

All software required for the EFTS switch can be categorized as either environmental software or applications programs. Environmental software is the manufacturer-supplied packages, including:

- *Operating System*—supports the effective, shared utilization of system hardware and software resources;
- *Transaction/Message Handling Software*—supports communication of messages from terminal to computer, computer to terminal, and from one computer to another;
- *Network Support Software*—descriptive, table-driven language used by a communications processor in controlling network configuration and operation;
- *File Maintenance Software*—provides data base access and update capability;
- *Recovery Software*—provides an automated means for re-establishing operations in the event of system failure (e.g., transmit messages previously received but not yet forwarded); and
- *System Utilities*—includes language processors, data manipulation routines, and other system support software.

The application programs are usually unique to a given switch situation and include those needed to perform the functions described earlier, i.e., message processing, settlement, report generation, and audit trail maintenance.

Network alternatives—terminal support

Several network configurations are possible to provide terminal support for the EFTS switch. Switch performance, economics of operation, initial development cost, maintenance costs, minimization of the number of communication lines and distance, and other factors should be considered in determining the most appropriate configuration in any given situation. Three possible alternatives are depicted in Figure 6 and are discussed below.

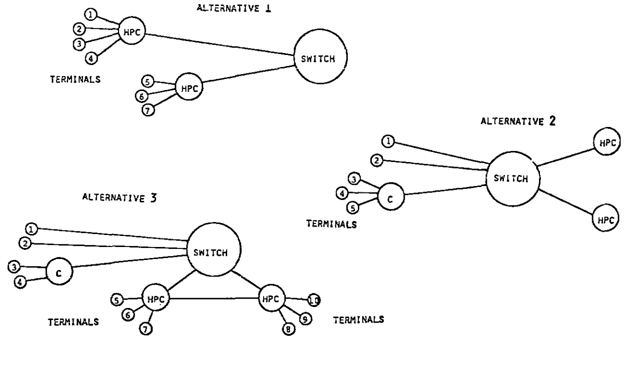


Figure 6—Network alternatives—Terminal support

- *Alternative 1—Computer/Computer Switch*—This approach would require that *all* terminals be connected to host processing centers with those host processors, in turn, connected to the EFTS switch. The host processors would have the responsibility for terminal and network control functions, including: communication line disciplines, error recovery, polling and addressing, and message format translation. Messages would be presented to the switch in a standard format.
- *Alternative 2—Terminal/Computer Switch*—This approach is at the opposite extreme from Alternative 1 requiring that *all* terminals be connected either directly or through a series of concentrators to the switch, and through the switch to the host processing centers. The switch, of course, would also handle interinstitutional settlement. In this case, the switch has complete terminal and network control including message formats, interface specifications, and network configurations.
- *Alternative 3—"Hybrid" Approach*—This approach would provide for:
  - Some terminals connected directly to the switch;
  - Some terminals connected to host processing centers and the host processing centers connected to the switch; and
  - Some computer centers connected directly to each other over high-speed lines (by-passing the switch for certain types of message traffic).

In the short term, Alternative 1 appears to be the most expedient because it reduces the complexity of interfacing various terminal devices (and related standard setting) and reduces the *switch* software and communications costs involved. Alternative 2 presents, in the longer term, the most likely point of evolution because it provides the centralized control and flexibility needed for network expansion. With Alternative 3, several key control questions exist relating to the integrity of the network in the event of failure.

Network alternatives—centralized vs. distributed switch

Figure 7 presents two alternative network design philosophies which are applicable: the centralized switch and the distributed switch.

- The *centralized switch* approach uses one or more computers as the heart of the network processing all transactions. For network configuration (a), transactions generated at terminals are transmitted to the switch and routed by the switch to the appropriate host processing center (and settlement accounting is performed).

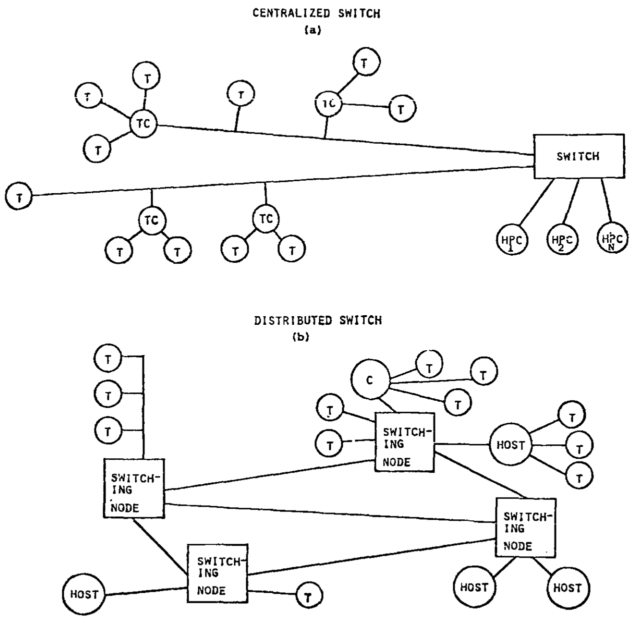

Figure 7—Network alternatives—Centralized vs. distributed switch

- In the *distributed switch* (b), each switching node is designed to be self-contained, operating independently of the other nodes in the network. Normally, at least two communication paths are possible to reach each switch node. Further, if the network is constructed such that specific endpoints (such as a host processor) have connections to two nodes (primary and backup), the functions of that endpoint would be available in the event of failure of a given node.

Backup considerations

The reliability of the switch network depends largely on the switch design itself. For most switch applications, the need for multiple processors is indicated. For the centralized switch, several backup approaches are possible as discussed below for a two processor example:

- *Foreground/Background Processors*—There are two processors; one CPU operates on-line performing all switch functions, while a backup CPU (with access to all peripheral devices) is available to perform off-line functions until the foreground processor goes down.
- *Load Sharing*—There are two processors, each of which services half of the network workload under normal conditions. In the event that one pro-

cessor fails, the second processor takes over its workload.
- *Hot Standby*—There are two processors; each processor is capable of supporting the network workload and processes each transaction separately. In the event that the main processor fails, the standby computer takes over network operation.

The distributed switch network contains inherent backup in that the overall workload is segmented; thus, only a portion is vulnerable at any particular time. Further, alternate transaction routing among nodes in the network also increases the network reliability.

Another factor affecting the reliability and integrity of the switch is the segregation (physical and logical) of switch functions. This segregation is possible at several levels:

- *Software Segmentation*—Use of modular software design to maintain the processing integrity of each of the functional segments described earlier;
- *Separate Processors*—Use of dedicated processors to perform one or more of the functions indicated; and
- *Sharing*—Assignment of one or more processors in the network to perform given functions; e.g., assigning a host processor to maintain all settlement information.

This segregation can affect the operational efficiency of the switch, its reliability, and its ability to recover in the event of an outage.

Switch security

The process of transferring funds between customer accounts and from one financial institution to another via depositor-activated or merchant-operated terminals is susceptible to many types of fraud. Switch designers must build security protection into the basic design. Figure 8 highlights some of the major areas of "vulnerability". Examples of possible fraud are: counterfeit, changed or duplicated cards; wire tapping; tampering with terminal devices; adjusting switch or HPC programs; modification of switch or HPC files.

Commonly considered approaches to achieving adequate security include:

- rendering the card counterfeit-proof and tamperproof by embedding various materials on or within the card during manufacture;
- encrypting procedures, such as enciphering the characters on the magnetic stripe, and enciphering all file data;
- physical security procedures for switch and host processing center facilities; and
- systems for signature verification, voiceprint, and fingerprint identification.

- PLASTIC CARD

- MAN-MACHINE INTERFACE
- COMMUNICATIONS INTERFACE
- SWITCH SOFTWARE
- SWITCH FILES
- SWITCH PERSONNEL AND FACILITIES
- HOST PROCESSOR (FILES, PROGRAMS, PERSONNEL, FACILITIES)

Figure 8—Security considerations

Message standardization

The issue of message standardization has a direct bearing on the cost of development and on-going maintenance of an EFTS switch, its operational performance, and the degree of cooperation among those institutions participating in the use of the switch. Consider two opposite approaches:

- *Standard formats*—This approach would require that all messages (i.e., terminal/switch and switch/host processor) be standardized. This would provide considerable ease of administration and control, as well as a lower base of development and operating costs. On the other hand, practical experience has proven that agreement on standards is very difficult to obtain and, during an interim period, the changeover to standard formats would require maintenance of dual formats with the attendant operational and control problems.
- *No standard formats*—This approach would require that the switch have available a set of terminal-specific and host processor-specific programs which are used whenever a given terminal (or host processor) interaction is initiated. It would permit any new terminal or host processor to be brought "on stream" with minimum switch-imposed restrictions or modifications. It would, however, involve a large investment in software devel-

opment and maintenance and could increase overall transaction processing time.

Between the two extremes, there exists the possibility of standardizing portions of message processing: such as between the terminal and the switch or between the host processor and the switch. Over the long term, as EFTS networks expand, standardization of message formats will become more important. As the number of host processors and other switch nodes increases, control and maintenance problems will also increase.

RECAP

The technology to support EFTS switch development in a range of alternative design configurations as described above is generally available today. EFTS development work is currently under way in pilot projects throughout the country and hardware and software vendors offer a variety of relevant product lines.

More detailed investigation is still required in several areas, specifically:

- *Security*—There is a need to determine the degree of security (over terminal devices, communications network, and switch operation) which is required to ensure against violations of privacy and fraud; and how that level of security can be delivered at a price which does not render switch operation prohibitively expensive.
- *Standards*—A lack of standardization will, in the long run, lead both to unnecessary duplication of effort and the intercommunication problems both within and outside of a given switch area. Standards will be required in message formats, communication line protocols, terminal device characteristics, and error detection and correction mechanisms.
- *Other Considerations*—Further definition is required in areas relating to settlement and audit trail including: float implications of switch operation (e.g., direct debiting of an account versus value dating of the transaction for future debiting); clearing arrangements for the financial institutions participating in the switch; and historical audit trail requirements for transaction, terminal, and store level reconciliation of customer and merchant accounts.

Are computers ready for the checkless society?

ABSTRACT

Once the furor over the legal and regulatory issues of electronic funds transfer dies down, the data processing industry will find several complications in the development of a systems architecture suitable for implementing a nationwide system. Apart from interface difficulties presented by the equipment and software designs of competing manufacturers, there are complications to the control of such a system that appear to merit the attention of the data processing industry. The purpose of this paper is to stimulate the exchange of opinions on how the industry should cope with differences in end-user protocols, different routing techniques, different methods of controlling terminal devices, the value of various communication line disciplines, and the overall management of a nationwide network.

BACKGROUND

For the past several years the move toward an electronic funds transfer system has been gaining momentum. The Federal Reserve System already transfers vast sums of money electrically; banking terminals are popping up in supermarkets and airports; the battle lines between the thrift institutions and the commercial banks have been drawn; and reliable digital communications are becoming available at an unprecedented rate. Even the most strident slow-payers can be accommodated in the systems being proposed. It seems inevitable that the flood of paper that is engulfing the financial industry is about to be abated by a worldwide network of digital computers and terminals. After all, stored-program digital devices can do anything!

The problem is that they don't; and there seems to be a labyrinth of data processing issues that will become critical, once the furor over legal and regulatory rules dies down.

To address these data processing issues, the Federal Home Loan Bank Board, in March 1975, invited industry to suggest an electronic funds transfer system that could evolve from the regional needs of a mythical metropolitan area called Middletown. The Federal Home Loan Bank Board provided a scenario that illustrated some of the problems being faced by the architects of an electronic funds transfer system today. The scenario carried the evolution of the EFTS system through several stages in which Savings and Loan Associations entered agreements with local merchants to handle debit and credit card transactions, installed banking terminals at shopping centers, added new functions, and included new S & L's into the evolving system. The scenario, which included enterprises with such picturesque names as Korn Krib Supermarkets and Marshall Prairie Department Stores, was made even more vivid by the technical difficulties posed at each stage of the evolution.

Several computer and terminal manufacturers' equipment was involved, and an equally complicated mixture of transaction types, communication line disciplines and business practices were represented. Respondents to the FHLBB invitation were not requested to submit the detailed design of a system that would track the evolution of the Middletown scenario through its various stages, but rather to postulate a system that would solve similar problems scaled for a metropolitan area with a population of from two million to five million people.

The purpose of this paper is to identify some of these problems that are of a data processing nature (ignoring legal and regulatory issues), to suggest promising directions, and to stimulate discussion among the architects of the future Electronic Funds Transfer System.

ASSUMPTIONS

The arrangement of the institutions on the topographic maps at the end of this paper has been synthesized from the demographic information in the scenario developed by the Federal Home Loan Bank Board and illustrates several points, other than purely technical considerations, that will affect the evolution of an electronic funds transfer switch. The evolution shown for the Middletown environment is intended to represent only a *plausible* evolution through the various stages under the assumption that no consortium is formed to bypass stages. In actual practice, the decision to install a regional switch may be reached at any time, so that some of the technical problems in the expanded scenario need never be addressed.

In the Middletown environment, we have assumed that some transactions may cross a state line. Although this consideration is difficult to cope with in the design of a generalized system, it presents a real-world problem because of the variety of inter- and intra-state communication line tariffs and because of state banking laws. This is a non-technical consideration that will influence the topology of the network.

The location of the thrift institution servicers in the downtown location suggests the possibility of collocation which would, if implemented, have a profound impact on the design of the communication system. We have, however, assumed that the thrift institution servicers are physically separated from one another and that communications lines are required.

The geographic layout of Middletown (as shown in stage 1 and 2a), suggests that these stages would be implemented by a combination of point-to-point and multipoint lines rather than by point-to-point lines only as was illustrated in the original scenario. In addition, reliability considerations may cause First Federal to install two separate multipoint lines in each of its branches. This would permit each branch to tie half its terminals to each line so that business could continue normally in the event of a single line failure. The practicality of doing this is dictated by the prices and the line routing of the local common carriers and is another illustration of a non-technical consideration that will influence network topology.

In the later stages of the evolution, we have assumed that the network would evolve as in the scenario with the thrift institutions and merchants entering agreements with one another at each stage. In order to preserve the staging of the scenario we have also assumed that the rival thrift institution servicers would somehow be able to overcome the technical problems of "looking like one another's terminals" and would accommodate one another's customers by developing and installing the software necessary to cope with the different transaction formats used by the various thrift institutions. This latter assumption, of course, is optimistic, but illustrates a natural tendency toward the evolution of a hybrid network. We have however, assumed that at some point (illustrated in stage 3D) a regional switch is installed and that S & L's subscribe to it through their servicers.

The remainder of this paper describes some key elements of network design and suggests that, once non-technical problems have been overcome and adequate computational "horsepower" has been planned for, the network design is dominated by data processing software and procedural considerations rather than by communications considerations.

NETWORK DESIGN CONSIDERATIONS

Figure 1 shows a simple hierarchical structure for an EFTS network. In practice, the network will be more complex than that shown, since it will frequently be advantageous for terminals to access the switch directly rather than via the computers serving the thrift institutions. (In the scenario, for example, Second Federal may decide to attach their teller terminals and their Merchant Operated Terminals at Fast Food directly to the switch, rather than through the FHLB data center 250 miles away. This decision would save 250 miles of communication line at the expense of increased switching load that would be generated by any "on us" transactions. This situation, can be expected in the actual EFTS network. (The decision will also be influenced by the compatibility of Second Federal's terminals with the switch.) Furthermore, traffic considerations will undoubtedly justify additional intercommunication links among terminals. Nevertheless, even the tree structure of Figure 1 illustrates five key considerations that will dominate the design of the EFTS network. These five considerations, listed on Figure 1 form the basis for IBM's Systems Network Architecture (SNA), and are being addressed by other implementers of specialized computer networks. As yet, however, there is no set of widely accepted standards for computer networking. No matter what standards are adopted by the Federal Home Loan Banking System, these management problems must be addressed

Figure 1—A simple topography

in the design of the EFTS network and the participating thrift institution servicers must modify their systems to conform to the EFTS network rules.

1. *Network Control*—In order to allow the future interconnection of EFTS switches, some form of distributed control must be used. Control includes responsibility for the equipment configuration in the network subordinate to the control locations, the loading of the communication programs in the processors and cluster controllers of the thrift institution servicers, the reaction to outages, and the activation and deactivation of equipment in response to changing workloads. The Systems Network Architecture, as currently implemented by IBM, concentrates control at the highest level of a tree-structured network and distributes responsibility for its execution to subordinate elements. In the EFTS, control would reside at the switch with the bulk of the responsibility delegated to the thrift institution servicers.

   Special arrangements must be made to crosstell status information between thrift institution servicers when direct links are installed. (In the scenario, for example, it is conceivable that a direct link could be established between two of the data centers, bypassing the switch, and dedicated to high volume transactions between these servicers. It is important that the overall network design not preclude this sort of connection if the member banks feel that it is to their advantage. This situation is invisible to the switch but requires the development of special protocols by the servicers. Further complications to network control are discussed later and must be resolved by the standards adopted by the Federal Home Loan Banking System.
2. *Path Control,* or routing, is the second key consideration in the EFTS network design. Many store-and-forward systems employ a fixed routing technique (with a small number of alternatives) that is specified when the system is initially program-loaded. If the EFTS is to be permitted to evolve into a national network, it should provide for an alterable path control technique so that traffic can bypass damaged parts of the network without requiring the reinitialization of the network. This means that addresses on data streams (routing indicators) will be read at several places in the network and decisions made as to the path to be taken. This will allow EFTS to achieve the efficiencies associated with line load balancing but complicates path control with the problems inherent in a spill-forward system of routing, namely: shuttling or "ring-around-the-rosey." This problem is not severe in the single regional system described by the Federal Home Loan Bank Board, but is a potential source of trouble if the fundamental network architecture is not sound.
3. A third consideration in the design of the access network is *link control.* Link control is the acknowledgment of the receipt of data and the control of errors on each hop through the network. The two common types of link control are forward error correction (FEC) and Automatic Request for Retransmission (ARQ). In FEC, sufficient redundancy is added to the data stream to provide an acceptable degree of assurance that errors will be corrected at the receiving end without acknowledgment. The ARQ approach concentrates on detection of errors and the retransmission of a block of data when an error is detected. Synchronous Data Link Control (SDLC), a form of ARQ, is employed in devices conforming to IBM's Systems Network Architecture. A similar line discipline is emerging as an international standard and is likely to influence the design of future EFTS links. In an EFTS system, SDLC could be used between SNA devices, e.g., between an IBM 3600 Financial System and a thrift institution servicer's machine. Because of the variety of machines employed by the thrift institution servicers, however, switching systems will probably employ the line disciplines prescribed by the manufacturers for links between the thrift institutions and their servicers.
4. *Device Control* is the fourth element in the design of the network. Standards are required to control the operation of the terminal devices (paper feeding, spacing, indicator control, etc.). More important, however, are standards that determine the operation of intermediate devices, such as the transmission control units of the switch and the thrift institution servicers and the cluster controllers of the S & L's. These controls are necessary for network security and to pace data through the network to assure that the available data buffer capacities are not exceeded by bursts of data.
5. Finally, *end user protocols* must be developed for the EFTS. These protocols, used by the thrift institutions, are essential for customer security and include authentications and special codes agreed upon by the industry. As EFTS evolves, a parallel evolution of end user protocols can also be expected to evolve to support new services offered by the thrift industry.

Figure 2 summarizes the key controls in the network access subsystem by illustrating the format of an en route message nested within the control protocols described above. While every attempt should be made to reduce the communications overhead incurred by these protocols, the EFTS users will probably find the cost of this overhead to be low in comparison with the costs associated with loss of control of the network. Other controls such as modem synchronization and signaling through a dial-up network are considered to be within the responsibilities of the supplier of the communications link, while still other controls, such as end-to-end acknowledgment and password protection

are considered to be the responsibility of the thrift institution servicers themselves. These controls, while important, are outside the scope of this discussion.

Figure 3 illustrates the hierarchy of facilities that is envisioned for the Electronic Funds Transfer System. At the Switch and at the Thrift Institution Servicers, computer installations will be required to perform the switching and communications line handling functions. (The switching function can include circuit, message, or packet switching as well as certain hybrid combination of these techniques sometimes referred to as "virtual channel switching.")

At the S & L's themselves, the ADP equipment is visualized as cluster control equipment and terminals. Cluster controllers control terminal equipment which is either locally or remotely attached. Cluster controllers contain a pool of equipment normally associated with "intelligent terminals" and perform a data concentration function so that multiple terminals can share a communication line.

Figure 4 shows some communications options to be used in the design of the EFTS. It is reasonable to expect that much of the access network will be provided by various communications carriers under contract to the EFTS operator.

The availability of the services shown in Figure 4 and their tariffs are constantly changing so that no useful purpose would be served by repeating them in this paper. There are, however, several trends in communications that will affect the implementation of the Electronic Funds Transfer System, particularly the access subsystem.

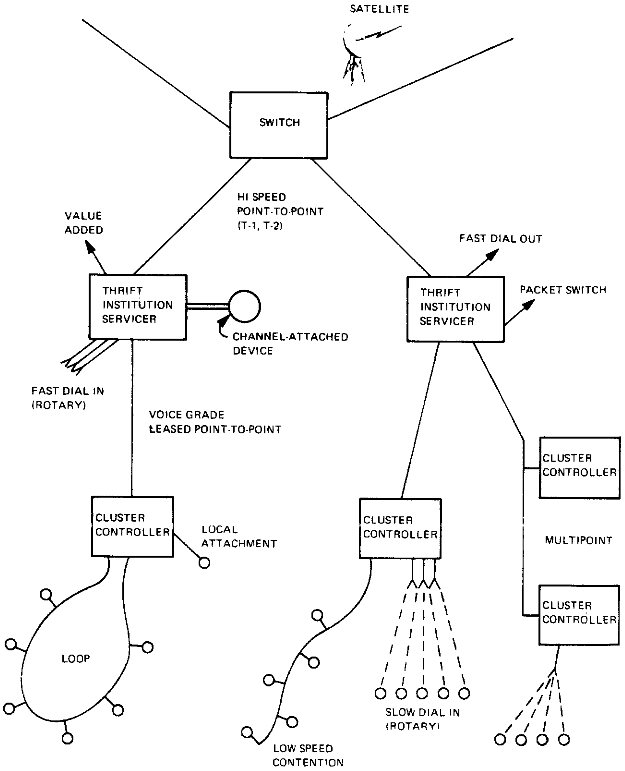

Figure 4—Some communications options

The move to digital communications

The communications industry is dominated by voice users who have traditionally been provided with switched analog circuits of approximately 3000 hz bandwidth. Digital users had to make do with the available services and adapt them to digital use through modems. Both switched and leased services are available under a variety of tariff structures. Data speeds range from the sub-voice level (50, 75, 100, 300 bits per second) through switched voice level 1200, 2400, and sometimes 4800 bits per second, up to 9600 bits per second that can be provided by present day modems operating over a leased, specially-conditioned voice-grade line. Higher speeds are available by leasing lines that have been derived from groups of voice channels (6, 12, 60 and 240 voice channels). New construction in the telephone system is employing digital communications techniques to an ever increasing extent. This is being done because the advantages of digital voice communications (circuitry is cheaper and easier to adjust) outweigh the disadvantages (up to 64 kilobits per second are used to provide high quality voice). The move to digital voice has an important effect on the design of the EFTS network. In the next few years both switched and leased digital service, at voice channel prices, can be expected to be available between major cities in the United States and will have channel capacities of 56 kilobits per second (derived from a 64 Kb/sec voice channel).

High speed access (T1) lines will also become available for data use at speeds up to 1.544 megabits per second and groups of these lines will probably be tariffed eventually to provide service up to the 96 megabit rate envisioned for digital television.

The use of satellites

Leased satellite capacity is an obvious candidate for the long haul trunking portion of the National EFTS of the future but a satellite system has a unique feature that may be advantageous even at the regional level. This feature is derived from an earth station's ability to "hear" everything repeated by the satellite transponder and thereby establish a fully interconnected or nodeless arrangement of earth stations.

This permits the design of a system that can set up and tear down point to point circuits on demand and can allow the EFTS to adapt to changing loads. Satellite capacity is currently available and several companies have planned satellite services that appear to be considerably more cost effective than equivalent ground service.

Distance sensitivity

For the past several years, the cost of providing communications service has become less sensitive to distance; that is, the cost of long haul communications has been falling and the cost of local terminations has been rising. These costs have not yet been fully reflected in the tariffs. The Government's encouraging of competition in public communications must inevitably result in tariffs that more closely reflect the costs. This will mean that the cost (to the EFTS operator) of a transaction will be relatively insensitive to distance and will be most influenced by considerations associated with the access subsystem (terminating arrangements, terminals, subscriber loops, etc.).

Dialup and switched networks

Until now, the use of switched communications for message service has been limited to low speed service over the teletype and voice networks. A trial offering of switched 50 kilobit service did not attract enough users and has been discontinued. As line speeds increase and become more widely available, dialup service may become an attractive method of communication in the electronic funds transfer system. Several new kinds of common carriers have been authorized within the United States and worldwide. These include specialized carriers offering a fast-dial fast-connect capability (under 1 second) and value-added carriers who lease lines from others and reoffer service by adding value such as error control, variable data rates, and switching schemes such as packet switching to attract data users who have highly intermittent traffic.

Special lines, loops, and channels

In addition to the conventional point-to-point communications lines available for the design of an Electronic Funds Transfer System, there exist several other kinds of access arrangements that warrant consideration. These include loops that reduce terminal polling loads by passing control from one station to another, high speed data loops being proposed for computer networks, and specially engineered customer-owned lines. Furthermore, there are no technical reasons that preclude the possibility of channel-attaching a thrift institution device directly to the switch. (Indeed, the concept of a "free standing" switch is technically unnecessary. If the member institutions were to agree, the switching function could be assumed by a thrift institution servicer as an addition to its regular functions.)

Complications to network control

As discussed previously, system control implies the ownership of terminals by cluster controllers, cluster controllers by higher level computers, etc. In a rigidly structured hierarchical tree network, the concept of ownership is simple. IBM's System Network Architecture, for example, provides for hierarchical system control in computer networks. If, as seems likely, the EFTS eventually departs from the tree structure, system control becomes more complex. Figure 5 illustrates a possible configuration of part of the EFTS network. If bank-to-bank links are permitted (or servicer-to-servicer), or if thrift institution servicers can access more than one switch, then the situation shown by Figure 5 occurs. Which switch is responsible for the integrity of the bank-to-bank communication? Does the thrift institution servicer authorize the dedication of a terminal to communication to a particular switch? Does it inform other servicers of the status of its subordinate terminals? These are the kinds of problems that must be resolved in the design of the access system control function.

Present-day computer networks usually call for some kind of control point, charged with the responsibility for configuration control, routing table distribution, statistics collecting, operator interface, system initialization, and other functions associated with the management of the network. The control point is sometimes responsible for controlling "sessions" between end users (terminals and computers). Sessions may be created at the time the system is generated (when the software is tailored to the needs of the network), they may be created at the time the system is initialized (when the network is first opened for traffic), or they may be created dynamically when the need for end-to-end communication is recognized. As the EFTS system evolves into a national network, dynamic session control from a single control point will probably be impractical. The EFTS can probably centralize most of the management at a single point (with appropriate backup) but the concept of sessions must eventually be modified to permit a terminal to be placed in permanent session with its "owner," a nearby, or regional control point designated when the system is initialized. This will permit distributed control and fixes responsibility for trouble diagnosis but, in turn, complicates the problem of routing transactions, guarding against lost transactions, and averting localized congestion caused by fluctuating traffic loads. These complications will be discussed next.

Complications to path control and routing

Figure 6 indicates some of the problems of network routing. If a thrift institution servicer has the exclusive responsibility for specifying the route that an EFTS transaction shall take through the network, it must be kept informed of the complete status of the network, including outages and congestion problems. The alternative is for the thrift institution servicer to

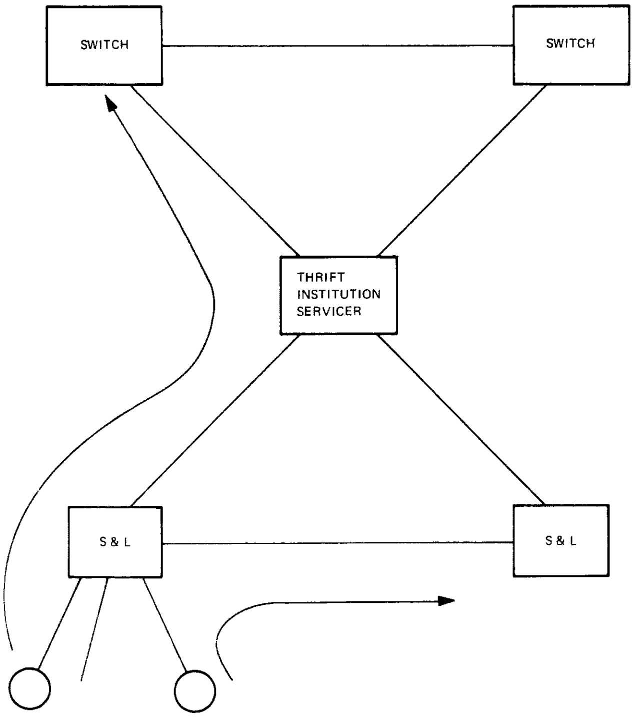

Figure 5—Complications to network control

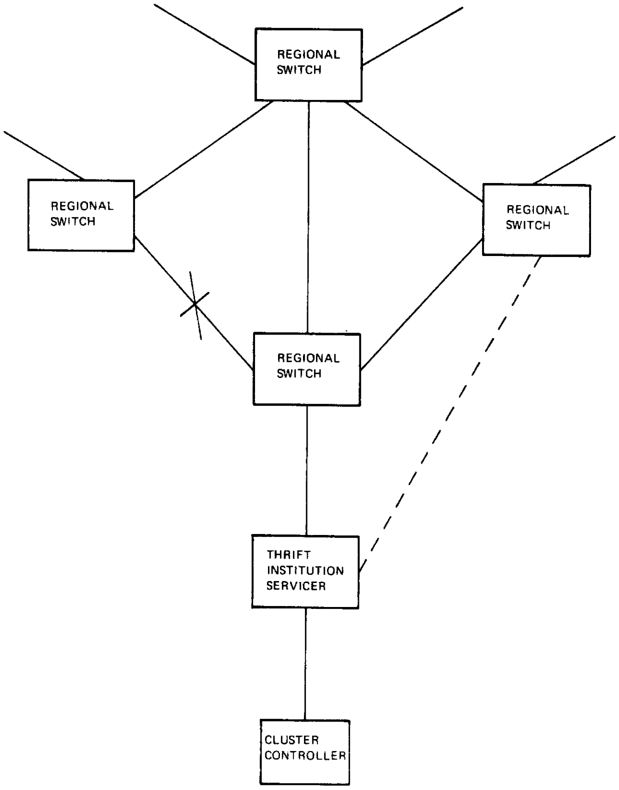

Figure 6—Complications to path control and routing

affix a routing indicator on the transaction and for the switches to assume responsibility for the path to be taken. If, as shown in Figure 6, the thrift institution servicer is permitted to home on more than one switch (This possibility is suggested in the Middletown scenario.) then the servicer must have the capability of determining which physical connection should be used to transmit a particular transaction. This logical decision may be influenced by time of day, information on the rest of the network, traffic loads and priorities.

If alternate routing is permitted in the National EFTS, then special precautions must be taken to prevent a transaction from circulating endlessly in the system. The technique currently employed in the U.S. telephone system involves a hierarchical system with alternate routing whereby a direct route is tried first, followed by an escalation to higher level of offices until a route is found. Lower-level trunks are engineered for high usage (i.e., the trunks are often busy and therefore efficient). This causes traffic to percolate up to higher level centers which are more generously engineered so they can cope with alternate-routed traffic that is generated by the overloads. Traffic engineering techniques developed over the years for the world's telephone system can be used to advantage in the design of the EFTS.

Complications to link control

Link control involves the transfer of a bit stream between two points. Problems in link control are dominated by the error rate of the communication line. If the line were perfect, or if the natural error rate of the line were tolerable because of some gross redundancy in the data being transmitted (as in a facsimile system) then link control would merely involve some gross protection against lost messages. For digital data streams with low redundancy, such as EFTS transaction, some form of error control is required so that a transaction can be accurately reconstructed at the end of each hop through the network. This can be performed by adding redundancy bits that are checked at the receiver for each transaction. Either variable length transactions or fixed length transactions can be used. The useful line speed of a link is a function of the raw speed and error rate of the line, the length of the transaction, and the amount of redundancy in the transaction.

Figure 7 shows experience of leased telephone lines typical of a few years ago. The system shown involves adding 8 error detection characters per transaction and retransmitting it if it is found to be in error. Notice that raw error rates are high for high bit speeds and that this requires extensive retransmission if the transactions are long. On the other hand, short transactions are also inefficient because of the overhead represented by the error control characters. In EFTS, because of the sensitivity of the data being carried, some form of error control will be needed. Because the line efficiency is sensitive to the transaction length used, careful attention to the error control problem is required before standards are adopted to minimize the effect of variations in the error performance of the communications link.

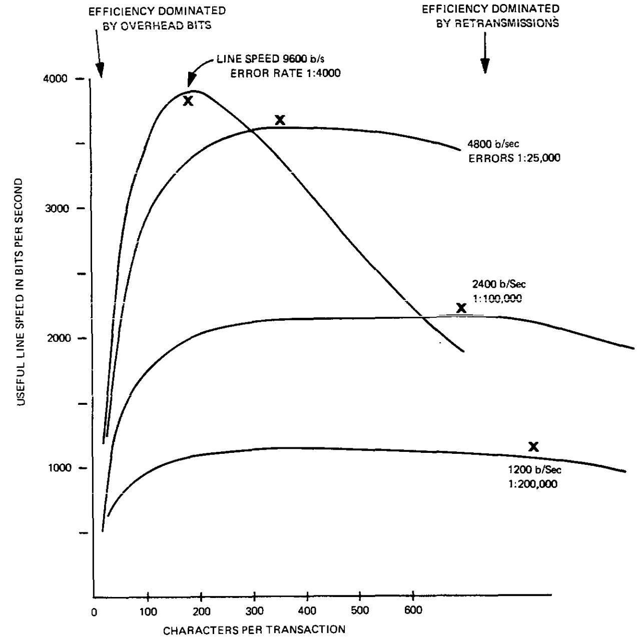

Figure 7—Complications to link control

Complications to device control

The problems of congestion in the EFTS will become severe when it evolves into a national system. In a data communications system with distributed control, overloads, when they occur, must be coped with by buffer storage capable of temporarily holding the traffic as it is moved through the system. Some means must be provided to prevent traffic from exceeding the output speed of the receiving device and from exceeding the buffer capacity of the intermediate devices (Refer to Figure 8). IBM's Systems Network Architecture accomplishes this through standardized messages among the intermediate devices that serve to regulate traffic through the system. Some similar set of device control protocols should be designed into even the early pilot models of the EFTS that will reflect the overload status of a device back through the network to control the flow of traffic through earlier stages.

Complications in end user protocols

The EFTS should be transparent to the users (i.e., thrift institution servicers). That is, once the addressing and input rules have been followed, the text of the transaction should have no effect on the operation of

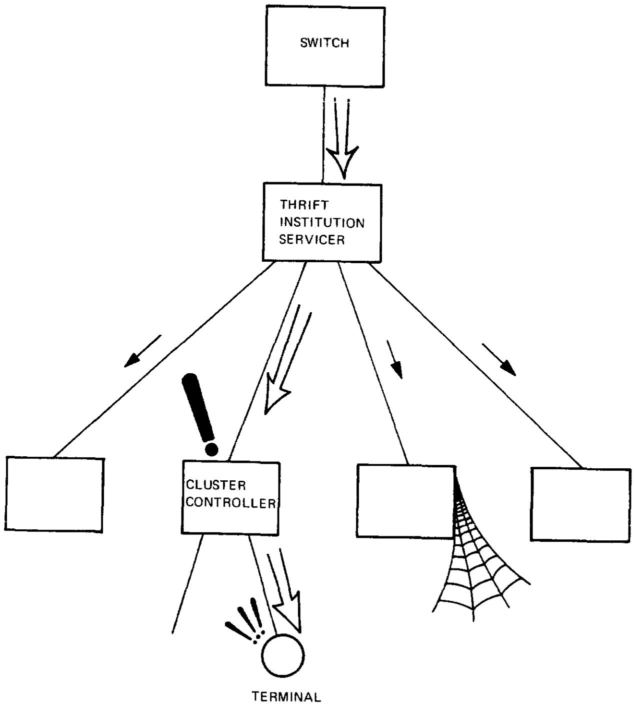

Figure 8—Complications to device control

the system, nor should the system have any effect on the transaction.

Such transparency is not easily achieved. Figure 9 illustrates four common pitfalls that cause problems. First, the link hardware may be affected by the content of the message. Consecutive streams of "1" bits or "0" bits sometimes cause problems. When these problems are overcome, the remaining problems are sometimes bizarre. There are instances of 27 asterisks causing a particular modem model to lose synchronization. In addition to link problems, the transmission control hardware may not be transparent. Certain dial telephone systems utilize specific frequencies in the transmission band for signaling and routing. These frequencies, if duplicated by the data stream, can cause misrouting. Routing software in intermediate devices can exhibit bugs years after its installation when some procedural change causes text to be interpreted as signaling information. Finally, there are incompatibility problems that may occur in the receiving devices themselves. The EFTS system is a long-term endeavor that will be characterized by the introduction of new devices over the years. It is essential at the start that a fundamental systems architecture be developed that will permit this evolution.

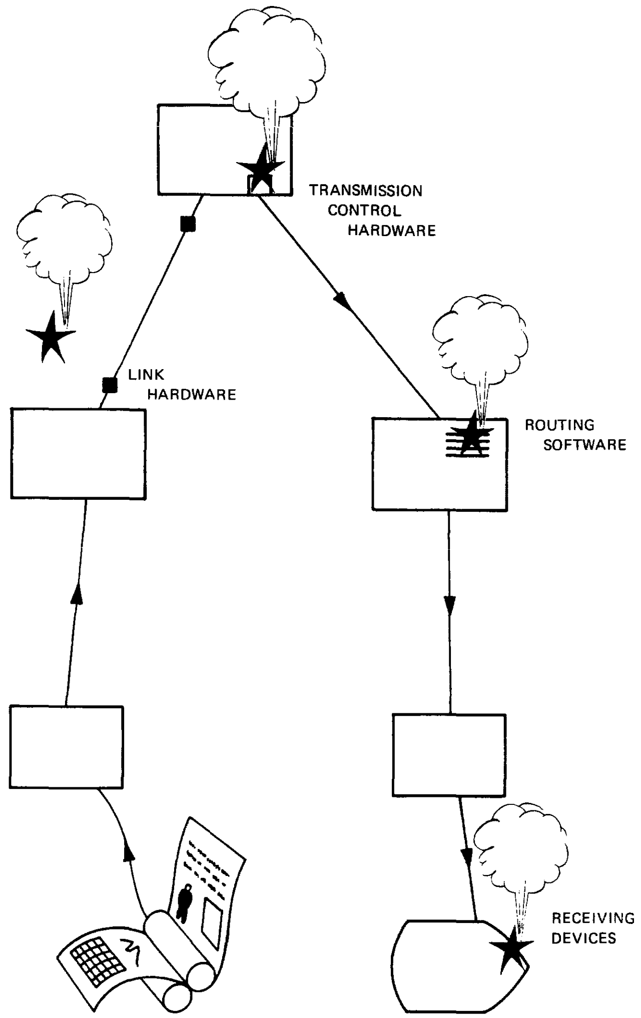

Figure 9—Complications in end user protocols

ARE COMPUTERS READY?

None of the problems discussed in this paper is insurmountable. Each data processing company offers a solution to at least some subset of these problems, and rival computer networking schemes have generated some lively discussions (some of which border on medieval theology). The Public, and the Banking, Communications and Computer Industries seem to be ready for the checkless society; yet the crucial component: A nationwide electronic funds transfer system seems to be an elusive goal. Comprehensive, cross-industry standards seem almost too much to expect at this time; but surely the computer industry can do better than it has in proposing at least the architecture for a bold, new approach to electronic funds transfer.

Personware

by H. W. BOMZER
University of Illinois
Urbana Champaign, Illinois

ABSTRACT

Personware is the human resource that makes it possible for hardware and software to perform the data processing function. Consequently, management is urged to invest in its maintenance and upgrading. The paper develops the effects of management objectives, user interface, organizational structure, job descriptions, and individual goals on a training program. Methods for implementing a program which will result in a high correlation of the skills inventory available, identification of skills required to meet functional needs, and specified employee objectives are discussed. Various educational techniques are shown to fit into a schedule which provides maintenance and upgrading of personware at a relatively low cost.

In the dynamic world of data processing management recognizes that successful performance involves not only hardware and software, but personware as well. In carrying out its plans for accomplishing increased productivity and greater efficiency, management cannot ignore the importance of the employees who perform the functions of the data processing business. Management seeks to satisfy the needs of its customers. Equally it must seek to satisfy the needs of the employees. It is only in this way that the organization can realize a full potential.

In this constantly changing world of data processing it is necessary for employees to be able to plan their futures. These plans should be consistent with the market demand for skills and the individual's ability to satisfy these demands. Inherent in his growth process is a recognition of one's own abilities, learning potential, behavior patterns, and needs as well as the anticipation of the employer requirements. With this in mind it is prudent to examine the present structure and needs for providing a frame of reference in which to plan for growth.

In providing for the professional development of its employees management is contributing toward the realization of its organizational objectives. This will occur if the career path plan which provides for training and progression is in consonance with the services of the organization.

During the past several years management has concentrated on acquiring larger, faster and more efficient machines. There has been increased emphasis on communications and on-line systems; higher level languages and special packages for retrieval have come into vogue; there has been greater sophistication in system development and the use of data bases. Concomitant with these changes have been reorganizations and realignment of personnel and their duties in order to effect efficient interaction and productivity. In this environment the data processing employee has become restless, sometimes frustrated and increasingly aware of the need for maintaining his technical skills. Not only is it necessary for the employee to maintain an adequate skill level, but he also requires a frame of reference in which to plan for growth. The objective of a career path is to provide the employee with the wherewithal to realize his potential and desires to the fullest while at the same time serving the needs of management.

How does management develop personware? This will vary from company to company, but in all cases it starts with the person and how he will fit into the organization. Management philosophy, its policies, procedures and structure are of considerable importance. For example, if the shop has programming teams as a modus operandi, then an individual who likes to "go it alone" may not function effectively in the team environment. A happy marriage for both management and the employee is predicated on mutual support.

Figure 1 illustrates schema that can be adopted to develop personware. It starts with management objectives. In terms of data processing, these objectives must be measurable.

Frequently, objectives set by management for data processing are beyond the control at the D. P. unit. Thus, management may state as an objective "Reduce the cost of inventory by X% over the next two years." Translated into tactics, this may involve the development of a new inventory system which substitutes on line input of data for an existing hand entry system. At the same time, management may set another objective "Do not increase the cost of internal service

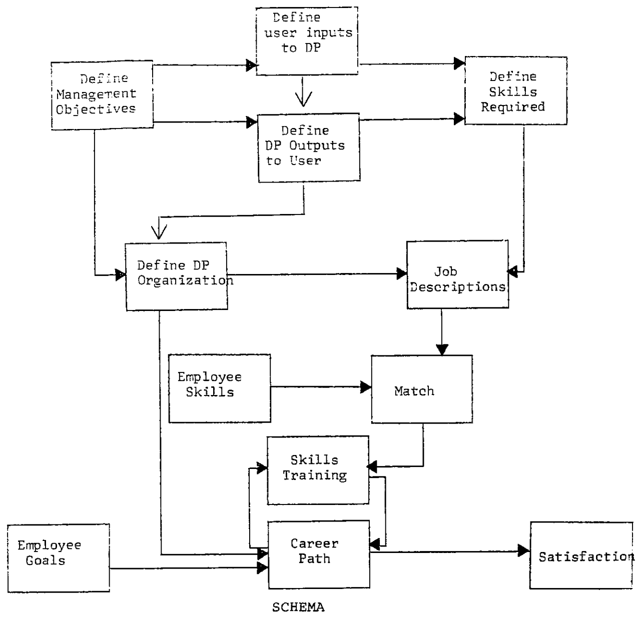

Figure 1

for the next year." If the data processing function in this organization is counted as service, management may impose a dilemma. The situation created by trying to satisfy both objectives can lead to frustrations which are not conducive to development of personware.

Within the D. P. organization objectives should be clear. To a large extent these are influenced by the D. P. budget. However, D. P. management should provide both long range and short range objectives of which employees are aware. Table I is a typical example.

A natural adjunct to objectives is a definition of services. The key to success lies with accepting input from the customer and producing output which meets his needs in a cost effective manner. The form of inputs and outputs affect performance as well as efficiency. However, from the employee point of view, they affect the skills that will be required to perform on the job. For example, consider a shop which operates strictly in a batch mode. Punched cards are the input and reports are the output. In this shop the analyst or programmer need not become proficient in terminal applications and languages. On the other hand, if it were a terminal oriented IBM shop, the analysts and programmers would be very much involved with such things as CICS, DMS, etc.

TABLE I

LONG RANGE

1. Realize in excess of 10% R. O. I.
2. Operate with centralized system and distributed network
3. Operate in Data Base environment within five years.
4. Provide security for user data

SHORT RANGE

1., Cut paper costs by 10% this year
2. Develop terminal oriented system for customer
3. Educate 2 analysts in Financial area to use Data Base
4 Identify data requiring limited access and install passwords.

When one considers the multiplicity of input and output techniques that are available, it becomes clear that training and education are continuing phenomena. The skills required for providing services and making transitions to improved and more efficient services must be inventoried. Training to maintain and upgrade employee skills are part of management's planning function.

A clear definition of the data processing organization is essential for the long term employee who envisions progress along promotional lines. Unfortunately, this is replete with traps and problems tied to wage scales and responsibility. Thus, a top notch analyst may aspire to a management position. However, there is no guarantee that even with proper training the analyst would be transformed to a good manager. Nevertheless, it behooves management to adopt an organization which can respond to its needs.

A typical organization chart is shown in Figure 2A. In this type of structure, a programmer entering the Applications section can see growth within the programming field. In fact, experience suggests that the hierarchy would require transferring from the Applications Programming section to the Analysis & Design section in order to progress to the manager position. However, the systems programmer would proceed by an entirely different route.

In Figure 2B the systems section is shown organized in a team approach. The lines of progression favor a project orientation. This construct produces

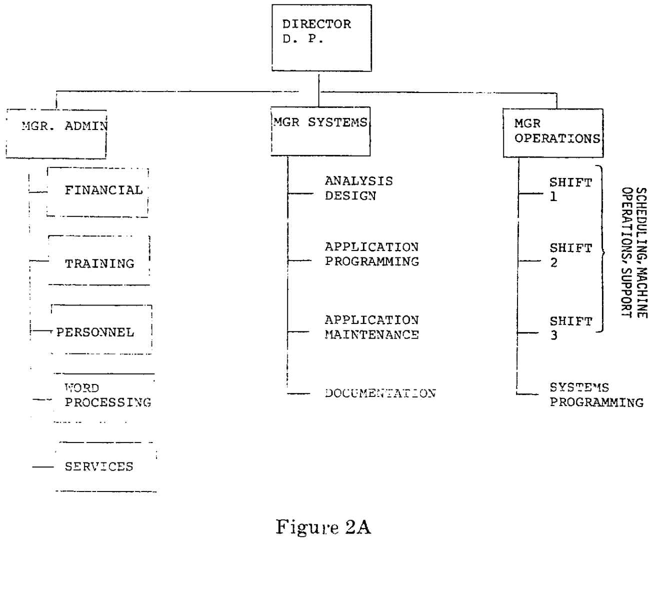

Figure 2A

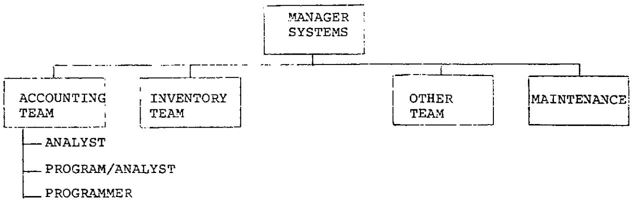

Figure 2B

people who are likely to be specialists in certain application areas. An employee who wants exposure to many application systems may want to carefully consider the policies regarding transfer from one team to another.

Personware, unlike software and hardware, is a self-evaluating mechanism. One of the references for performing the evaluation is a description of the incumbent's job. A "Job Description" would show where the position fits in the organization. It summarizes the responsibility and authority of each position, the tasks to be accomplished, skills and education required, and general information useful for evaluating performance. Figure 3 illustrates a job description format similar to that used as a guide for some Civil Service positions in Illinois.

A match of employee skills with job requisites provides a basis for implementing a training program. Depending on the size of the D. P. department, the amount of times scheduled for training and availability of employees for training, management may choose to offer several methods for accomplishing the desired results. Short courses are provided by several private firms who have developed instructional material. Lectures can be attended when the vendor schedules them at specified education centers; or, for large D. P. organizations, they can be scheduled on site. In addition to lectures, much of the basic material is available in self-study courses. Programmed instruction manuals represent one such format. Lessons are designed to instruct, quiz, and review as students progress through the text. In some cases, text material is augmented with practice "work type" examples. Another approach to training relies on multi-media. This technique usually involves a combination of reading, listening to audio tapes, viewing video tapes, and self tests in a guide book. To employ this technique requires an investment of $1500-$2000 in the video and audio equipment. However, it provides an extremely flexible means to provide training at various levels.

Management should be concerned with the progress of employees. Records can be kept by the personnel office, a responsible training office, or the employee's immediate supervisor. In a large department, a format for maintaining the records can be developed. The immediate supervisor should have the record available and use it to plan and encourage additional training.

Figure 4 illustrates a simple format which has been employed at the University of Illinois to maintain

training records. On a single sheet, the supervisor can see the inventory of skills required in the department, the level at which those skills exist, the training that has been taken to achieve a given skill level, and the status of training for each person in the group. Based on this chart, a schedule of training can be arrived at between the employee and the supervisor. Plans to reinforce skills or acquire new ones can proceed in harmony with production needs.

The accumulation of skills and worthwhile experience helps the individual develop. Management gauges the employee progress and provides the nourishment. However not all employees have the same goals, nor do all employees require the same nourishment. The career path plan should contain the characteristics for meeting the needs of both management and the employee. There are a number of ways by which the individual measures his goal attainment. These include status, responsibility, authority, salary, working environment, technical support, opportunity for improvement, and other fringe benefits. A career path plan provides the employee with a tangible reference for measuring his progress toward achieving his goals. The plan is somewhat constrained by the data processing organization and its philosophy. However the demands of the industry supply management with sufficient opportunity to reward the deserving employee. As the individual develops he becomes a valuable asset to the employer. The development of this "Personware" is potentially the highest payoff item in an operating budget. It deserves the attention worthy of this potential.

From data entry supervisor to data entry specialist

by CAROLYN M. DUNNING
Pertec
Santa Ana, California

ABSTRACT

For many years data entry lagged behind all other aspects of data processing. Originally, there were card punches where data was entered a character at a time. Then came key tape making buffering a common concept to data entry. Buffered key punches provided the same advantages of key tape, but had more flexibility. Then key-disk entered the scene and data entry became computerized. Data could be entered faster and more accurately than ever before.

What does this mean to the data entry industry? Operators do not have to be as well trained as before. But the greatest impact is felt at the supervisory level. 'Mini-analyst' training should be provided for those individuals interested in supervising key-disk installations. These classes should cover terminology, hardware components and some form of programming as well as the use of peripherals and options common to key-disk systems. Typical problems that can occur, both from an operator and the system should be discussed with methods to assist in analyzing them. Control procedures should be outlined.

Well-trained supervisors can help provide a more efficient data entry department and can be an asset in designing the data entry systems of the future.

For many years, the lowliest task associated with data processing was data entry. The manipulation and output of information progressed by leaps and bounds. Faster accounting machines, calculators and the advent of computers. Look how far computers have advanced in 20 years! The growth has been phenomenal. But what happened with data entry? Computers were processing more information at faster speeds every day. It was beginning to become a problem to find enough input to feed these hungry monsters. Why? Because data was still being keyed into cards one character at a time on equipment that was only as fast as the mechanics of the machines would permit. Keyboards had to be interlocked to prevent the operators from getting ahead of the card punches.

The introduction in the early 1960's of the IBM 029-059 card punches and verifiers produced two features that were indicative of things to come in the world of data entry. One was the automatic left zero option that gave birth to the concept of buffering data as it was keyed. Data could be keyed and corrected before it was actually punched into the card. Not only that, the operator didn't have to count and key leading zeroes. Granted, only integers could be buffered and the maximum was eight digits, but it was a beginning. The second feature that was new, was the photosensing on the 059 verifier. Cards could be read more quietly and much faster without waiting for any mechanical action to occur.

The next milestone for data entry was the introduction of the key-tape. Now an entire record could be buffered and massaged and corrected before being output. Just as important, the operator did not need to be inhibited by the mechanical limitations of the machine. Faster electronic keyboards were made which had a feature called n-key roll over. This 'remembered' keystrokes therefore assuring none were omitted, nor the operator locked out. Record sizes could be increased from 80 characters providing the ability to enter more data at one time.

Although key-tape machines were much faster, they had other serious limitations that made their use somewhat impractical for many applications. It was impossible for the operator to see an entire record all at once. Data would have to be read character-by-character. Another limitation was the inability to insert records within a batch. Missing records had to be appended to the end of the data batches which was not always feasible. Also, although both data entry and verification could be performed on the same machine, it was not convenient to do so. Since it is common practice for an operator not to enter and verify the same batch of data, this meant either switching tapes or machines. Therefore, key-tape was found to be very inflexible.

However, cards hadn't given up the battle yet. Then came the advent of the buffered card punches. Now an entire card image could be keyed into a buffer without physically punching a card until column 80 had been passed. While still being limited by the 80 columns in a card, the number of program levels was increased to provide the ability to key more data from a source document at one time. Now data entry had the best of two worlds; the speed and accuracy of key-tape with the flexibility of cards. Gone were the clumsy drums and their nemesis, starwheels. Programs could be stored in memory. Card punches could have the faster, electronic keyboards. As one card was being punched, the operator could begin keying the next one. Skips and dups were performed at electronic speeds. Operator statistics and the generation of batch totals was possible. Automatic emitting of data was available on some machines, as well as the automatic sequencing of program levels. Both punch and verifier were housed in the same machine. What a tremendous help this was in scheduling! No more worrying about the ratio of punches to verifiers. Throughput was increased tremendously.

Then all of a sudden, data entry grew up. Key-disk entered the scene and "Look Ma, we're computerized!" Now data entry had entered the same league as the big guys. Information is entered onto a disk with the assistance of a mini-computer. This data can be massaged and manipulated as much as desired. It is then usually written to tape for the mainframe computer to process. On most systems, it can optionally be transmitted directly to the mainframe, either over a telephone line or a direct interface. The advantages to this type of system are numerous. Data can be validated as it is keyed. Calculations can be performed and the results can be automatically entered into the records. Likewise, constant data. Now it isn't a question of keystrokes, but truly a matter of throughput. The data entry department has finally become a respected member of the data processing community. And this is just a beginning.

What does all of this mean? First of all, operators do not need to be as well trained as with the earlier key punches. Although key punch keyboards are standard, optional typewriter keyboards make it easy for typists or clerical personnel to become data entry operators. Information can be easily entered at the source, eliminating or greatly reducing the possibility of errors, which typically increases turn-around. Programming is no longer a factor since most systems are 'preprogrammed' with all operators using the same programs. Extensive procedures need not be remembered as most key-disk systems can prompt the operators as well as alert them to error conditions.

Well and good for the operators. But what happens at the supervisory level? Here is where the greatest impact is felt. Now to be really effective and utilize a key-disk system to its greatest potential, the supervisor should be a 'mini-analyst' with a fundamental knowledge of basic computer systems and data management. Gone are the cards with the visual evidence of work that has been completed. Data is now in a 'never-never land' called a disk. But how do we really know it is there? What does it look like and what happens to it now? These and many more questions plague a supervisor who is frequently answered with a "Don't worry about it. Just do exactly what you have been told to do and everything will be alright."

Key-disk has been over-simplified by many vendors. Who wants to frighten the supervisor with a lot of confusing terminology? After all, a very competent mainframe programmer wrote all of these programs and all that needs to be done is for the operators to enter and verify the data, the supervisor to write it to tape for the computer and then delete it from the disk. Simple, right? But what is wrong with this logic?

Let's start with programming. There's a world of difference between a program for a mainframe where an operator selects it and it executes with very little interference, and a program for a key-disk system where many operators sit and use it for hours at a time. A poorly written mainframe program can be slow and inefficient memory-wise, but this has little, if any, effect on the operator. On the other hand, a badly written key-disk program may not only be inefficient as far as the processing goes, but it can be very tedious for an operator to use. Who is best qualified to write a data entry program? A mainframe programmer or systems analyst whose primary key punch experience comes from punching their own programs (usually freeform) while in school or a key punch operator or supervisor who has been making program cards and punching and verifying data for years. These people know what is necesary for entering data easily and accurately and should be best qualified for writing programs that are going to be used by all operators on a system.

Another area of concern that is created by a key-disk system is the terminology that is used. A supervisor must be familiar, not only with standard data entry terms, but also those associated with computer operations. While most key-disk manufacturers have attempted to keep the terms data entry oriented and as simple as possible, this is not always feasible. For example, what about tape writes with blocking factors, translations, labels, etc.? And how about bits, bytes and words? We didn't have all of that with cards. The worst problem we had may have been trying to translate the holes in the cards into characters if the print mechanism failed. Otherwise, we just handed a deck of punched and verified cards to the computer operator and everything else was taken care of.

Some key-disk systems must compile programs before they can be used. That really is scary. With card punches all we had to do was create a program card, either put it on the drum and lower the starwheels or read it into memory and we were ready to go. If the program card wasn't quite right it was a simple matter to change it. Simplicitly was the key word.

What is the point of all of this? Well, many schools and colleges provide very extensive computer training, both for programming and operations. And some schools also provide key punch training. But what about a person who is interested in learning about a key-disk system? Oh yes, manufacturers provide training, but only on their equipment and usually only for customers. Normally, these are rather abbreviated and do not cover a lot of things a key-disk supervisor might want to know. A mainframe programming or systems class taught at the college level is more than most data entry supervisors would need, or want. They aren't interested in becoming mainframe programmers. So why not provide educational classes tailored to suit the needs of a key-disk supervisor? Data entry is advancing at a rapid pace and experienced, qualified individuals are necessary to create efficient key-disk departments. Again, who is more qualified to handle this task than an operator or supervisor who has been entering data for a long time and understands the needs and problems associated with data entry? This is a 'people-oriented' environment more so than any other area of data processing. It can be a very emotional situation.

What kind of course would this be? It does not need to be concerned with all of the problems of a large mainframe computer, but should be more like a 'mini-analysts' course, tailored for individuals who want to work with some type of computerized data entry system. It must be generalized to cover the common features and functions of most key-disk systems, which is a large order since none are totally alike. However, there are many characteristics that are common to all, or most, systems.

An explanation of computer concepts and terminology is vital. Bits, bytes, words, binary, ASCII, EBCDIC, software, hardware. These are terms that are thrown around by the customer engineers or systems analysts working with a key-disk system. But what do all of these words mean to the supervisor? I think an understanding of some of these terms can help the supervisor communicate better with the people who have to answer questions and service the system. It will also help allay some fears of the 'unknown'.

The difference between hardware and software should be explained. As any one who has been in the real world of data processing knows, it is often very difficult to isolate problems between software and hardware. A supervisor who has some understanding of them can possibly better define a problem that may be occurring with the system. The hardware components that are part of the system should be explained, the most common factor being the disk. This should be covered in sufficient detail so the supervisor has a clearer understanding of its function. Tracks, sectors and AU's should be explained, as well as some explanation of a volume table of contents (VTOC). Some systems require the disk be initialized regularly. The purpose of this and its effect should be explained. Most systems also use some type of WARM and COLD START procedures. The difference between the two functions should be defined as well as what will happen if the wrong option is accidentally selected.

Tape drives are very important to most key-disk installations. Their care and use should be thoroughly covered. Proper cleaning and usage of both tape drives and tapes is very vital to producing good, clean output as the improper handling of tapes can create many errors from the data entry department. The cleaning of tape heads and a recommendation of what should be used to clean them is important. The benefit of having tapes certified regularly should be discussed. Since most drives are loaded and unloaded in much the same way, this could be demonstrated with students actually mounting and dismounting their own tapes. Terminology connected with tape drives should be discussed. For example, the difference between 7-track and 9-track tape drives should be explained, bits per inch and the difference between 800 bpi and 1600 bpi as well as parity and its purpose should be covered. An explanation of the appearance and purpose of BOT (beginning of tape) and EOT (end of tape) markers and how are they sensed is vital. Cutting the lead from a tape and putting on a new BOT marker should be demonstrated. EOF (end of file) should be defined. These are things that will confront a supervisor who may have no idea as to what is meant.

A most important aspect of any key-disk training is some form of programming. Although all systems use their own type of programming, there are many common factors that can be discussed in a generalized way. Most systems use at least some type of 'checkbox' programming. This is usually merely a fill in the blanks procedure to tell the system what is wanted. It usually contains field descriptors, the most common being field size and shift (alphabetic, numeric and in some systems, lower-case alphabetic). Other controls can also be defined in the checkboxes. One of these might be data type which specifies exactly what types of characters can be entered into a field and provides a character-by-character validation as the field is keyed. For example, a field may be programmed as alphabetic, but numerics and blanks are also allowed. Data type would have to specify this. Or perhaps a field can only be numeric, with no alphas or blanks permitted. Another common control is how the field can be exited. Perhaps it doesn't need to be exited at all and as soon as it is completed, control automatically goes to the next field. Or maybe a field release must be depressed before continuing to prevent overflowing into the next field. The extent to which a field must be keyed may also be specified. Perhaps a field must have every position keyed (none can be blank), or maybe it must have some data keyed, but not necessarily be filled. Maybe it must not be keyed at all and the system will insert some type of constant or calculated data. Justification and fill can be programmed so the operator does not need to remember whether a field must be right-justified and zero-filled or left-justified and blank-filled. The system will handle it automatically. Range checking and batch balancing frequently can be programmed in a checkbox program.

Since most key-disk systems allow rearranging the data for output (commonly called reformatting), fields can be organized so that it is easier for the data entry operator. Various types of verification can be programmed, such as key, sight, to-balance or not verified. In many instances, verification can be greatly reduced, or even eliminated.

In addition to checkbox programming, many systems use some type of higher level programming language, the most common being similar to COBOL. It might be well in a class of this type to cover the general concepts of computer programming, particularly the logic of COBOL such as IF, MOVE and the arithmetic statements ADD, SUBTRACT, MULTIPLY and DIVIDE.

Most key-disk systems have some method of prompting the operator. The purpose and general use of prompts should be discussed, such as the most effective way to program them so that they are meaningful to the operator. Peripheral equipment such as teletypes and line printers should be discussed. Since each system probably utilizes these options differently, their use can only be discussed in a general way. However, feed controls, carriage tapes, top-of-form, and other common characteristics might be explained. Since most data is usually entered in an unedited form, (no commas, periods, dollar signs, etc.) and printed reports will have these characters inserted, editing might be mentioned. Examples of the most common editing functions should be provided.

With the increasing use of data communications, a discussion of this feature might be appropriate. Since this is a very complex area it must be generalized and greatly simplified. A brief description of the most common protocols might be good as well as factors necessary for initiating a transmission or receive.

Since most systems use some type of full CRT display, the generalized areas of display should be discussed. For example, there are usually one or more status lines, a message line and several lines for displaying data. An explanation of what is displayed in these three areas is appropriate.

A discussion of error messages and the most common types of operator errors is necessary. This might include common errors such as keying an invalid character, attempting to key too many characters in a field or keying data that is not within a specific range. Most systems also provide the capability of creating some types of individual 'tailor-made' messages. A recommendation of what these messages could be and where they should be used would be helpful.

Relatively common system problems should be covered. This might include such things as not being able to bring up the system, a terminal or entire system hanging or not being able to locate a batch of data or a program. Things to look for when any of these conditions occur should be outlined. It can help a customer engineer isolate a problem if a supervisor has previously tried to analyze what is happening. Common operator problems should also be explained, such as keying an incorrect batch name or number, or opening a batch under the wrong mode. Most systems also have some type of search procedure. The parameters available should be discussed.

The supervisory functions are basically the same for all systems. The purpose of the most common ones should be explained. This might include things such as tape writes, deleting data from the disk, system saves, obtaining a disk status, assigning a new name or batch number to an existing batch of data, printing to a line printer or requesting batch status. Generalized operator statistics should be discussed.

Control procedures are a very important area of a key-disk system. Batches must be carefully and accurately logged and monitored as the work progresses. The log must be periodically checked against what is on disk and the status of the batch. (Has the batch been completely entered? If so, has it been verified? Does it contain any invalid data? Is it in- or out-of-balance?) These are things that are very important when the data is output. When a write is performed, batches must be checked against the log to be certain that all desired batches were written, and no extraneous batches were included. Disk status must be checked regularly to assure that the disk does not get full since in most instances, this can create severe problems. Deletes must be very carefully monitored and system saves regularly scheduled. System crashes where data is lost is not a common occurrence, but just one crash can be a disaster in that hours, or even days of work can be lost if the data is not properly backed up.

Well-trained key-disk supervisors can be a great asset to the industry in optimizing the quality of data going to mainframe computers. They can also be very instrumental in providing good, valuable input for creating better data entry systems in the future. Data entry is still in its childhood. There will be many changes in the years to come and the term 'data entry specialist' will be just as common to data processing as systems analyst or programmer. Now is the time to start training these specialists for tomorrow.

A modern beginning programming course*

by ROY F. KELLER
Iowa State University
Ames, Iowa

ABSTRACT

This paper describes a beginning programming course. It represents an approach to the "right way" to teach programming independent of any programming language. This is accomplished by thinking of programming as a two part process—(1) constructing an algorithm and (2) translating the algorithm into a program in some chosen programming language. Basic structured programming constructs are used for constructing an algorithm and translation is demonstrated by translation of control constructs into FORTRAN.

INTRODUCTION

The following quotations are a good way to introduce this paper:

(1) "Over the past decade, computer science has suffered a loss of innocence. No longer can a programmer be a gullible optimist, convinced of a program's perfection by success with a few chosen data. A program must be seen to be *correct*, and *clarity* has become essential. One of the keys to clarity is the set of control structures used, and the debate over the choice has been lively." Ledgard and Marcotty.[1]

(2) "One point should be made clear. We must distinguish between the programming language and the notation used while programming. One doesn't program *in* a language but *into* it." Gries.[2]

(3) "Yet it is fair to say that almost none of the elementary programming books say anything about problem solving, about orderly thinking, about expressing algorithms clearly and simply. The only conclusion to draw is that the students are not being taught how to program; they are being taught a language." Gries.[2]

(4) "It is insufficient to present the endproduct and expect the beholder to perceive its structure by inspection or even deep meditation. Instead, the beholder must also see at least part of the programmer's thought process, starting from the original (very abstract) version and proceeding to the end product via a clearly presented sequence of clear transformations and refinements." Denning.[3]

(5) "We have outlined three views of what a program should be. The final form of development is suitable for communication to a computer; a carefully documented sequence of forms is suitable for communication between programmers; a proven sequence of forms is suitable for communication to posterity." McKeeman.[4]

(6) "I now believe that it was a fundamental error to feel that we could think in a programming language." McKeeman.[4]

(7) "I would like to see the S.P. forum redirected towards a less hopeless task than finding the perfect programming language or formally defining S.P. itself. If we take the definition to be simply the construction of efficient, readable, understandable, modifiable, and verifiable programs, we can discuss ways to globally reach these goals by educating the people who do programming. Since it follows from the axiom that no amount of construct-clipping will make the typical graduate of a "data processing" school even a potentially good programmer, we must find something that will. What can be said to be the *proper* use of goto's, conditionals, and global variables (and block structures, pointers, etc.)? What are general guidelines to follow with respect to procedures? How does one go about modularizing a task?" Flon.[5]

The ideas in these quotes along with those expressed in the many papers dealing with programming and structured programming[7-12] form the basis for the following ideas in developing a beginning programming course:

a. The primary issue in programming is one of constructing a solution to a given problem to be programmed.

b. The solution should be "correct" and "readable." (Where correct means the solution solves the problem intended and readable means the form of the solution is "easily" understood by people.) Concepts of efficiency and reliability in programs come after correctness and readability. These ideas should come later in a more advanced course. However, a beginning course

* This work was supported by the U.S. Energy Research and Development Administration under contract no. W-7405-eng-82.

should promote practices which lead naturally to higher level considerations.

c. Constructing a correct and readable problem solution can best be done through a sequence of refinement steps starting with an abstract form and ending with a form easily translated into most any high level programming language.

d. In the refinement process problem solving constructs for constructing *well structured algorithms* are essential.

e. The purpose of a programming language is so that a problem solution can be expressed in a form understandable by a computer. A programming language is not often a good language in which to think or to document. It may be that expecting a programming language to serve both as a language (1) in which to think and (2) in which to make a computer understand is expecting too much.

A beginning programming course based on the above ideas has been taught since Fall 1974. This paper reports on the course contents and to some extent on its success as reflected by student and instructor surveys.

BASIC PHILOSOPHY FOR A BEGINNING PROGRAMMING COURSE

Based on the above, our approach to teaching programming was to focus carefully on what is essential to constructing a "well structured" solution to a problem in the form of an algorithm. What problem solving constructs are needed? Is there some hierarchy in such constructs so they can be developed naturally?

We divide programming into two parts:

Part I: constructing a "well structured" algorithm,
Part II: translating the algorithm into some programming language. (a program)

An algorithm is defined to be a problem solution, in the form of a sequence of statements which can be executed by a human using any devices at his disposal. A program is a problem solution in a form understandable by a computer. A "well structured" algorithm is to be a *correct* and *readable* one.

Dividing programming into the above two parts makes it possible to teach much of programming independent of any particular programming language. Part I is problem dependent and Part II is programming language dependent. In addition Part II can be taught by showing how to translate a particular Part I construct into appropriate statements in a chosen programming language. Thus the details of a language can be studied in the context of how to use it.

Our philosophy for a beginning course is to naturally develop problem solving constructs for constructing correct and readable algorithms and then show how to translate these into language statements in such a way to preserve the structure of the algorithm in the program. Thus we have "structured programming" in any programming language.

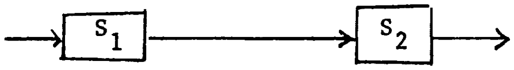
CONSTRUCTS FOR CONSTRUCTING ALGORITHMS

The details regarding the development of a set of constructs and pedagogically how to develop these can be found in Keller.[6] Here we shall list them along with some explanation or reasons for the construct. (All constructs are developed in context of a problem to be programmed starting with problems requiring simple constructs and progressing to the more complex ones.)

a. Basic constructs (or concepts): value, constant, variable, identifiers (names), expressions (operators and operands), statements, assignment statement, read and print statements. The crucial concepts here are the "ideas" of *a value, a constant, a variable* and of value and name association. Initializing values and assigning values form the basis for programming.

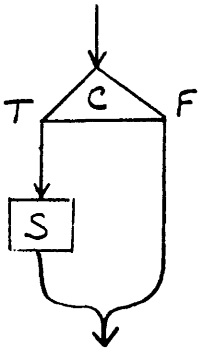
b. Decision making constructs (control mechanisms): an action (execution of a statement); sequence of actions, if-then and if-then-else constructs; while-do and repeat-until constructs. These constructs can be represented by flow diagrams and developed naturally in the following order.

(1) action 
(2) sequence of actions

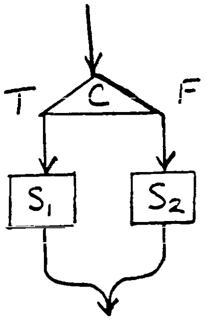


(3) if-then: *if* C *then* S

(Where C is a condition and S is a statement or sequence of statements.) The concept is to do S zero times if C is not satisfied (F) or once if C is satisfied (T).

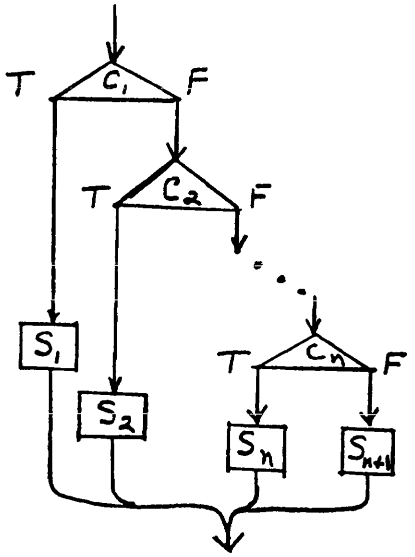


(4) if-then-else: *if* C *then* S_1 *else* S_2



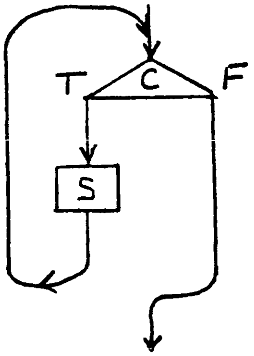
The concept is to do S_1 if C is satisfied; S_2 if C is not satisfied. Always one, S_1 or S_2, is to be done.

(5) nested if-then-else: *if* C_1 *then* S_1 *else if* C_2 *then* S_2 *else* . . . *else if* C_n *then* S_n *else* S_{n+1}.



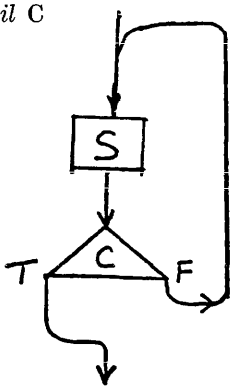
The concept here is to select one sequence to be done from many (more than two). This represents a natural extension of if-then-else.

(6) while-do: *while* C *do* S



The while-do concept develops naturally from if-then. If-then implies S is done zero or one time and the while-do extends doing S to more than once, i.e., iteration, while still preserving the idea of doing S zero or one time.

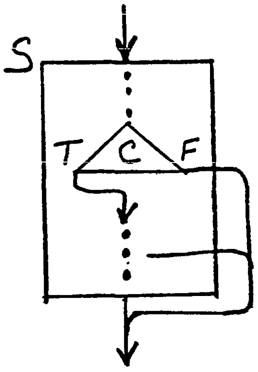
(7) repeat-until: *repeat* S *until* C



The concept is to do S repeatedly until C is satisfied.

These are the D and D′ structures (without the case construct) found in Ledgard and Marcotty[1] that have been studied by Dijkstra and others (See Reference 1 and references therein for further details on control structures.)

(8) repeat-forever: *repeat-forever* S



The concept here is to iterate forever through the sequence S which will contain one or more *exit* constructs of the form:

if C *then exit* or *exit* alone

Exit is always to the statement following S. In a beginning programming course there is seldom a need for more than two exits. This construct is a natural extension of while-do and repeat-until and obviously includes them.

c. Modularizing constructs: (Blocks and procedures). This includes:

(1) the concepts of local and global variables and how to specify their scope using some form of a declare statement;

(2) procedures as independent blocks with information passed through the formal and actual parameters. (This includes function procedures.)

The essential point for the student to understand is that modularizing comes naturally when one constructs an algorithm in a refinement fashion.

d. Data structures and value types.

Throughout all of the previous subject matter simple data structures (simple variables) are implicit. Iteration is developed by introducing a one-dimensional array data structure, introduced by considering a problem to be programmed. Multiple dimensional arrays and multiple dimensional structures are next developed. At this point the goal is that the student see clearly that developing an algorithm starts with his visualizing the data structures which are appropriate to the problem and naming these structures in such a way that he has names for substructures. He then must write statements involving these structures which when executed will solve the problem intended. The above constructs are his means of getting the job done through a sequence of refinement steps.

Character and Boolean values are next introduced again by considering appropriate problems. These data values give rise to taking a closer look at expressions, in the sense of operators and operands, and expression evaluation.

e. Verification of algorithms.

Throughout the refinement process of developing an algorithm, verification of each refinement step is heavily emphasized. Most of this is "hand" verification, testing decision points and iteration termination. In some cases simple proofs can be inserted to show a part of an algorithm (module) is correct.

Each refinement step is followed by the programmer proving the refinement is correct either formally or experimentally by hand execution with trial data. If great care in verification is taken, then a minimum number of bugs are introduced in an algorithm and programmer time is used efficiently.

Refinement steps and verification are never tidy. Many trial refinements are tried, determined to be incorrect by trial verification and replaced by other trial refinements. This is what programming is about; the student learns by doing. This is how he learns to *think* about the process of constructing a program.

TRANSLATING ALGORITHMS TO PROGRAMS

All the previous ideas are based on problem solving constructs needed for constructing algorithms which are correct and readable. These are essentially independent of any major programming language.

At this point any programming language could be introduced and studied from the standpoint of translating problem solving constructs into programming language statements. Of course it would be great if the major programming languages had these constructs. Unfortunately they do not. Someday major programming languages will contain these constructs, however, there will still remain some translation effort necessary for syntax reasons alone. In constructing an algorithm the programmer can ignore many details that a computer requires, but, a person does not. He can use indentation, one statement per line, etc. to make the algorithm readable for a person. Many of these human readable forms may never be machine readable. So some translation will be required for machine readability. The point is that *people read algorithms and computers read programs.*

The translation process is really not very difficult even for a language similar to FORTRAN. We illustrate translation to FORTRAN of the decision constructs using the FORTRAN logical IF statement: (These and other translations can be found in one of References 13-17.)

a. *if* C *then* S

```
        IF (C) GO TO then
               GO TO next
then  S
next  CONTINUE
```

Where *then* and *next* represent statement numbers and C must be translated to a logical expression in FORTRAN.

b. *if* C *then* S_1 *else* S_2

```
        IF (C) GO TO then
               GO TO else
then  S1
               GO TO next
else  S2
next  CONTINUE
```

(Where *then, else* and *next* are statement numbers.)

c. *while* C *do* S

```
while IF (C) GO TO do
             GO TO enddo
do S
             GO TO while
enddo CONTINUE
```

(Where *while, do* and *enddo* are the statement numbers.)

d. *repeat* S *until* C

```
repeat S
    IF (C) GO TO next
             GO TO repeat
next CONTINUE
```

(Where *repeat* and *next* are statement numbers.)

e. Repeat-forever translation is obvious. Exit translates to a GO TO *exit.*

Translations for variables, constants arithmetic expressions and Booleans expressions are straightforward. Procedures and functions procedures translate to subroutines and functions respectively in FORTRAN.

Blocks do not translate directly into FORTRAN; local variables must translate into global ones unless a subroutine or function is used for translation. Other programming languages avoid many of the FORTRAN translation problems.

While the above translations represent good ones they are by no means the only ones possible. These translations are the most natural and keep the structure of the algorithm present in the program. By use of comments in the FORTRAN program the translations can mirror even clearer the structure of the algorithm. Our experience has shown this is not of much use provided the final algorithm and selected refinements are maintained along with the program for documentation purposes; again the idea is that people read an algorithm and the computer reads a program.

SUMMARY AND CONCLUSIONS

This type of course in programming using FORTRAN has been taught to approximately two thousand students mostly non-computer science majors by large lectures (150 plus students) and small (25 students) recitations. Lectures met twice a week; recitation once a week. Fall 1974 was the first time.

General reaction from students has been favorable. For the first time in our experience students feel they are *learning* to program and feel they can. About sixty percent of the students reported in a survey that they felt "competent" to construct a program in FORTRAN. In a survey reported on by Krietzberg and Shneiderman,[18] in the preface of their book, only ten percent reported they felt "competent" to construct a program. It seems clear that the emphasis on constructing algorithms by refinement and verification is what makes the difference.

A total of five faculty members and more than twenty graduate assistants have been involved. With few excepts all agree that algorithm construction is most crucial and should be the emphasis in a beginning course. Most feel that regular size classes (about 30 students) would be much more effective than large lecture sections. It is very difficult to teach problem solving via large lectures.

Both students and staff feel that two languages are involved and this seems to create some difficulties for the student. The top students overcome this easily, but, others have troubles. It takes a while before the student realizes that the problem solving constructs are for thinking about the problem and its solution and the programming language is for translating into.

Further support for this type of programming course can be found in the conclusions of the paper by Ledgard and Marcotty.[1] We list their four points here. More detail can be found in their paper.

1. "From the programmer's viewpoint, theoretical results based on the conversion of one program form to another under restrictive conditions may not be practical significance."
2. "The need for higher level (above D and D′) control structures remains unproven."
3. "The utility of the goto is seriously questioned."
4. "The utility of D′ structures over D-structures is supported." (D-structures are: actions, compositions, if-then-else and while-do. D′ structures are: any D-structure, plus if-then, repeat-until and case statements.)

We feel all of these except the case statement are important for the beginning programming course. Case statements and other control structures (BJ_n, RE_n etc. See Reference 1 for definition of these and other control constructs.) should be introduced in a more advanced programming course.

In our approach the argument for or against the goto is quieted for the goto never appears in an algorithm. If used in a translation the goto mechanically causes the correct transfer of control specified by the algorithm. Thus program structure and correctness are independent of the goto. Readability is present in the algorithm refinement levels kept with the program for documentation purposes.

Instructional computer systems for higher education

by CHARLES J. PRENNER
University of California, Berkeley
Berkeley, California

and

ALFRED Z. SPECTOR
Harvard University
Cambridge, Massachusetts

ABSTRACT

In most universities, increased instructional utilization of computers by many departments has been the rule. With the associated diversity of instructional requirements and evolving hardware capabilities, the choice of a proper computer system for this environment has been made more difficult. In this paper, a review of the requirements for such a system is presented and the alternatives are analyzed in light of these requirements. It is shown that non-interactive systems are the least desirable educationally and furthermore, that the economic justification for their use is no longer as strong as in the past. In support of this, a description of an inexpensive interactive system currently in use at Harvard is given.

INTRODUCTION

With an increased need for instructional computing in higher education and tighter university budgets, educational administrators must determine which computer systems provide the highest educational benefits at the least cost. Questions of interactiveness, size and performance must be considered. They can only be answered by an analysis of the user community, of the various possible alternative systems, and of the costs of these systems in light of the conditions on a particular campus.

THE USER GROUPS

In order to determine the desirable attributes for an instructional system, a survey must be made of the various user groups and of their individual requirements. Unlike many systems where essentially one class of end-user is supported, educational systems typically must host a widely variegated user community.* It is convenient to classify the users into four categories: (a) those who utilize the computer for introductory programming courses, (b) users from intermediate and advanced computer science courses, (c) users from non-computer science courses utilizing the computer as an instructional aid or tool, and (d) users consisting of instructors and staff. Each group is analyzed in turn.

Users from introductory computer science courses

This group utilizes the computer to obtain a general understanding of the techniques of computer science. In this category are general interest students, future computer science majors and students from the physical or quantitative social sciences. Although it is true that the individual goals of the students may vary, most students share the same computing requirements. Mainly, they must all cover a large amount of information in a short time. They must also be given a broad and balanced view of the subject matter. Finally, because of their lack of experience, they require especially simple system conventions and a protected environment which provides for easy detection and correction of errors.

A computer system that suits their needs must be capable of supporting a suitably rich set of programming languages as well as providing reasonable conventions for their use. Since introductory students will undoubtedly make many mistakes, easy debugging of programs and clear diagnostics must be provided. Finally, as all neophytes have difficulty in coping with what appears to them to be convoluted conventions, these must be held to a minimum.

* Computer aided instruction, (CAI) *per se* is considered to be a different use of computers and is not considered in this paper.

Users from non-introductory computer science courses

This group requires a wide variety of languages in which to program and the ability to develop, debug and test programs as quickly as possible.

For example, students in this category may have courses in programming language design or implementation where it is necessary for them to obtain experience with the languages. Alternatively, they may be taking a course in algorithms and have frequent need to implement their solutions to problems. At this stage in these students' training it is important for them to be exposed to as many different programming situations as possible; the computer system should not give them a myopic view of their field of study.

Users from non-computer science courses

The members of this user group are learning both to utilize the computer as a tool in their respective fields by carrying out assignments which illustrate basic methods, and also to use library packages to aid them in their work. For example, students in this group may be in an econometrics or statistics class where they are performing sample regressions using library packages, or developing their own software to do this.

This group, being diverse, may yield many requirements. It is composed of future mathematicians, social and physical scientists and various kinds of applications programs are needed for their support. Thus, this group will also require a wide class of programming languages and a powerful library of applications programs.

Usage by instructors and staff *

These users typically have enormous time demands on them and thus require responsive, time-saving systems. It is essential for faculty to have the ability to develop pedagogical and applications libraries quickly and easily.

In terms of other requirements, those of this group may be correlated with the needs of their students. If the needs of the users in the groups described above are met, the needs of this user group will be met as well.

There are three main requirements in an educational computer system which can be distilled from the needs of the four user groups described above: (1) support for a wide variety of programming languages and applications libraries, (2) provision for quick program development and easy debugging, and (3) simple, sensible conventions.

It is important to note that *no* program execution speed requirements have been postulated. This is because repetitious and time-consuming program executions are not commonly found on the usual instructional university machine. While it is true that some students will utilize the computer to solve problems using library applications programs, the tasks tend to be small since the computer problems assigned in most courses are the minimal sized examples which demonstrate the desired principles or techniques.

Thus, system throughput is not critically dependent upon program execution speed. Rather, it depends on *program development efficiency* because constant program development is the activity which best characterizes the university instructional computer system.

ALTERNATIVE SYSTEMS

The needs of the various user groups may be met in different ways. The users may be supported on a variety of machines, each offering distinct facilities. For example, there may be the need for some special purpose computers to act as real-time laboratory aids or to be used stand-alone in an operating system course. However, the needs of most users will be supported either on non-interactive systems (batch) or on interactive time-sharing systems. It is to these systems that we next turn our attention.

Non-interactive systems

The non-interactive, or batch, machines are usually fast and capable of executing the largest programs. However, execution-speed/size efficiency is not obtained without a price. Batch machines are inefficient as a tool for program development, especially in an environment in which a large support staff is unavailable. In addition, they are unusable in situations where interactiveness is a requirement. Finally, in some sense, they are an improper model of a computer to present to the student, especially the neophyte.

As a program development tool for those learning to utilize computers, batch machines are very wasteful of both machine time and more importantly, human time. Associated with batch machines is the notorious *batch cycle*. This consists of the four step process which must be repeated numerous times while writing and debugging programs: (1) the program must be written or corrections made, (2) program (and job control cards) or corrections must be keypunched, (3) the card deck must be submitted and (4) the print-out must be awaited. This cycle is especially onerous in an instructional environment because students will make large numbers of mistakes, both conceptual and typographical. The latter mistakes are compounded by the fact that students *are not professional keypunchers*. Thus, the batch cycle will be repeated an excessive number of times even in the course of easy program development. This ties up both operator time, student time,

* The reader should note: that this paper is concerned only with instructional uses of computers in the university. If it is desirable to have the faculty and staff utilize the instructional machine for their own research purposes, the requirements can grow considerably.

and burdens the system with a constant influx of trivial tasks.

Further problems with program development are associated with the fact that debugging aids are necessarily static on a batch machine and therefore, they are not nearly as flexible as the dynamic aids on an interactive system. Again, this is an especially grave deficiency in a university environment due to the large number of errors that students will make.

In addition, the very fact that batch machines are non-interactive means that restrictions are placed on the flexibility of the system. Certain kinds of computer usage cannot occur at all and other kinds not very easily. For example, the batch machine is not usable in a laboratory situation where a student wishes to quickly analyze data necessary for an ongoing experiment. In other situations, it may be very desirable, though not strictly necessary, for the user to dynamically view the results of a program and be able to interact continuously with it.

The final disadvantage of batch systems is a psychological one. In using a batch machine, the student must necessarily learn of the computer as a static machine. The student sees the computer as a monolith which can talk only *at* him, never *to* him. Undoubtedly, this is a bad view to give to the student, especially the introductory student who may be uncomfortable with computers in the first place.

In summary, batch machines have the capability of executing large programs efficiently but provide an inadequate program development medium for students. They are restrictive in the kinds of tasks in which they are useful and are a poor model to present to neophytes. It should be noted, in light of the conclusions on the needs of the user groups, that the ability of batch systems to execute large programs efficiently is not extremely valuable on an instructional system. It is a capability which is not necessary for this environment.

Thus, the batch computing system does not fulfill the requirements of the user groups and is not a good choice as the basis of an educational computing system. This is not to say that batch machines do not have a place on campus. In the bulk of computer usage, efficient machine utilization is vital and batch machines can be used effectively. However, in contexts where there is almost constant program development and great diversity of needs, batch computers are not suitable.

There has been a variant on the batch machine which has given to the batch system some of the attributes of interactive systems. Systems like Wylber[1] have provided some degree of interactiveness and at the very least, allow the user to dispense with key-punching. To the extent that the system can provide interactive facilities, the system can meet the requirements described earlier.

Interactive systems

Although, interactive computing is an old concept in educational systems,[2] it is still rarely utilized.[3] The machines which are utilized for interactive computing are very diverse and encompass great differences in flexibility, machine cost, performance, and even interactiveness. Some systems have the capability of running in a batch emulation mode, while others provide no such opportunity. Some systems utilize only one language while others support many diverse languages. In this section, we classify the different types into four categories: (1) large scale time-sharing systems, (2) traditional mini-computer systems, (3) large mini-computer systems and (4) networked systems.

The large scale time-sharing systems are characterized by *many* simultaneous users, relatively large size and speed, and high flexiblity. In fact, the systems tend to be so large that many universities have too little computing to fully utilize a whole machine. Thus, the system must be shared with others. This can lead to high communication costs and other problems associated with an environment in which there is not complete control over the computing resource. However, as will be seen, from strict performance criteria, these machines do an excellent job of satisfying the educational requirements.

Since the large time-sharing machines are fast and possess large address spaces, they can run the most complex instructional programs. In addition, the large address space allows the use of many different language systems as well as the use of large flexible software designed to simplify the program development task. Furthermore, they can allow for any amount of interactiveness including on-line editing, dynamic program debugging, and graphics. Some systems even provide a batch mode in which more complex, time-consuming tasks can be run.

Of course, these machines do not have the efficiency advantages of the batch machines in raw execution power but as has been argued, this is wasteful in an educational (non-research) environment. In fact, it is argued here that even these large time-sharing machines, like the large batch machines, have built into them an amount of execution efficiency beyond that which is required in the instructional environment.

Traditional mini-computer systems have tried to provide the services of their large counterparts but with more restrictive environments and less powerful processors. Many systems have only a single language available, typically BASIC, and can handle between 5 and 15 users simultaneously. These machines have many of the advantages of the large time-sharing machines and thus satisfy some of the requirements of the user groups. However, they are not powerful enough to meet the flexibility requirements.

These machines are interactive and thus allow ease of debugging, instantaneous turn-around, and quick program type-in. However, due to both the restrictive-ness of the operating systems which run on them, the speed of the CPU and the restricted main memory size, they cannot support languages powerful enough for many users. For example, the "BASIC only" systems are suited for some kinds of programming but certainly cannot fulfill the requirements for an intermediate course in computer science.

Thus, these machines do not fulfill the requirements of the user groups because of their low flexibility. They are not a good choice for a university system.

Large scale mini-computer systems are based on the great advances in hardware technology that have allowed for the creation of much larger and more powerful mini-computers. Although many of these machines have limited processing speed and memory restrictions, they are much more powerful than the mini-computers which were available only a few years ago. We contend that one or more of these machines are sufficiently powerful to provide for almost all of the educational computing needs for a university. Typically, each can serve between 20 and 50 users, each user having the ability to perform a wide variety of commands and utilize a wide variety of languages.

The reason that this can be achieved is that most requests for service in the instructional environment are trivial ones which have correspondingly little need for raw computing power. Thus, a relatively large number of users can be supported on a system of only moderate power. Occasionally, some students' requests will be beyond the power of the system. But, in the authors' experience, the number of such requests is typically small. For these students, alternative arrangements can be made.

An approach that may be used in the future is to connect a number of large-scale mini-computers directly to a powerful central processor in a hierarchical network. If any of the mini-computers become overloaded, they may send some users' requests to the more powerful machine to be executed. In this way, reasonable response time can be maintained on the small machines. In addition, the small number of users whose computations would normally overflow the large-scale mini-computer systems may be accommodated.[4]

Thus, of the time-sharing approaches, only the use of the more traditional mini-computer based system does not meet the requirements of the user groups. If the university administrator is concerned with performance alone, the large scale time-sharing system would be his choice. However, as the cost of such a system may exceed the funds available, it may be necessary to choose among the other alternatives.

COSTING THE VARIOUS SYSTEMS

The university administrator, after taking into consideration the merits of the various kinds of computer systems, as discussed in the previous section, must choose between systems based on their educational cost-effectiveness. This determination is exceptionally difficult[5] and is a two part analysis. First, the cost per standardized resource unit must be determined. Second, the educational benefit per such unit must be evaluated.

If educational effectiveness per unit resource is not considered, it is possible for a computer system to appear to be less expensive than it actually is. For example, it is easily conceivable (and even expected) that a student may require more runs on a batch system in order to debug and test a program than on an interactive system. Thus, even if the batch system were to have a smaller cost per job executed, the overall cost of program development could be higher.

The difficulties in determining cost per resource unit are also considerable. The construction of a standardized unit with which to compare systems is in itself a difficult task. This can be seen to be extremely hard when comparing batch and interactive systems. However, even on a single system, it is difficult to present clearly the assumptions that go into the determination of some costs.

Thus, whenever a definitive assessment of the benefits and costs of a given system is made, it should be kept in mind that the task is extraordinarily difficult and that the results of any studies should be viewed cautiously. Finally, explicit specification of the numerous assumptions used in any study are required if the study is to have any meaning.

The authors' experiences have been with educational time-sharing systems. However, it has become clear to them that even when comparing and attempting to describe the attributes of systems in this category alone, the number of items which must be considered is very great with respect to the description of the costs of a given system, and of its attributes.

For example, on interactive systems, it is common to use *connect cost per hour* as the yard-stick of cost. This is usually defined by the following fraction:

$$\frac{\text{Initial Cost/Yr.} + \text{Operating Cost/Yr.}}{\#\ \text{Connect Hours/Yr.}}$$

where

$$\text{Initial Cost/Yr.} = \frac{\text{Hardware} + \text{Software Cost}}{\#\ \text{Years of Amortization}}$$

But, it should be immediately seen that this fraction can vary substantially, perhaps by an order of magnitude depending upon the interpretation of the various terms. For example, are actual yearly connect hours utilized, or some "reasonable" figure which could be assumed to be the maximum (or minimum) number available? Or is the "reasonable" number of connect hours based on raw hardware limitations or upon the maximum number of users which can obtain some reasonable response time? There are, of course, many more questions which could be asked.

It should also be noted that the cost from university to university can vary greatly. Perhaps, the university can support some percentage of the cost of the instructional machine by utilizing it for some research or some grants can be obtained to cover certain parts of its development. Also, there can be wide variations in the cost of the hardware from institution to institution.

Because of these difficulties, no attempt is made to provide a detailed cost comparison of various time-sharing systems. Unfortunately, this would be the only way to demonstrate that large mini-computer based systems are cost effective. But this would be difficult, in general, since there will be instances where circumstances particular to a given institution make a different kind of system more cost-effective. Instead, a detailed case study of the Harvard undergraduate time-sharing system is presented.[6,7] This system is one in which the authors have extensive experience and one which has been running long enough to provide comprehensive data. In the particular situation in which it is used, it appears to provide for extremely inexpensive instructional computing. It also appears likely that there might be many comparable situations.

A LARGE MINI-COMPUTER BASED SYSTEM EXAMINED

The present Harvard undergraduate time-sharing system (HRSTS) is utilized in the support of the computing requirements of most undergraduate courses, some graduate courses and a limited amount of research usage. Among others, courses in applied mathematics, economics, mathematics, engineering, music, and even Arabic utilize the system. The hardware used is a Digital Equipment Corporation PDP11/45 processor,[8] 240K bytes of core memory, a fixed head disk for swapping, 116 Megabytes of on-line disk storage for files, a high speed printer, card reader, paper tape reader/punch, 2 DEC-tape drives and about 28 terminal ports.

The operating system used is a modified version of Bell Laboratory's UNIX system.[9] The language processors currently in use on the system are 2 assemblers, 2 text editors, numerous high level languages including BASIC, FORTRAN, C,[10] PPL,[11] ECL,[12] and LISP as well as a wide variety of utility programs. The user command interpreter was specially designed for ease of use based on past experience with other time-sharing systems.

The system is operational 23 hours a day, 7 days a week with periodic maintenance disturbing this schedule somewhat. The load conditions vary from semester to semester. During the first semester, PPL is used heavily by the 400 students of Harvard's general introductory computer course. During the second semester, the assembler and LISP are most heavily used due to an intensive introductory computer course for more advanced students. During both semesters, FORTRAN and BASIC are utilized extensively by students dealing with numerical methods and due to continual system development, the language C is also highly utilized.

The system is operated by one full-time administrator and numerous "terminal watchers." The latter are students who are hired by the university to act as combination operators, programming assistants, and systems programmers. During most of the day, they are available. This is especially valuable for the large number of beginning users.

The use of terminal watchers highlights one of the cost advantages of the university owning its own system. The cost of the terminal watchers is low due to the lower cost of student wages and the fact that a payment from the university to a student is really an intra-university transfer payment which is not too costly to the university and very beneficial to the student.

The present operating costs for the system are sketched in Table I. It should be noted that the budget is inflated by four items: (1) the cost of the terminal watchers, many of whom would not be necessary if it were desirable to have only operators on duty during usual hours or if such personnel could be recruited from the teaching staffs of the courses using the system, (2) the high cost of having rented, high speed video display terminals, (3) the high cost of maintenance contracts with the various manufacturers (as opposed to in-house maintenance), and (4) the cost of having dial-up lines on the system. The latter cost shows that communication costs are a very important consideration in the overall costs of a time-sharing system. In a different environment, the costs could be reduced significantly.

The capital costs for the system have been amortized over a three year basis and come to approximately $50,000 per year. The amortization period is not based on the life expectancy of the system for the system is now 18 months old and there is every expectation that it will last considerably longer than an additional 18 months.

The system usage, over the Spring and Fall semesters of 1975, is shown in Table II. As can be seen, the total number of connect hours utilized during the year is 43,500. It is the belief of most people associated with the operation of that system that this number of connect hours is close to the maximum that the system can support.

Based on the *actual* connect hours of the year 1975, the connect cost per hour is approximately $3.20. It

TABLE I—Approximate Operating Costs for HRSTS

Item/Description	Amount
Terminal Watchers & Other Salaries	$41000.
Supplies	$ 5000.
Telecommunications	$ 9000.
Terminal Rental	$22000.
Maintenance	$13000.
Total	$90000.

TABLE II—Total Connect Hour Usage of HRSTS during 1975 by major usage category

Category	Spring	Summer	Fall*
Applied Mathematics	7685	—	300
Arabic	99	149	400
Biology	232	110	1100
Chemistry	1492	215	100
Economics	29	55	200
Engineering	496	115	300
Grad. School of Design	1028	10	1500
Independent Usage	1053	488	1000
Mathematics	753	93	300
Natural Sciences	297	28	8100
Physics	1159	575	300
Social Sciences	346	90	100
Statistics	362	11	500
Research	336	135	200
Sys Work/Term. Watchers	3288	1995	4000
Other	450	1270	800
Totals	19105	5339	19200

* projected based on Dec. 20, 1975 totals.

should be noted that this figure does not include an extraordinary once-only development cost of $50,000 for some of the system software. If the reader is concerned with duplication cost of the system, this figure should not be taken into account since most of the software is now freely available to other educational institutions.

HRSTS COSTS IN PERSPECTIVE

The determination of the relation of these costs at Harvard to real costs in other situations must necessarily take into account the following consideration.

(1) *Usage*—The system at Harvard is highly used, often in the very early hours of the morning. The impact of this is substantial on the connect cost per hour figure cited above.

(2) *Communication Costs*—At Harvard, there are many dial-up lines available. If the terminals are in one or more centralized locations on campus, the number of dial-up lines can be reduced substantially.

(3) *Overhead*—The costs given do not include the cost of utilities, room space nor the *de facto* use of some of the administrative structure of the Harvard University Science Center.

(4) *Operator Attendance*—The cost of operator coverage could vary substantially at other installations depending upon the availability of students to handle this function and the amount of coverage desired. It could conceivably be made the responsibility of teaching assistants.

(5) *Peripheral Hardware*—Considerable peripheral hardware exists at Harvard that might not be needed elsewhere. However, additional items might be necessary if real-time or graphics applications are desired.

(6) *Application Programming Costs*—These are specifically not included in the connect cost per hour figure cited above except to the extent that they are handled by the terminal watchers. In some situations, it might make sense to include these costs.

(7) *Amortization*—The period at Harvard is three years. It might be more reasonably set at five to seven years.

(8) *Specialized System Software*—Most of the software used at Harvard may be obtained free by other universities. However, the development of new software might be required for certain situations.

(9) *Hardware Advances*—The compatible Digital Equipment Corporation PDP11/70 processor[13] can support at least twice as many users without very great increases in cost.

It is possible to reduce the cost per connect hour to $0.50 per connect hour under favorable circumstances (no dial-up lines, operator coverage by teaching assistants, local maintenance, longer amortization, and purchased low cost terminals). Since most environments will differ somewhat from this extreme, the expected costs will be in the $1.00 to $3.00 range.

CONCLUSIONS

The low cost of HRSTS lies in the fact that the hardware is tailored to the needs of the users. Such systems utilizing large mini-computer systems, tend to be just powerful enough to support the vast majority of the users' demands. In the future, it is conceivable that a hierarchical network based on machines of differing power will be the logical extension of this. Easy computing tasks will be serviced by the simplest and lowest cost machines with the more diffcult tasks being passed on to larger machines.

This division will allow the cheapest machines to be utilized in most instances and the more complex and expensive machines will be saved for the limited amount of overflow. This approach will allow the benefits of the largest time-sharing systems to be coupled with the very low costs of the mini-computer based systems.

Today, a large mini-computer based system, not unlike Harvard's, can offer very low cost, flexible computing that satisfies most requirements for an educational system. The services provided by such systems are much more suited to the needs of the university user community than are those provided by batch or single language systems. Although not as powerful as the large scale time-sharing system, they are sufficiently powerful to satisfy the needs of most users. Furthermore, such systems can be run with very low cost, with connect costs in the $0.50 to $3.00 range.

ADP training systems—Organization-wide training for increased productivity

by JACK L. STONE and ALEXANDER P. GRANT
Computer Education International, Inc.
Washington, D.C.

ABSTRACT

In most organizations with medium to large computer centers, management attention is primarily focused on technological gains as the major method for improving data processing services and utilization. However, computer system productivity can also be increased through effective organization-wide training.

To improve on training currently available to most organizations—OJT, standard courses provided by the hardware manufacturer or independent suppliers, and self-study packages—a systems approach to training is suggested, named the ADP Training System (ATS). This approach employs proven systems methodology to plan, develop, and implement fully documented ADP training to improve job performance of all personnel who manage, operate, or use the computer center facilities and services. An ATS is tailored to meet specific needs of the organization.

ATS planning includes determination of organization needs, available resources, and program constraints. It documents objectives, scope, costs and master schedules.

ATS development includes course definitions, development schedules, and course materials development. It provides implementation schedules, instructor's guides, student materials, and support materials.

ATS implementation includes administration, execution of courses, evaluation and redirection.

After a discussion of ATS concepts, a case history of an ATS program which involved the authors is presented.

It is concluded that an ADP Training System provides management the planning and control capability to implement organization-wide training for new systems and technology on a cost-justifiable basis.

INTRODUCTION

As the use of automated data processing for commercial applications has become more and more widespread, it has become increasingly worthwhile to examine those factors that influence the cost/effectiveness of ADP systems. This paper addresses one such area: organization-wide training for increased productivity. It advocates the application of total system concepts to the development and implementation of training programs and presents an example of the use of those concepts in an actual situation.

In most organizations with medium to large scale computer centers, personnel costs exceed the costs for computing equipment and software; nevertheless, management attention continues to be focused on technological gains as the primary method for improving data processing services and utilization. Granting that processing costs can be substantially reduced with improved hardware technology, it is also true that the over-all effectiveness of complex data processing systems can be improved through effective organization-wide training.

However, in many, if not most, organizations, computer center hardware and software have surpassed the capabilities of existing programs to train personnel to manage, operate and use this technology. In many organizations ADP training is only available on an ad hoc basis, often unplanned, and provided as on-the-job training, instruction at a computer manufacturer's or independent supplier's education center, and self-study of textual or audiovisual packages. In short in many organizations, ADP training tends to be episodic, fragmented and directed toward the satisfaction of unanticipated needs.

After extensive experience as vendors of training services to many organizations such as those noted above, the authors have developed and implemented a systems approach to training that they call ADP Training Systems. The ADP Training Systems method employs proven planning, systems and training methodologies to produce a fully documented ADP training program that is directed toward improvement of on-the-job performance of all personnel who manage, operate or use the products of an organization's automated data processing system. Each ADP Training System is developed for a specific organization and has as its major objective satisfaction of that organization's training needs in a coherent, timely and economic manner.

An ADP Training System is an organization-wide program for the training or re-training of personnel to meet new or changing job requirements that are occasioned by changes in the scope or level of automated data processing technology available to the organization. It is concerned with a broad range of personnel, including: top executives; middle management; project administrators and supervisors; users; systems analysts; applications and systems programmers; and operations personnel. It is characterized by an orderly, planned process of installing an effective operational training capability to support all of the training needs of the organization in an economic, efficient manner.

The scope, complexity and depth of penetration of a specific ADP Training System is dependent on the size, complexity and needs of the specific organization for which it is intended. In any case, to some extent it always includes three functions:

(1) Planning;
(2) Development;
(3) Implementation.

Planning—This function includes determination of: the organization's training needs; the resources available to support a training program; and the considerations and constraints that must be taken into account in developing and implementing the ADP Training System. The function's outputs are a set of planning documents that define: the objectives of the ATS; its scope and content; its probable cost for development and operations; and the estimated timeframe for development and operation of the ATS.

Development—This function includes: definition of the individual training courses required; setting development schedules; selection or development of course materials. The function's outputs are: a program implementation schedule; instructor's guides; student materials; class schedules, class announcements and other ancillary materials.

Implementation—This function includes: administration and execution of individual courses; evaluation of students, instruction, and overall system operation; modification or re-direction of the system as needed.

PLANNING FOR AN ADP TRAINING SYSTEM

In order to do a creditable job of planning for an ADP Training System, it is necessary that the planner have a reasonable understanding of the goals, activities and organization of the company or agency for which the ATS is intended. The normal investigative and analytical techniques used in any system study are applicable to this problem. Once the organization itself is understood, the ATS planner can move toward definition and documentation of the organization's training needs and objectives.

The fundamental goal of training in any organization is, or should be, to improve performance on the job. Specific, more detailed, objectives flow from this goal. Any departure from this goal will necessarily result in a decrease in the cost/effectiveness of the system. Courses of an academic nature, while useful in the long range, do not necessarily support the organization's operational objectives and are, therefore, difficult to justify. It is more cost/effective to encourage individuals with academic interests to pursue course work at a local college or university.

Training, within the operational organization, for both technical and non-technical personnel should be oriented to specific job functions and particular ADP applications. With this strategy, both management and employees can better understand the value of ADP training: management can more easily evaluate the financial investment in terms of increased personnel productivity and the ability of personnel to handle increased responsibilities; employees can more readily accept the training as a vehicle for improved performance on the job, self-development, career enlargement, and professional growth.

In addition to satisfying the basic goal of improved job performance, an ADP Training System should be tailored to meet the special needs of the organization, including: selection of topics to relate the instruction directly to the installed or anticipated computer configuration; development of computer-oriented student problems; off-hour or part-day scheduling of classes to accommodate the regular workload of the students; and, when appropriate, the development of case studies based on actual experiences at the installation.

Planning for an ATS should also include consideration of factors that influence training costs. In the authors' experience, appreciable cost savings can be effected through implementation of training programs on-site which allows use of installation-owned classrooms and equipment for instructional purposes and eliminates student travel expense and idle time. For an on-site course, $50 per student for each instructional day* appears to be an achievable goal for groups of 12 or more. This number should be contrasted with $75 to $150 a day per student at typical classes held by manufacturers and producers of commercial seminars.

Some other considerations that bear on the development of a plan for satisfying the training requirements of an organization faced with technological change, relate to the training curriculum. First, training must be implemented for all personnel categories involved with the computing center or using its products. Such training may range from a two-hour seminar for top executives to a six month case study in systems analysis and design. Training should not be limited to tech-

* Six classroom hours

nical professionals, i.e., analysts and programmers, but should be extended to technician-level personnel, i.e., coding clerks, computer operators, tape librarians and so on, and to users, managers and executives. In addition, each training course should be related to a specific personnel category. Courses should be organized as a progressive sequence of formal classroom instruction, interleaved with practical OJT assignments as appropriate. Refresher and review courses of short duration should be planned to provide technical updates, answer questions regarding current operations and future plans, and to minimize the normal tendency of individuals to drift away from established systems and procedures.

The outputs of this developmental phase consist of a set of planning documents, including:

(1) A statement of the objectives of the ADP Training System;
(2) A description of the course content of the ADP Training System;
(3) A summary estimate of the resources required for the ATS including a cost estimate for each major class of resource;
(4) A proposed schedule for the ATS;
(5) An outline and summary for each course including planned OJT segments. The documentation for each course should include:
    —The behavioral objectives of the course.
    —A profile of the typical target participant including: prerequisite training and experience; current work assignment; and proposed work or job functions to be assigned at the completion of the course.
    —A topic outline of the course content.
    —A description of the proposed instructional methodologies for the course.
    —A description of student materials.
    —A proposed schedule for the course.
    —An estimate of the resources required for the course including a cost estimate for each major class of resources;
(6) A plan and schedule for development and implementation of the ADP Training System.

The completed ATS planning package is presented to management for review and concurrence. Any needed revisions to the plan should be made before proceeding to the next developmental phase.

DEVELOPING AN ADP TRAINING SYSTEM

Upon acceptance by management of the ATS plan, the ADP Training System package may be developed and documented. The major outputs from this activity are:

(1) The ADP Training System Catalog;
(2) Course announcements;
(3) Structured training course packages.

The ADP Training System Catalog is an edited version of the approved ATS plan. It is in a form suitable for distribution to prospective students. Publication and distribution should be in accordance with normal policies of the organization. Course announcements are extracted from the catalog as needed.

The structured training course package consists of two major components: the instructor's guide with its supporting materials and the appropriate student materials. The basic instructor's guide is composed of:

(1) A narrative exposition of behavioral objectives, content and instructional methodologies;
(2) A course schedule;
(3) A listing of student materials;
(4) A set of lesson plans which set forth a detailed description of: instructor activities and instructional aids; the instructional content of the unit; lesson objectives; and student activities.

Appropriate student materials are developed or selected and procured, and are coordinated with the instructor's guide.

IMPLEMENTING AN ADP TRAINING SYSTEM

Implementation of an ADP Training System consists of system administration and course presentation. The system administrator need not be an educator or teacher, but he should have a firm grasp of the objectives of training and of good administrative practice. His functions are to: select or approve instructors; announce courses in a timely fashion; administer the student selection process; assure the availability of needed facilities, materials and equipment; evaluate overall system operation; and prepare appropriate management reports.

Instructors should be selected from professionals in the data processing field who have achieved a reasonable balance among technical experience, instructional experience and communication skills. Experience has shown that instruction in technical subjects requires an unusually high degree of instructional talent which includes not only a good background in the subject matter, but also a high level of empathy with the students.

It is important that the ADP Training System and its constituent courses be properly announced and supported to insure that all prospective students and their supervisors are aware of the available training opportunities and can have the time necessary to plan for their attendance. Elements of the announcement strategy include: letters from the chief executive requesting support of the training function by line management; the early distribution of the ADP Training System Catalog; briefing sessions for prospective students to explain the program or courses and to answer their questions; course announcements through bulletins or other communication media in the organization.

Each prospective student for each course should be screened to assure that he satisfies course prerequisites and that his post-training assignment will be appropriate. In addition, the system administrator should assure that each student's current work schedule has been adjusted to allow class attendance.

Effective training requires that students receive all documentation appropriate to the subject matter. For example, students training in hardware/software technology should receive personal copies of appropriate technical manuals; students in introductory courses should receive text books written at levels commensurate with their capabilities, e.g., executives should receive texts written at a general level. Other student materials such as charts, diagrams, templates and the like should be distributed as needed.

Audiovisual materials can be valuable instructional aids. Such aids reinforce textual and oral presentations and provide an enlivening change of pace. However, such materials must be integrated with other course activity: each audiovisual segment should be both introduced, and followed up by the instructor. The system administrator's responsibility in regard to audiovisual support is to assure that both materials and any required equipment are available when and where needed.

It is important that administration of the ATS be handled just as any other project; therefore, the training administrator should prepare periodic management reports regarding overall performance and adherence to budget.

In the authors' experience, classroom operation is most successful when well structured and tightly disciplined. In this approach, daily quizzes based on outside reading assignments and the previous day's class work provide a sharp focus on the instructional content of the course. Each class session starts with a quiz which is then corrected immediately in a process that provides the framework for discussion and clarification of the previous session and reading assignment. The extensive testing is used primarily to reinforce learning and to provide the students immediate goals for learning. It is only secondarily used for evaluating student progress.

As appropriate, many instructional methodologies are used, including: oral presentations by the instructor; audiovisual materials; laboratory exercises and workshops; and outside reading or project assignments. The particular methodologies used in a specific course are dependent on course content, course scope, and the type and level of persons being trained.

A CASE HISTORY

This case history involves the ADP Training System that was established for a large federal agency that was upgrading its computer capability. Its second generation equipment was being replaced by a large third generation computer with advanced software support and remote terminal and RJE capability. Implementation of the new system was contracted to an industrial firm who provided on-site technical assistance, system development, computer center management and training. The implementation plan extends over a five year period.

In the early years, the training plan was to provide basic technological training and to develop an in-house training capability. It is intended that the contractor will gradually phase out as agency personnel become capable of picking up responsibility. At the end of five years, it is intended that the agency will be managing all aspects of its operational and training program.

The original plan called for training programs to be set up for approximately 100 programmers and analysts, 50 computer operators and support personnel, 350 terminal users and operators, and 150 executive and middle management personnel. The initial training period extended over approximately 18 months ending in December, 1975. The original plan called for approximately 500 days of instruction over this period. The authors' company participated in a substantial portion of the technical training of personnel.

Although the program was reasonably successful, some areas of possible improvement are documented for future reference. Such comments relate only to segments of the program that were produced by the authors.

At an early date, a master plan and schedule was produced by the prime contractor and accepted by the agency's management. This plan had a reasonable array of courses scheduled in progression from basic to more advanced training. The authors' company was engaged as a subcontractor to produce courses to meet the plan's specifications.

These courses dealt with four training areas:

(1) Systems programming;
(2) Programming languages;
(3) Operator training;
(4) Terminal user training.

The systems programming training consisted of thirty instructional days presented over a four month period. This schedule permitted students to attend class part-time and to perform their regular assignments during out of class hours. The instructional goals were met, but not without difficulty. The students' job assignments imposed a heavier and heavier burden as the application conversion program proceeded. Additionally, the four month time frame tended to dilute the instructional impact of the course. A better result would have been attained by organizing the content of the course into two or three courses of shorter duration.

The courses in COBOL, FORTRAN and JCL were only partially successful. Although the courses were announced with appropriate prerequisites, no significant controls were exercised over attendance. As a result many students did not meet the prerequisites and had great difficulty with the course. Additionally, many students lacked any real job-connected objective to be met by this training, that is, neither current nor prospective job assignments required use of the knowledge and skills to be attained by successful completion of training. The presence of a substantial number of such individuals in these courses seriously compromised the effectiveness of the training.

The objective of the three day operator training course was to indoctrinate second generation computer operators and production control personnel with third generation ADP system concepts. The presence of production control personnel in this course presented some difficulties since, in contrast to the computer operators, they had little prior ADP training. In any case, training for computer operations personnel is a complex problem, because such personnel represent a wide range of interests, backgrounds and capabilities, and frequently lack the motivation and study skills needed for mastery of complex technical subjects.

Terminal user training, presented in a four day course, was quite successful. The course, intended to introduce administrators and professional personnel to the use of remote terminals to access an inter-active programming system and an on-line data base management system, was of sufficiently short duration so that student interest was easily maintained. Since this was an introductory course, the divergent backgrounds and objectives of the students did not constitute a severe problem; however, in the future, the course outcomes could be improved by grouping individuals with similar interests into separate classes. In this way, both the instructor's presentation and the workshop sessions which are an integral and important part of this course could be more specific to each group's interests.

Many of the problems encountered in producing the courses discussed above, flowed directly from a lack of strong, sustained management interest. At the beginning of the program it was recognized that an inhouse training capability was required. Four full-time agency people were initially assigned to the program; however, after a short time, management decided that those individuals were needed elsewhere and the inhouse training function was abandoned.

This shortfall in management interest was strongly felt, since the training courses that made up the program were provided by four different organizations. Lacking strong program administration, each provider interpreted the plan in its own way and handled its part of the program in its own style. The overall effect was that the benefits realized from this ADP Training System were less than might have been reasonably expected.

Nonetheless, much about the ADP Training System was right: the organization's training needs and objectives were properly defined; a realistic and effective training plan was documented; a large number of good training courses were developed and implemented. The shortfalls in the student selection process and in program administration should not be allowed to obscure the very real benefits produced by this ATS.

Teaching art through computer graphics

by JOSEPH SCALA
Syracuse University
Syracuse, New York

ABSTRACT

The computer is becoming an important tool for the production of works of art. Art students are becoming increasingly interested in tapping the potential of the computer in the area of static and animated graphics. This paper deals with my personal experience in teaching art through computer graphics, at Syracuse University, to art majors and students from other academic disciplines.

A very exciting experience for me in the past two years has been establishing a computer art division within the department of Experimental Studies in the College of Visual and Performing Arts at Syracuse University and teaching a number of very enthusiastic students from a number of different academic backgrounds.

Students have access to the Syracuse University Computer Center, with the following hardware: an IBM 370 computer, the DEC-10 system with 128K core and a VB10-C display, two high speed line printers, six ADDS CRT terminals, 100 DEC writer terminals, a 14 inch Cal-Comp drum plotter and a 33″ Cal-Comp drum plotter with three pens. Students may use these facilities in conjunction with the university's video, film and animation studios. Art and science students have accepted the computer as a viable tool for the creation of art. Not all students have reacted positively, but the vast majority of students discovered a positively fantastic environment to create in, bringing together the blissful marriage of art and technology.

The computer may be the universal tool, not only a device for scientific and engineering progress, but a tool for artistic progress as well. The computer is malleable, like clay, making it a perfectly applicable medium for manipulation by artistic minds and hands. Naturally, the digital computer alone cannot create art. Artists need hardware and software they can understand. Fortunately, there have been a number of ingenious software systems designed for them. The two principal systems that most of my students use at this time are MINI-EXPLOR and PSPLAT.

MINI-EXPLOR was created by Ken Knowlton and the name EXPLOR stands for the production of images from **E**xplicit **P**atterns, **L**ocal **O**perations and **R**andomness. MINI-EXPLOR is a FORTRAN coded version of the EXPLOR language which allows the student to become familiar with many of the FORTRAN language subprograms and other FORTRAN details from a graphical point of view. The paper output is 132 spots wide by 140 lines long. The display output is 1024 points x 1024 points using run length vectors which are multiply interlaced.* Each individual image can be produced as many times as the artist wants and each individual point or area of points can be changed explicitly or changed randomly by the student's program. There are also subroutines which allow for growth and combination patterns. The graphic output produced on unlined white paper is immediately suitable for framing and editions can be run off in a matter of minutes. In addition, other media such as paint, pastels, different colored line printer ribbons and photography can be combined with the graphic output to bring the images into yet another visual plane. Taking a photograph of the printer output image, developing the negative, making a kodalith from the negative and applying that to the production of a photo-silk screen, photo-lithograph or photo-etching have produced dramatic and colorful prints.

Images generated on the display can be filmed in single frame to produce an animated sequence. The film can then be placed in a film chain in the television studio and these images can be manipulated through the special effects generator, resulting in a color video tape which can then be kinescoped if desired.

Some students prefer to generate sequential images on paper output and single frame each image in our animation studio using the Oxberry animation stand. The advantage of this technique is that the artist can add hand-done animation to the computer graphic, adding other media and images as well as color, giving surprisingly unusual results.

MINI-EXPLOR produces output in four level grey scale. The total grey scale in a single image is easily

* Rather than the conventional video scan-line ratio of 1 to 2, this system uses a ratio of 1 to n.

separated into three images containing one grey level each, with a simple program, allowing the student to add optical color through filmic techniques to his or her animated sequence.

In addition, MINI–EXPLOR designs are beautifully suited for making rugs, weavings, textiles, needlepoints, collages, and relief sculpture.

I have found that in the beginning of my course those students who have a background in FORTRAN and mathematics, usually the computer science and engineering students, are able to produce more interesting designs with greater facility than the art students, who usually have not more than one year of high school algebra and no programming experience. Eventually, there is a leveling off point and then art students begin to excel.

In the second semester of the course art students reach a point where they can begin to use the language effectively enough to establish a personal style. With MINI-EXPLOR this often requires the creation of the student's own subroutines and the delineation of a clear and purposeful aesthetic concept. Even then the imposed stylistic format of the software gives the work a certain 'EXPLOR' character but this becomes less important if the concept is strong. The hardware also contributes a stylistic character to the output but the artist is free to mix media and in this way, if he or she wishes, can effectively eliminate any reference to the software or the hardware to suit the aesthetic concept.

Two other factors that students can capitalize on when using MINI-EXPLOR are the built in random number generator and the 'expand' program which was written by David Carr, a computer science major, at Syracuse University. First, the random number generator activated by the MINI-EXPLOR function NE (Min., Max.) used in a program can lead to interesting designs not necessarily predictable in advance. Here the art comes in by making the right choice of what works and what doesn't work in the final image. Chance has often played an important role in artistic creation and can be used as a valid parameter in creating a work of art.

Second, the 'expand' program enables the student to enlarge his or her line-printer image to any proportional size by joining the side edges of the standard line-printer paper together for the increased width. The only limiting factor is how much paper is available. This property adds an exciting new dimension to the MINI-EXPLOR system and to computer graphic art in general. One advantage of our MINI-EXPLOR system is that for a non-real time system, it is fast on returning images. This is very important in teaching traditionally trained art students who aren't used to waiting around to see what they have created. Using TTYOUT, the DEC-writer terminals return the hard copy image almost immediately so the art student can make the necessary visual critique of the work and proceed to modify the results through further programming or by hand. Designing on a display is even faster, waiting on line for over an hour for a printout is very bad and quickly discourages the creator.

I have found that art students who enjoy writing programs tend to stay with MINI-EXPLOR and desire to delve deeper into how the total system works from a programming point of view. MINI-EXPLOR motivates art students to want to create their own language for their own personal visual statement and gives science students an opportunity to apply his or her previously acquired programming skills for a purely aesthetic purpose. The science and engineering student is able to create visual images, using a familiar medium which relates directly to his educational and personal experience, without spending long amounts of time trying to master a traditional art skill which requires the traditional art talent. By this method the aesthetic experience has a direct transfer to the student's daily technological involvement.

MINI-EXPLOR is also an excellent software system to teach FORTRAN programming graphically to anyone.

PSPLAT is a FORTRAN program written by Richard H. Blocher of Washington University, St. Louis, Missouri, and more or less simulates another program, SPLAT, which was written for artists by John E. Skelton and Daniel J. Donohue at the University of Denver. SPLAT stands for Simplified **Pro**gramming **L**anguage for **A**r**t**ists.

PSPLAT (poor man's SPLAT), is a simple non-numeric computer language which is an excellent software package for introducing art students to computer graphics and should be used as an introductory course. The language uses statements composed of words which the artist can understand in terms of non-technical language. Everything is categorized by commands under headings like Creation, Manipulation, Looping, Branching, etc. which eliminates the need for the art student to go through tedious programming details. The output is principally by cal-comp plotter but we have output on our display as well, and this system has animation capabilities. We run PSPLAT by batch on the IBM 370 computer and MINI-EXPLOR on the time-sharing DEC-10 computer. This gives the art student the experience of using both types of systems. With PSPLAT the art student is working with a pre-defined symbol, such as a circle, square, polygon or line and draws and manipulates these symbols by writing a program, which is closer in concept to the way a traditional drawing is made. The art student can often visualize his or her final design in his or her 'mind's eye' making the process very comfortable for the student and a friendly rapport is established quite rapidly between the person and the machine.

In many cases the designs generated with PSPLAT are extremely complex and would have taken much more time if they had been executed by hand. The creator is thereby freed from doing the work and has more time to devote to thinking about developing new concepts for design possibilities. What often results is that the final images would not have been possible using traditional media.

I call PSPLAT a closed system because it doesn't lend itself easily to change by adding additional subroutines. MINI-EXPLOR, on the other hand, is an open system and encourages the addition of subroutines.

What is remarkable about using PSPLAT is that art students have been able to develop individual styles fairly quickly and neither the software nor the hardware has greatly hindered this stylistic development.

As I mentioned before, art students who turn on to programming in FORTRAN and get aesthetic satisfaction out of the programming challenge continue working with MINI-EXPLOR. Students who prefer a more traditional output continue with PSPLAT, and some art students choose to work with the system which can best provide the desired results for their aesthetic concepts.

The limitations of the software and hardware have not greatly hindered the development of individual style and the results can or cannot have a computer-made look, depending on what the artist wants. All media and materials impose certain limitations on the artist in the same way that the computer does. Whether the visual images generated by a computer system will ever constitute a major art movement remains to be seen. But when the artist transcends his media and materials with his unique personal vision and strikes human chords of sensuality, existence and human essence, we get art. I believe a number of my students have created art with the computer and this strengthens my belief that the computer is the most important technological achievement that has been made for the arts and will affect the course of art greatly in the future.

There is still much to be done in terms of hardware and software for the arts. Computer systems have to be designed to respond with greater sensitivity to the artist's sensitivity and expectations. I believe, at this time, that the major interest in computer graphic science is in the area of moving graphics for film and video, but static art is still the major movement in the art world and computer graphic science can contribute greatly to the future of static art images.

Artists are always searching for new forms and new ways to express their visual concepts. To use the familiar pleases the masses and saddens the individual. I believe the computer has the potential to provide new ways for the artist to create new forms, and I am looking forward to the computer becoming a standard studio tool for the creators of the visual image.

Oswego, New York

ABSTRACT

This paper deals with the use of computers by artists as a means of aesthetic expression, considers several theories of the validity of art created through the assistance of computers, and discusses the author's personal reasons for beginning to use the computer as an artistic tool.

Sometimes, in the eyes of the uninitiated public, there is a vast dichotomy between artists and persons who use machinery, particularly electronic machinery such as the computer. Artists, according to public opinion, are intuitive, somewhat irrational, almost always illogical, often slightly eccentric, and create by some internal inspirational force, some muse, which takes the artist by the hand and leads him or her to the ecstasy of the act of creation.

Scientists, and especially those scientists who work with computers, are often considered to be highly rational, totally logical, definitely non-eccentric. Computer scientists create through a completely intellectual comprehension of the tools with which they work, with inspiration a folly to be tossed at the artist.

Contrary to popular opinion, and quite fortunately, none of this is true. At least, none of it is *entirely* true. Sometimes artists create with a high degree of logic and intellectual rationality. Often the work done by computer scientists, even in the writing of new programming languages, borders on conceptual art.

In reality, there are few differences between artists who use computers and computer scientists who use computers, except in the intent of the user, and in the knowledge of the software and hardware being used. Computer scientists use the computer to solve previously insoluble problems, to do mathematical modeling, to illustrate phenomena which could not be illustrated in any other way—for a multitude of scientifically necessary reasons.

But why do artists use computers?

Throughout the history of art, the artist has sought new means for expressing ideas. Many of the ideas expressed through art, and the tools used in the expression of these ideas, have been direct reflections of the existing ideas and tools in the society in which the artist lived. Take Michelangelo for example. If he were living in this country today, he would probably have painted "The Creation" on the walls of the White House instead of on the ceiling of the Sistine Chapel. Only it wouldn't have been "The Creation." It would have had a Bi-Centennial theme.

Paint itself, long taken for granted as a tool for artistic expression, was at one time many centuries ago, a new technology.

So the artist adapts.

Today we live in a highly technological society. We have quietly gone out of the Age of Machinery and discovered ourselves plugged into the Age of Electronics. Everywhere we look, we are surrounded by the ramifications of the two most pervasive electronic devices ever created: television and the computer. The influence of television is more apparent to persons in the general public; approximately ninety-seven percent of the homes in the United States have at least one television set. In fact, our country boasts of more television sets than toilets. It has become, for the masses, an accepted medium, and a very visible one. For this reason, it is non-threatening to a person in the general public, although, for the intellectual elite, it is often a very real problematic threat. The entrance of the computer into the lives of Americans has been more subtle. To the uninitiated, the computer is a techno-monster which messes up bank statements, puts erroneous amounts of money onto paychecks, and generally terrifies the mass public, who see it as a machine which could ultimately overthrow humanity.

It is, of course, none of these. The computer, programmed by persons who know how to do so without error, is one of the most important tools of learning that has ever been invented. It can, essentially do anything the intelligent programmer wants it to do.

An artist living in this highly technological, electronic world has basically two choices as to how he or she will handle aesthetic expression. The artist can either choose to ignore these new electronic tools, and deal only with traditional tools of art, thus making the statement that electronic means of artistic expression are invalid and anti-art. Or the artist can choose to use these tools in an attempt to create thus-far totally new imagery, or in an effort to prove that electronic technology can indeed be humanized.

It is my feeling that the artists who are currently tackling the new technologies to create art are making the most significant contribution to the world of art, despite the fact that most art critics disagree with this theory.

Poet T. S. Eliot, in an essay entitled "Tradition and Individual Talent," offered a definition of art which stated that a work could be considered art if it, first of all, fits into some prior tradition of art, and secondly, if it adds something new to this tradition which significantly changes the tradition of art.

Artists who ignore the computer and television are fitting into the established tradition of art; through ignoring the technologies with which we live, however, they are adding precious little to this tradition.

Artists who are using the computer to create aesthetic statements are obviously adding something new to the tradition of art, not only through the types of imagery they are able to achieve, but also through the use of a totally new tool. And contrary to the arguments of many artistic traditionalists, computer artists do fit into the general tradition of art. Static computer graphics have a parent in painting; still graphics can be judged aesthetically by the same standards that static art has been evaluated through the centuries. Animated computer art also has a place in the general tradition of art. First of all, good computer animated art, whether it is implemented in film or video, also fits into the tradition of painting, since each single image in a computer animated piece is carefully composed, utilizing juxtapositions of color, form, perspective and planar relationships. Computer-animated art also fits into the tradition of film, and, through its often mathematically choreographed imagery, into the tradition of the fluid movement of music, albeit visualized music.

The field of computer art is still too new for a solid aesthetic to have been formed, stipulating which computer-assisted art is truly art and which is merely interesting experimentation. Some basic ground rules can, however, be stated. First of all, the intent in the creation of the work can be considered. If a person manipulating computer imagery intends to create art, his or her work must at least be considered for artistic judgment. If, in addition to this, the finished computer-assisted art presents to the viewer imagery which is new, unconventional and visually interesting, it deserves further consideration as art.

Also, in the art world, it is common knowledge that if other artists accept a piece of art as aesthetically valid, it takes still another leap toward being seriously considered art. If, therefore, artists relate to a piece of computer-assisted art, it has gone one more step toward qualifying as art.

Problems do arise, however, in evaluating computer-assisted art. Although some artists using the computer have a strong understanding of the internal operation of computer hardware and software, there are many more who do not and who are, therefore, compelled to create their art in collaboration with a computer scientist or programmer. This in no way invalidates the value of the art, although, in the communication process between artist and computer scientist, many difficulties in language must be overcome. For example, an artist might say to a computer scientist, "I'd like a piece of film which bursts forth from an epicenter, then moves around in circles for a few minutes, then swirls across the screen in something that looks like a tornado." How does the computer scientist translate this into a viable programming assignment? With difficulty. But it can be done, and often the results are far more striking than if the artist had manipulated the imagery alone, since the scientist can add his or her own knowledge of what can be done with the computer, thus adding dimensions that the artist might never have conceived alone.

Another parameter to consider in discussing computer art is the fact that some of the most aesthetically beautiful computer-generated imagery has been produced by scientists as an offshoot of their scientific inquiry. Since the intent in the creation of this imagery was not to create art, it probably cannot be considered art. But increasingly, as computer scientists see the beauty, as well as the scientific validity, of the output they produce, these scientists are making choices that certain of their images are indeed artistically valid, and therein enters the intent to show art.

What seems to be happening is that artists using computers are becoming more knowledgeable in the field of computer science, and computer scientists are becoming more aesthetically aware. Soon there may be a point at which computer scientists are computer artists, and computer artists become competent programmers.

My personal involvement in computer-assisted art arose as an offshoot of my work in video. I discovered that, using video alone, I was unable to obtain the types of imagery I visualized. The computer gave me a new means of creating visual input for my video tapes. I personally have chosen not to use straight computer-animated input for my video tapes; in order to produce the imagery I envision, I utilize computer input on film, then do video-graphic manipulations on this imagery. Some of my finished pieces retain the quality of the original computer-animated input; others have been so manipulated through video techniques that they no longer retain the look of computer graphic animation.

Whatever techniques artists choose to use in their manipulations of computer graphic art, it seems that the computer has become one of the most useful tools available today to the artist who is in tune with his or her times.

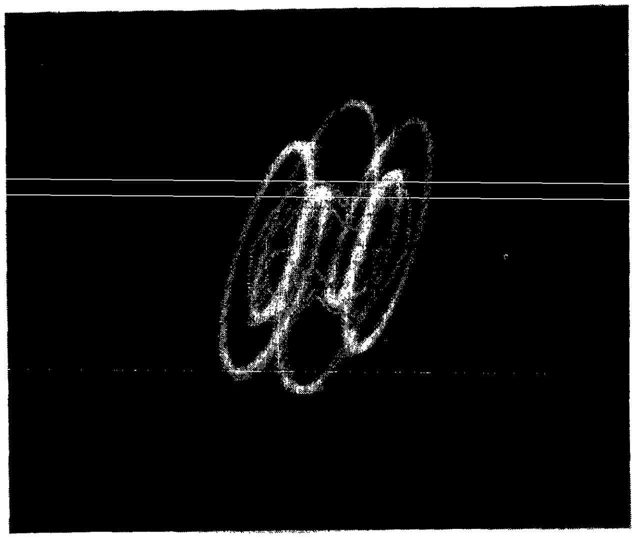

Illustration I—From SCOPE I, videotape by Patsy Scala. In this piece, fewer videographic manipulations were introduced in converting the analog computer imagery to video. The work retains much of the original quality of the original computer animation.

Illustration III—From WIPEPOEM, videotape by Patsy Scala. In this piece, red, green and blue refracted laser light was distorted by analog computer voltage and videographic manipulations. The piece retains little of the look of computer animation; yet it can be judged compositionally by the same standards that traditional paintings are judged.

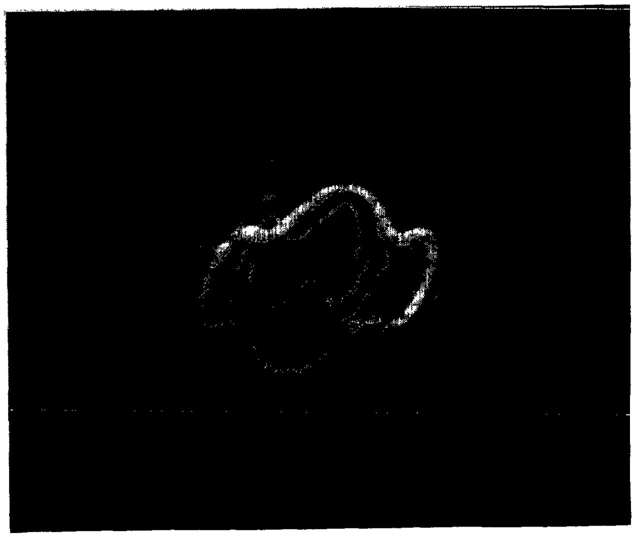

Illustration II—From SCOPE II, videotape by Patsy Scala. In this piece, composed of analog computer generated imagery, the videographic manipulations do not obliterate the "computer look" of the piece.

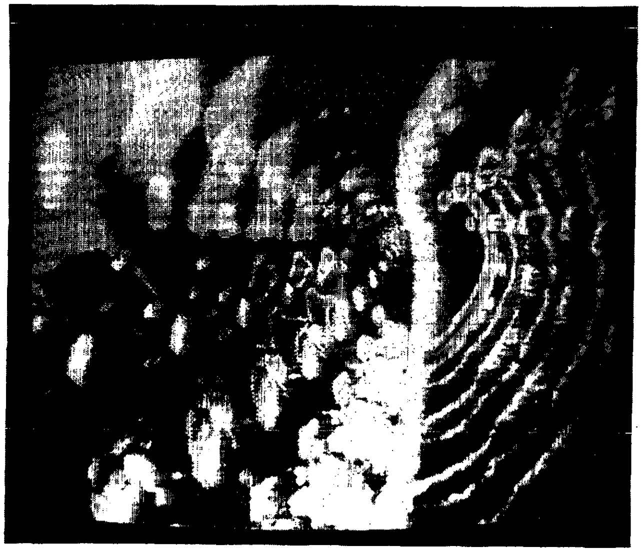

Illustration IV—From WIPEPOEM, videotape by Patsy Scala. Again, the analog distortion of laser light, and three levels of videographic manipulations leave the finished piece with little of its original computerized quality.

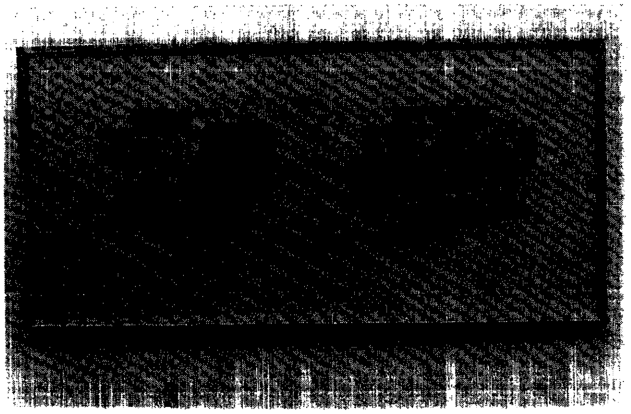

Illustration V—AZTEC I, by Joseph Scala. This piece, generated through Kenneth Knowlton's EXPLOR system, was hand colored by the artist to give it the look of Aztec tapestry.

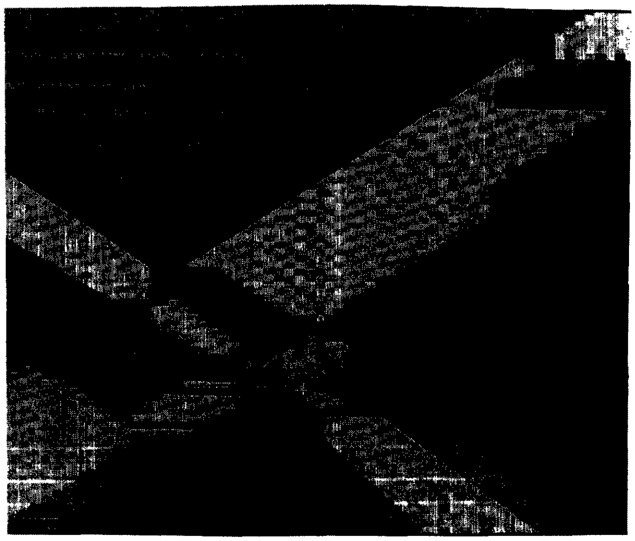

Illustration VI—EXPLORING III, by Joseph Scala. This large painting, done on computer printout paper, was based on Kenneth Knowlton's EXPLOR program, yet the addition of paint gives it a very different character from typical computer art.

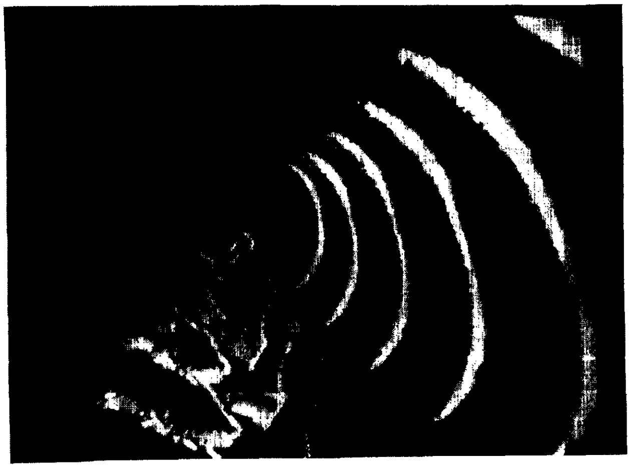

Illustration VII—From WIPEPOEM, videotape by Patsy Scala.

The digital component of the circle graphics habitat

by THOMAS A. DEFANTI
University of Illinois at Chicago Circle
Chicago, Illinois

ABSTRACT

This real-time interactive computer graphics system derives from the author's dissertation[1] at the Ohio State University (National Science Foundation Grant GJ-204, Charles A. Csuri, project director). The system, called "The Graphics Symbiosis System" or "Grass" was first designed to help artists interactively explore computer art without the constant companionship of a programmer. Over the past three years, it has been expanded at the University of Illinois at Chicago Circle (Figure 1) and is now the image generation portion of a short-order full-color animated videotape production facility called "The Circle Graphics Habitat." Combined with Dan Sandin's Image Processor, the system[2,3] is sufficiently powerful and flexible to be used in real-time performance context[4] here at UICC.

INTRODUCTION

The hardware is a standard PDP-11/45 computer with a Vector General 3DR display scope. In addition, we have a data tablet, thirty channels of analog input devices (dials, slide potentiometers, joysticks, etc.) and several channels of analog output (built by Larry Leske) to drive the Image Processor.

Figure 1—The Grass user's console

Primary inspiration for the structure of the language was the DECsystem-10 operating system and its text editor TECO, and Ron Baecker's animation system "GENESYS."[5] About ten person-years of programming effort up to now has resulted in about ten thousand lines of code in assembler. Persons primarily responsible for implementing the software will be identified by their initials as we progress: Tom Chomicz (TC), Dean Daniele (DD), Tom DeFanti (TD), Mike Dearing (MD), Nola Donato (ND), Manfred Knemeyer (MK), Gerry Moersdorf (GM), T. J. O'Donnell (TO), Ralph Orlick (RO) and Bob Rocchetti (BR). Gerry Moersdorf was responsible for about half the code in the Ohio State implementation. Grass currently has six running installations.

This paper will communicate the program structure of Grass. It would be good, however, to first describe briefly what is expected of the system by university authorities and users. The system, with the Image Processor, is used by professors, instructors and advanced students in preparing animated educational materials in less than geological time. Educational animation makes demands on a system which are computationally and conceptually more complex than standard plotting. The system has to be both easily learned and powerful enough for use by expert programmers in animations like continental drift or a dynamic explanation of how television works. A friendly review of the Circle Graphics Habitat may be found in Reference 6.

Educational animation systems are exciting to develop but not always as much fun to use. Educational animation is rarely free and loose. Fortunately, to continue the good feeling of pure, uncompromised creation, we now have an annual event in April which, like a faculty recital in music, is a performance, but of animated 3-D images and color image processing along with live music (Figures 2 and 3). We believe that jamming on equipment like this demands more from the human engineering side of design than ordinary real-time graphics. More on the philosophy of

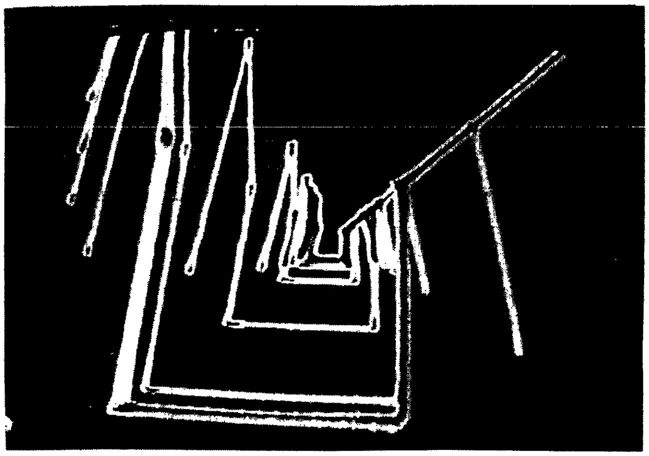

Figure 2—A still from 'Peano Boogie' by Sandin, Morton and DeFanti, a live performance. Colors are sky blue, raspberry red, lemon yellow and orange orange

the Circle Graphics Habitat may be found in Reference 2.

For the technical discussion that follows, it is assumed that the reader has knowledge of interactive graphics to the level found in Newman and Sproull.[7]

TECHNICAL DESCRIPTION OF THE GRASS LANGUAGE

Grass has two essential types of primitives: commands and pictures. Commands are kept as ASCII strings terminated by carriage-returns. Pictures (often called "sub-pictures" in the literature) are user-defined displayable lists of 3-D absolute vectors compiled into binary code acceptable by the Vector General display direct memory access processor. On disk, both commands and pictures are normally kept as ASCII strings (we always wanted to be able to read what was on the disk). Both commands and pictures in Grass are higher-level primitives, and this concept is essential to the design of the system. In addition, both may be broken down into the lowest level components if desired (i.e., ASCII characters and x, y and z endpoints) and both may be grouped into hierarchies whose elements have much the same behavior as the primitives themselves. The user first learns the command primitives like ROTATE, MOVE and SCALE to manipulate graphical images. Non-programmers do not have to think of images as endpoints or manipulate instructions as individual characters. This differs considerably from the approach taken in typical FORTRAN graphics packages where the user is assumed to be an expert programmer.

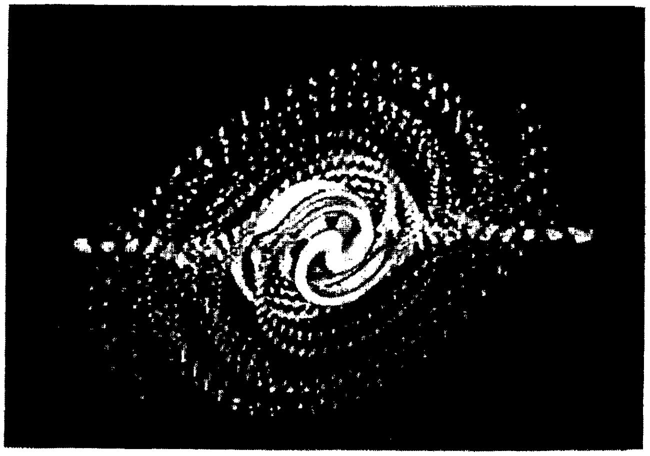

Figure 3—A still from 'Wednesday Night Spiral' by Sandin and DeFanti, a live performance

USE AND CONTROL OF PICTURES

Pictures in Grass have user-assigned names and are displayable lists of vectors prefixed in core by a control block. The user indirectly communicates with the control block for each picture by using commands like ROTATE, MOVE and SCALE rather than by setting bits. At interrupt level, the system updates and writes these control blocks out to the display's internal registers which drive the hardware features of the display (see Reference 8 for a complete description of the Vector General Scope). Updating of the control blocks is done at programmed interrupt level six and the vector display is done by direct memory access over the UNIBUS. The maximum number of pictures concurrently displayed is an assembly feature, presently set to sixty. To the user, all pictures are effectively processed in parallel. The commands that set up to use the hardware are:

MOVE PIXNAME,x-DEVICE,y-DEVICE, z-DEVICE

> Translates picture named "PIXNAME" to current values of the x-, y-, and z-DEVICEs until disabled (that is, the command has to be issued one time only, but any time the DEVICEs are changed, the update is done automatically). A DEVICE is defined as either an analog input device or an integer variable. Example: MOVE TITLE,D2, D3,D4 moves the picture "TITLE" on dials 2, 3 and 4.

SCALE PIXNAME,DEVICE

> Scales all three dimensions of the picture on the DEVICE until disabled. Also available are SCALE/X, SCALE/Y and SCALE/Z which scale in individual axes. Example: SCALE/X CIRCLE,A scales the circle horizontally on variable A.

SETINT PIXNAME,DEVICE

Sets the intensity of the picture to be continuously variable on the DEVICE until disabled.

SETCUT PIXNAME,DEVICE

Sets the z-axis depth cueing and z-axis cutoff feature of the scope until disabled.

The system hardware excels at rotation. Consequently, the ROTATE command, a very high-level primitive, has many options:

ROTATE PIX,AXIS,SPEED-DEVICE

Gives simple rotation about the x, y or z axis (specified by AXIS) at a constant speed of rotation determined by SPEED-DEVICE. If angular position rather than speed is desired, ROTATE/D is used for this and all the following ROTATE commands. (By MK and DD.) Example: ROTATE TETRA,Y,K rotates "TETRA" around the y-axis using variable K for the speed of rotation.

ROTATE PIX,AXIS,SPEED-DEVICE,
TILT-DEVICE

This rotation uses the second DEVICE to control the angular position of the axis of rotation in the plane through the origin perpendicular to the AXIS specified. It is a strange rotation to describe on paper but it is a highly useful rotation for interactive use. (By MK and DD.)

ROTATE PIX,AXIS,SPEED-DEVICE,
TILT-DEVICE,X-DEV,Y-DEV,Z-DEV

This rotation gives arbitrary origin rotation capability. It tends to produce elliptical rotations, the backbone of complex animated sequences (as in Disney's Fantasia). Again, it is non-intuitive and requires feedback to use. (By MK and DD.) Example: ROTATE COPTER,X,D0,D1,D2,D3,D4

ROTATE PIX,7,SPEED-DEVICE,X1-DEV,
Y1-DEV,Z1-DEV,X2-DEV,Y2-DEV,Z2-DEV

The "seven-dial" rotate allows the user to specify the endpoints of an arbitrary axis of rotation. It is the rotation preferred by programmers describing scientific phenomena in terms of rotation. (By TC.)

ROTATE/X PIX,DEVICE
ROTATE/Y PIX,DEVICE
ROTATE/Z PIX,DEVICE

These rotations are compounded with any of the above rotate commands to produce more complex effects. Grouping of pictures allows further compounding of transformations.

PATHMOV PIX,PATH-NAME,SPEED-DEVICE

This command tangentially moves the PIX along a PATH (which is simply any picture, displayed or not) with the given speed. It is basically an extension of Baecker's p-curve.[5] (By TC.)

These commands stay in force and cause constant updating to the values of the DEVICEs until disabled by the FIX or RESET commands. None of the above commands actually change the vector list since all the functions are done by the hardware.

Many commands do, however, change vector endpoints. The most used ones are:

SMOOTH—does a binomial smoothing of a vector list (BR).
PERSP—does perspective projection (TC).
CLIP—clips one picture against another (like film matting or video keying) (TC).
WINDOW—does normal 3-D windowing (TC).
SHADE—shades in outline with vectors (BR).
SOFT—carries out the hardware transformations on the vectors by software (DD).

The precise syntax of these commands is contained in the on-line HELP file, a copy of which may be had on request.

As is usual with sophisticated refresh graphics systems, the pictures appear to be parallel processed. They are controlled in parallel by turning dials (which are polled at interrupt level 30 times a second) or by manipulating variables. The user can also get at the individual endpoints of pictures with the GETPOINT and ZAPPOINT commands, build pictures with the PUTPOINT command, or draw them in using the tablet or other digitizers. (There is also complete software for text appearing on the Vector General (by BR and TO)).

In addition, the user can group pictures together and create a tree structure hierarchy of control on these grouped pictures. Pictures are grouped for convenient reference, and the groups respond to all the hardware transformation commands just as pictures do. Most often, the GROUP command is used to create multiply articulated structures like Professor Csuri's airplanes, helicopters and witches on propeller-driven broomsticks[9] as well as very complex rotations and translations. Grouping may be carried on to 59 levels (the same assembly feature as before). Note that the user does not have to know about tree structures, lists and pointers to use any of these commands because the system housekeeping does all the chaining. For knowledgeable users, the TREE command gives a schematic of the hierarchy developed. A two hour-long videotaped lecture describes the internal workings of the system algorithms.[10]

Storage allocation (by TD and ND) is by a "best-fit" algorithm. About 10K of 16-bit words is available to the user for vectors, text, command strings and disk-resident command modules. Many Grass commands, especially user aids like TREE and software transformations like PERSP, SHADE and CLIP are not core-resident. Code (by GM and RO) automatically fetches the appropriate modules into core and executes them. They are automatically deleted. When done, the total overhead amounts to about a tenth of a second.

Garbage collection (by TD and ND) dynamically tries to maintain large blocks of storage. It is called by the user commanl "DELETE" or automatically invoked by system housekeeping whenever appropriate.

As an example, a videotape[11] to illustrate that 3-D rotations are not commutative (Figures 4, 5 and 6) was done using the following code:

```
GETDSK BFLY1            (get butterfly from disk)
COPY BFLY1,BFLY2        (make a copy)
ROTATE/D BFLY1,X,D1     (rotate on x axis)
ROTATE/Y BFLY1,D2       (then compound with
                          y rotation)
SETINT BFLY1,D3         (control intensity on
                          dial 3)
ROTATE/D BFLY2,D5       (rotate on y axis)
ROTATE/X BFLY2,D6       (then compound with
                          x rotation)
SETINT BFLY2,D7         (control intensity on
                          dial 7)
GETDSK 3DAXES           (get the axes up)
GROUP 3DAXES,           (group and call the
  BFLY1,SAM               group "SAM" BFLY2
                          gets in for free)
ROTATE/D SAM,X,S1,S2    (rotate the whole thing)
```

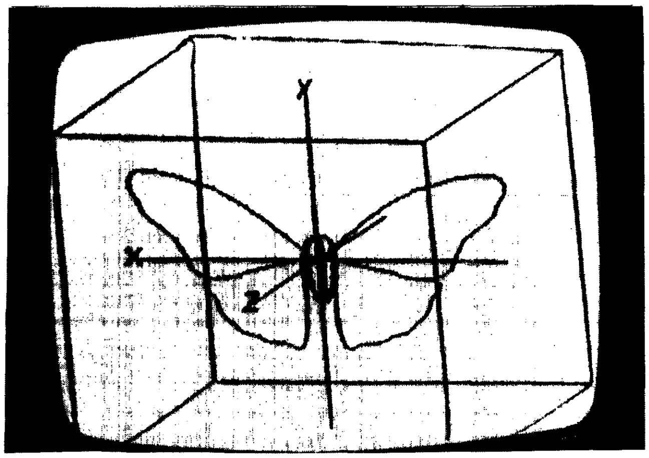

Figure 4—The butterfly in its original position

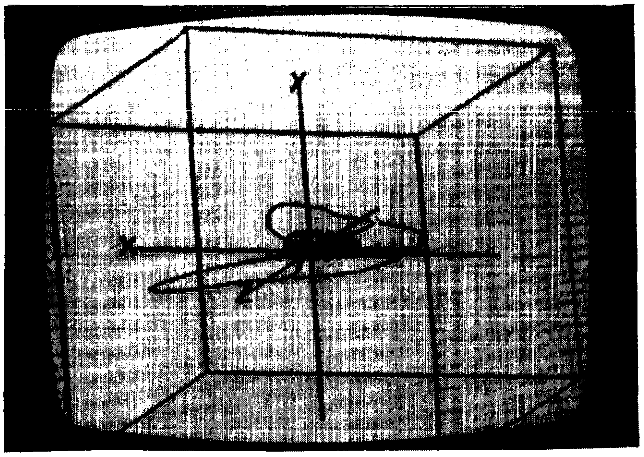

Figure 5—The same butterfly rotated ninety degrees around the x-axis and then ninety degrees around the y-axis

Now, by turning dials 1 and 2 enough to get ninety degree rotations about the x then y axis, the first butterfly takes one position. Turning dials 5 and 6 enough to get similar rotations about y then x axes, the second butterfly goes to a different position. It is quite easily seen that the two are not equivalent. That is, 3-D rotations are not commutative. (Rotating the group "SAM" allows the third dimension to be seen more clearly. The intensity controls allow independent fading of the two butterflies for clarity.) Given the existence of the butterfly and the axes on disk, the entire videotaped sequence took less time to produce (about fifteen minutes—some of which was dedicated to aesthetic judgment and color choice) than to describe.

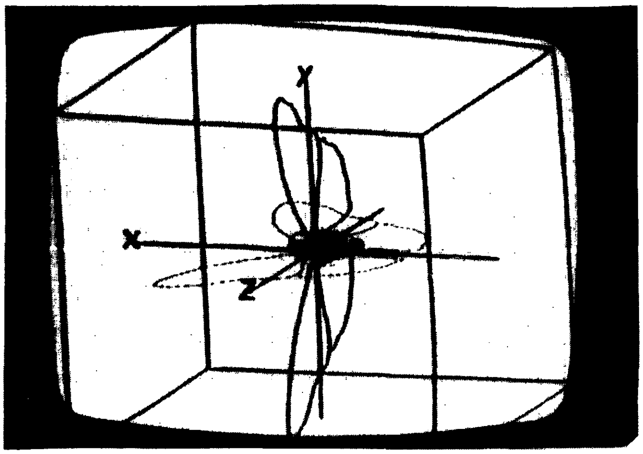

Figure 6—The same butterfly at half intensity contrasted with another butterfly rotated ninety degrees around the y-axis and then ninety degrees around the x-axis

USE AND CONTROL OF COMMANDS

The foremost design criterion of the command language in Grass has always been habitability, a term adopted[12] which means the quality of a system that makes it easy to learn and use. In many ways, the linguistics of graphics languages are quite unnatural for describing animation and many people do much better by waving their hands. On the other hand, the power of linguistic structures is undeniable, especially when modeling scientific data.

Programming on someone else's system is always frustrating. What really matters is whether you get anything done while being frustrated. We have tried to design a system to help users at all levels to get things done.

The basic tenets of habitability are usually obvious—mnemonic command names, predictible syntax, good error messages, high feedback—but they are rarely implemented in full because the detail work in coding is immense. The leisure time for attention to such detail is hard to come by, especially if the users are overwhelmingly power-conscious and impatient programmers. In a short-order videotape laboratory where users are by and large professionals donating their time to improve the quality of their classes, non-alienation is the item of highest priority. General fun and productivity seem to follow. Again, more of this philosophy is found in Reference 2.

A command in Grass is a string of characters terminated by a carriage return (CRLF) or a semi-colon in the case of multiple commands on a line. In order for the system to process a command in any context, originating from anywhere, the string of characters is simply passed to the line processor (LINEP) which interprets the string, dispatching to the proper command module. There are two general formats:

```
COMMANDNAME ARG1,ARG2,ARG3,...
  (for most commands)
    Example: SCALE WIDGET,D0
VARIABLE=EXPRESSION
  (for FORTRAN-style commands)
    Examples:
      A=A+10
      K=K-D0/2   (note use of dial 0)
      FA=ATN(FP)+SQR(FQ*(FD-FE))
```

If the command is not core-resident, it is fetched from the disk (all disk-resident commands are written in position-independent code), executed and deleted.

Commands are typed in line by line on the video terminal (VT05). Since many of the commands set up processes at interrupt level, the system may be used exclusively on a line-by-line basis as with a text editor. The previous rotation example was done this way, as was a twenty-minute film with witches chasing butterflies and airplanes flying around the globe, at a time (1972) when the language had only line-by-line capabilities. Almost all programs written in the language start as a few commands typed in and tested one line at a time.

The next step in command processing is to take commands stored in a file so they in essence become like the roll of a player piano, or the paper tape for a milling machine. Many text editors allow this type of command usage. This grouping of commands is often called a "macro."

Macros in Grass are simply groups of commands—a concept easily grasped by all our users. In compiled languages, macros are called "subroutines," but this terminology was not chosen because Grass macros are often not subordinate to anything conceptually. Macros do not require preambles, declaration statements, end statements or other formalities associated with subroutines.

To give the player piano roll in Grass a variable fast-rewind and fast-forward, control is transferred with the SKIP command. Its argument (e.g., SKIP 3) specifies how many CRLF's to pass over forwards or backwards. The argument may also be a label, in which case the transfer is to that label local to the current macro. Transfer to other macros is with the DO command whose argument (e.g., DO SETUP) is a macro. If this macro is not core-resident, it is automatically fetched from disk and then interpreted. The CALL command is similar except that it uses the system area of the disk and tries to find a compiled version of the macro (see below for details on the compiler). As will be seen later, the syntactic form of the macro call with parameters is very close to the form of commands so that system macros can appear to be system commands to the user.

Conditional branching and command execution is done with the IF command whose syntax is simple:

```
IF VARIABLE=EXPRESSION,ANY COMMAND
  Examples:
    IF A=B,SKIP -5
    IF D0 GT 0, IF A LT -100, DO FIXUP
```

In any case, control returns to the statement following the DO when the indicated macro is finished.

Macros may be generated in several ways. The system editor can be used to enter and change ASCII files on the disk or in core. Macros may also be created by typing a name followed by a colon as in the following example:

```
SETUP:<GETDSK GLOBE
SCALE GLOBE,D0
ROTATE GLOBE,X,TX,TY
  (using the tablet x and y)
GETDSK TITLE
MOVE TITLE,D6,D7,D8>
```

To execute this macro, one types "DO SETUP" or simply "SETUP" (providing it is not a system name). Often, immediate execution is desirable. The "unnamed" macro, entered thus:

```
<ANY COMMANDS
  . . .
  . . .
  . . .>
```

is automatically executed upon typing the final angle bracket. In addition, when this type of macro finishes, it is automatically deleted. Only named macros may be stored on the disk.

The system uses a VT05 video terminal at 2400 baud for user communication. This choice was originally made (by MK) to keep the Vector General screen free for images to be recorded by a camera. One version of Grass uses a keyboard interfaced through the Vector General and space at the bottom of the screen for the same purpose. At any rate, the system can afford to be fairly wordy with messages without much delay.

Being strings, macros can generate other macros using the string variables ($A through $Z in Grass) and the string manipulation primitives given by concatenation and the SEARCH command (MD and TD). This feature, exploited only by fairly experienced users, allows very plastic fabrication of executable statements in Grass. String variables are executed by putting them alone on a line after construction:

```
$A='GETDSK GLOBE
SCALE GLOBE,D0'
$A
```

Passing parameters is usually clumsy in programming languages. Indeed, we have only recently implemented a habitable way of passing parameters between macros (by RO). Like everything else in the system, macros are used interactively. Rather than burden users (who often cannot yet write macros) with having to know which parameters to supply, macros are usually written to ask questions:

```
SETUP:<PROMPT "WHICH PICTURE DO YOU
  WANT"
INPUT $A        (system types a "?" and waits
                user then types in a name)
GETDSK $A;SCALE $A,D0     (a multi-command
                          line)
ROTATE $A,Y,D1>
```

Effectively, any picture on the disk may be gotten, scaled and rotated with this macro. Similarly, one can input numeric values (e.g. INPUT FA) as numbers or expressions. The PROMPT command is the general typed output command, and may be used to print strings or numbers and combinations thereof:

```
PROMPT "THE SQUARE ROOT OF 1000 IS ",
  SQR(1000)
```

However, once the user is familiar with the macro, he may type "DO SETUP,GLOBE" or simply, "SETUP GLOBE" which looks like a Grass command. Either construction may be imbedded in another macro without any reprogramming of the original macro—an important feature since many users cannot decipher complex macros written by others. Note that the PROMPTs are automatically suppressed as long as enough arguments are supplied. If the user leaves off an argument, the system will wake up the PROMPTs and start asking the questions again. Of course, overrides are available to force INPUTs or PROMPTS if desired. Arguments may also be passed in global variables.

Variables in Grass have fixed names and are either local to macros (LA-LZ, fixed; EA-EZ, floating) or global (A-Z, VA-VZ, WA-WZ, fixed; FA-FZ, floating; $A-$Z, string; and AA-AZ, fixed and floating arrays). Analog inputs are global (D0-D9, dials; S0-S9, slide potentiometers; JX,JY,JZ and KX,KY,KZ, joysticks; P0-P3, more dials). Digital inputs include the tablet (TX,TY,TZ or pen-press) and function switches (FS0-FS15). Analog outputs are global too (OA-OH). Variables are prenamed in Grass because otherwise the interpretive overhead for arithmetic would really be immense. Prenaming also eliminates the need for declarations of variables (except for array dimensions).

The external inputs are polled every 1/30 second by the system. Currently under construction is a flexible input box with variety of connectors and amplifiers to aid in prototyping new input devices such as your body or musical instrument to produce a set of Grass variables. Having so many analog input devices, by the way, may seem confusing to the reader, but these physical extensions to the system can be intuitive and therefore easy to use.

Macros work despite the parsing overhead because the primitives of the language are generally rather high level and parsing is only a fraction of the code executed in doing the command. The higher the level of the primitives, the more practical the interpreter becomes. Note also that often one does not care how long something takes to parse as long as it is done in say, less than 1/60 second.

However, for low level primitives like addition or expression evaluation, the interpreter may execute a thousand instructions to add one to a variable. This is a major reason compilers are still preferred for arithmetic calculations. As soon as we started doing scientific animations as well as computer art, a fast arithmetic capability became essential. Thus, The Habitable Compiler was written (by RO). It takes assignment statements and some commands (notably GETPOINT, ZAPPOINT and PUTPOINT) and compiles them into PDP-11 machine code which executes very quickly. Whatever the compiler does not understand, that is most commands, it keeps as ASCII strings which are passed to the resident interpreter during execution. Thus the compiler retains the benefit of the interpreter and yet gains the speed of compiled code where essential. One usually debugs the macro first and then, if speed is a problem, compiles it. The compiler is disk-resident and rarely takes more than a second to load in and do its job. Compiled macros may be stored on the disk (in binary) and recalled at any time. In addition, macros that contain only arithmetic code are re-entrant so they can be set up to execute at interrupt level with the VIP (Very Important Program) command. VIPed macros are used when variables must be calculated perfectly in synch with the display refresh or when a higher priority task is useful. Few higher-level languages allow users to schedule subroutines at different priority levels.

To give a quick idea of the compactness of Grass macros, Donald Warren Collins wrote an architectural preview system[12] first on the IBM S/360 in FORTRAN taking some 132K 32-bit words, then in PDP-11 RSTS-11 BASIC taking 28K 16-bit words with multiple overlaying. Finally, he rewrote it in Grass, thus making it interactive. The Grass version took about 2K 16-bit words of storage, not including the 13K interpreter, of course.

DRIVING MACROS

Most of the contribution this system has made to habitability in graphics is noticed when actually executing and debugging macros. The constant real-time user control combined with the analog input devices makes this system usable as a performing instrument. Some of this control comes from parallel processing of pictures and, if the user desires, macros as well.

Animation often involves several more-or-less independent things happening simultaneously. Grass can be asked to set up a ring structure of macros so they can be executed in parallel. With two macros, the commands are interleaved. More than two macros requires grabbing lines from each one, one at a time, round-robin fashion. In addition, unless specifically requested otherwise, a macro in this ring structure automatically starts over again when finished. All this housekeeping is initiated by the DOLOOP command (by TD):

```
DOLOOP MACNAM1,MACNAM2,...
```

where the MACNAMs may be macros or compiled macros. The unnamed macro is retained for convenience in setting up background jobs:

```
DOLOOP <A=A+D0/100
B=A*2>
```

and so on. The system continuously listens to the VT05 keyboard for a line to be typed interactively and slips it in, executing it with no noticeable delay in most cases. Provisions for one macro waiting for another to complete and selective removal from the ring also exist.

As might be imagined, there is some overhead associated with the DOLOOP feature, but compiling the macros usually helps make the overhead quite unnoticeable. The need for and desirability of a parallel execution structure in graphics is more fully developed in Reference 3. Alan Kay's SMALLTALK language for children also implements this type of parallelism for 2-dimensional graphics.[13]

Two major conceptual simplifications of using macros result from parallel execution. First, the user can develop small animation sequences separately and then combine them later with little or no reprogramming. Without the parallelism, a total rewrite of the macros would be required. Second, the user may wish to incorporate macros written by others in his animation sequence, macros whose logic he may not understand. Again, without the DOLOOP structure, this would be very difficult.

Grass also has well-developed "panic-button" control structures (by TD) to abort or temporarily interrupt macros. First, CONTROL-C (holding the control key while typing a "C") stops any macro or compiled macro, kills the DOLOOP structure, stops any output, cleans up any scratch files like unnamed macros and sets the user back to command input level. It is the most common way to exit a macro in an infinite loop.

CONTROL-W temporarily stops printout until pressed again (2400 baud is too fast to read) and CONTROL-O cancels any output.

The real crowd-pleaser in the system, though, is CONTROL-S. It suspends execution of any macro or compiled macro, even if DOLOOPED. The user is put in command level and he can type commands to check variables, or anything else. The macro continues when the user types "RESUME." Since performance graphics, especially the jamming variety, requires constant real-time debugging with two hundred people looking over your shoulder, CONTROL-S comes in very handy. The combination of background DOLOOPED macros and CONTROL-S give the user the impression he is always in control.

ERROR MESSAGES AND DEBUGGING IN GRASS

Grass has about one hundred fifty error messages, only one of which is truly cryptic ("Undiagnosable syntax error"). When an error occurs, the whole command is printed out on the VT05 with a little arrow under the part that caused the error, followed by the error message. The user is then put into the same mode that CONTROL-S initiates, at which time he can correct the mistake and RESUME or type CONTROL-C to abort. Along with the feedback on the screen, these error messages and interactive fixups account for about ninety percent of the user debugging activity.

The harder-to-find logic errors are usually tracked down by the LIST command (by GM), the TRACE command (by TO) or sometimes the DOLOOP code. LIST simply prints each line of a macro as it executes. TRACE, adopted from SNOBOL, takes variable names as arguments and then prints out the value of the variables every time the variables are changed along with the location of the change. As a last resort, a macro to sense an elusive logic error may be parallel processed with the defective macro to discover the problem. For instance, assume variable A is never supposed to get to zero but it is anyway. "DOLOOP <IF A EQ 0,LIST>" will turn on the LIST feature as soon as A goes to zero. Obviously, more exotic bug traps can be constructed.

Error conditions may also be trapped and further processed by the macro writer. The ONERROR command sets up an asynchronous error recovery procedure for use when an error happens:

```
ONERROR VARIABLE,ANY GRASS
  STATEMENT
```

When the error occurs, the error number is put in the variable indicated for use by the error recovery routine and the Grass statement following the comma is executed in place of the line in error. Since errors can be as benign as not finding a file on the disk, system macros are written with ONERROR frequently to help the novice user. As might be imagined, considerable detail work was done to assure PDP-11 stack integrity when commands in error are replaced by ONERROR code. Note that the Grass statement in the ONERROR command can be a macro call like "DO FIXUP."

The expert user can take advantage of the asynchronous nature of the ONERROR command to speed up loops. For example, in the following program which zeros the z-value of each vector, the end-of-picture condition (K= −1) must be tested:

```
ZEROZ:<PROMPT "NAME OF PIX FOR Z-AXIS
  ZEROING"
INPUT $L
N=0
N=N+1
GETPOINT $L,N,X,Y,Z,K      (set the nth point in
                            variables x,y,z and k)
IF K NE −1,ZAPPOINT $L,N,X,Y,0,K; SKIP −2
                   (if K= −1, it is the end of picture)
PROMPT "DONE ZEROING">
```

Now, if "ONERROR A,SKIP 2" is placed somewhere before the last four lines of this macro, the test for K= −1 may be eliminated because the GETPOINT index (N here) will go out of bounds and generate an error. "SKIP 2" will be executed in place of the line in error and the control will pass to the last PROMPT. Such tricks can even work with compiled macros, a housekeeping feat of some proportion.

In summary, Grass provides many ways of controlling, debugging and interacting with pictures and macros. Since so much of the control can be parallel, the user occasionally feels like he is conducting rather than watching a plotter. Music has always been a performing art and artists now have the tools to perform visual scores. The task now is achieving the control subtlety in performance graphics that we know and love in music.

CURRENT LIMITATIONS OF GRASS

Grass as a system has for some time been pushing against walls created by equipment speed, memory limitations and the nature of the refresh display. Currently, the PDP-11/45 we use has only 28K of usable memory, of which 3K is used by the disk operating system. The user is left with 10K of space to use. Given the software overhead, the maximum number of parallel full-screen vectors that can be displayed flicker-free is about a thousand, although they can all be rotating, moving and scaling. We have to operate in a flicker-free environment because our television-based system is not sophisticated enough to operate in anything but real-time.

Adding speed to the PDP-11/45 is fairly simple with an add-on cache memory, but not cheap. Adding to the memory requires memory management, and a considerable amount of reprogramming. And CRT's that are faster by an order of magnitude are still a gleam in the designer's eye.

A major limitation to the habitability of Grass is that not all users have linguistic skills—or type well. Non-linguistic approaches to subset problems like constructing complex 3-D pictures are possible using light-pen or tablet menus. We now have several small grants to investigate performance-time control structures for computer graphics.

Braille grade II translator program

by MONIQUE TRUQUET*
Université Paul Sabatier
Toulouse Cedex, France

ABSTRACT

This paper describes the Computer Translation of French inkprint into Grade II. It will be a reminder of what I have presented during two workshops and a conference, increased by the last modifications.

THE FRENCH GRADE II

The Translator program was written in Basic FORTRAN IV two years ago and it has undergone some modifications. We are going to present the method used. To recognize EXPRESSIONS like c'est-à-dire (that is to say), to recognize WORDS, CONTRACTIONS, NUMBERS—we use a syntactic analyzer with a list structure and a hashing table. The organigram presented (Figure 1) shows the different ways of the program. The grammar used follows. We have chosen for axiom TEXT and the grammar is written on the Backus Normal Form.

TEXT::=(TERM Σ TERM) followed by (PUNCTUATION MARK Σ PUNCTUATION MARK)
TERM::=SPECIAL SIGN/EXPRESSION/WORD/NUMBER
WORD::=LETTER Σ LETTER
NUMBER::=DIGIT Σ DIGIT
SPECIAL SIGNS are in a TABLE the form of which is a Tree
EXPRESSIONS are in a TABLE the form of which is a Tree
LETTERS are in a TABLE
DIGITS are in a TABLE
PUNCTUATION MARKS are in a TABLE

Expressions

It is the grouping "Pour ainsi dire" which is translated but not Pour (for) then AINSI (so) then DIRE (to say). To find an expression let us see in Figure 2 that the checker has to know if the first letter is or A or C or D or E or L or N or P or W or S or T or V. In supposing that it is A, we have to survey the "Tree" in Figure 3.

If no expression is found then the checker search is to isolate a word.

(a) *with A we can found*:

Au contraire	→(on the contrary)
Au-dessous	→(below
Au-dessus	→(above)
Aujourd-hui	→(to day)
Autant que	→(as far as)
Autant qu'	→(as far as)
Autre chose	→(something else)
à part	→(except for)
à cause	→(on account of)
à mesure	→(in proportion as)
à peine	→(hardly)
à peu près	→(nearly)
à présent	→(now)
à travers	→(through)

(b) *with P*

Parce que	→(because)
Parce qu'	→(because)
Par conséquent	→(therefore)
Par exemple	→(for example)
Par suite	→(consequently)
Par-dessous	→(under)
Par-dessus	→(on top of)
Peu à peu	→(little by little)
Peut-être	→(perhaps)
Plus tard	→(later)
Plus tôt	→(earliest)
Pour ainsi dire	→(so to speak)

The tree which permits us to find the expressions which begin by the letter A is represented in Figure 3.

Words

Supposing that a word is recognized then a hashing method is applied and the word is searched in the

* Centre d'Informatique de Toulouse (France).

Figure 1

Braille dictionary. If it is, the program takes the equivalent Braille if not the program search of the word is composed with contractions.

Difficulties encountered

(1) *To obtain a Braille Page correctly:* the program has to obey precise rules and it has to replace consecutive spaces with only a space.

(2) *to use the contraction method:* if some groups of letters are forgotten the program cannot continue; it was the case for the groups:

AI3→(aî)
AI2→(aí)

but the correction is easy.

(3) *to treat homonyms:* (we must specify to the program those which obey the rules that they will be preceded by the special sign "::").

- like CONVIENT:

I am spelling this word because it has not the same pronounciation; it depends on the meaning. This could be a form of the verb "CONVIER" (to invite). It is pronounced CONV(I) or the verb "CONVENIR" (to agree with) is pronounced

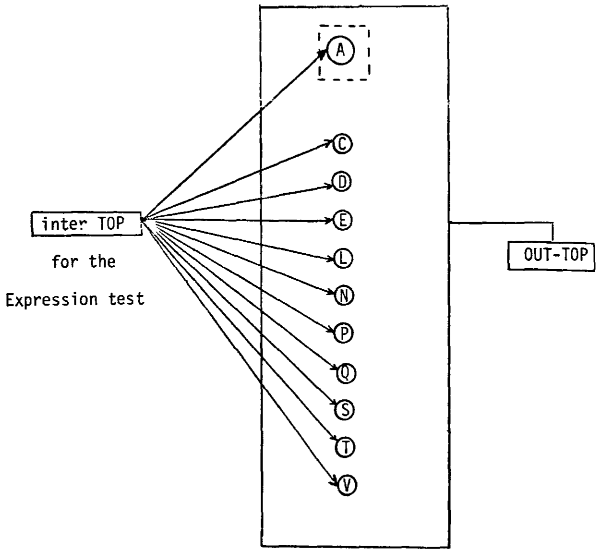

Figure 2

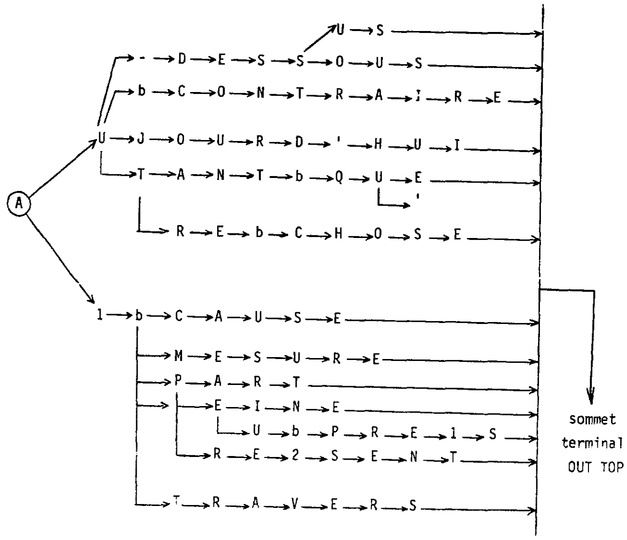
CON VI (IN). If it means to invite, the Braille translation is (CON)-V-I-(ENT). If it means to agree with, the Braille translation is (CON)-V-(IEN)T. "To agree" obeys the rules and with the sign mentioned above the program directs this word to the contraction table.

- like FILS:

If it is the "SON" it is pronounced (FIS), the Braille translation is F-S. If it is the "threads"



A
U → S
- → D → E → S → S → O → U → S
b → C → O → N → T → R → A → I → R → E
U → J → O → U → R → D → ' → H → U → I
T → A → N → T → b → Q → U → E
'
R → E → b → C → H → O → S → E
1 → b → C → A → U → S → E
M → E → S → U → R → E
P → A → R → T
E → I → N → E
U → b → P → R → E → 1 → S
R → E → 2 → S → E → N → T
T → R → A → V → E → R → S
sommet
terminal
OUT TOP

Figure 3

it is pronounced (FIL) and the Braille translation is F-I-L-S.

(4) *to write foreign words:* foreign words and proper names must be written in grade I preceded or with a capital, or with the special sign which shows to the blind that the word which follows is in grade I.

(5) *to know if a word must be translated or in grade I or in grade II.* It is the case for the words SI (if) or PUIS (then) or CELUI (this one or that one). When they are not followed by a punctuation mark they can be translated in grade II if not they must be translated in grade I and preceded of course by the special sign "integral".

MODIFICATIONS

We have seen that a part of the words put in the dictionary can be translated by the contraction method. This is interesting because we have only one word to add to the contraction table and with the prefixes, suffixes of this table we can produce all the words of the same family.

With the word "EGAL" (EQUAL) written E2GAL we can create

E2GALE
E2GALES
INE2GAL→(IN)-(E2GAL)
INE2GALE→(UNEQUAL)
INE2GALES

but we cannot obtain

E2GALITE2	→E-G-T	(equality)
E2GALITAIRE	→E-G-T-R	(equalitarian)
E2GAUX	→E-G-X	(equal)
E2GALEMENT	→E-G-M	(also)

and these words stay on the dictionary because they don't obey the contraction rules.

With the word "POINT" we can create about 40 words so it is very interesting.

Here are some:	POINTE	head, touch
	POINTU	sharp
	POINTAGE	checking
	POINTEAU	needle
	POINTS	points
	POINTER	to check

Remark: If we want to obtain the words E2GALITE2, E2GAUX by the contraction method we must change the sense of the test of the word. At the present time we begin by the right as some suffixes are longer than prefixes, but for the new method it will be necessary to begin by the left to isolate first the prefix, then the root; but will the Braille text obtained be more correct than now because of some roots which begin by the same letters than some prefixes?

CONCLUSION

This year we have a Braille device which satisfies us so we have the care to translate texts for a special school for blind (ASEI)* and for students of the Letter University. French grade I is very important for young children, grade II for the others, and the special schools need translations. Students of our University need above all Braille mathematics and we are going to write the program. Later we'll try to create Informatic trainings for the blind at our Informatic Center of Toulouse. At the present time we work more easily thanks to a French organization IRIA** which sent us some money to pay an Engineer and the making of a French Braille device built by the society SAGEM‡ so that it will be better in the future.

Interfacing computers for the physically handicapped—A review of international approaches

by GERALD A. RAITZER, GREGG C. VANDERHEIDEN and CRAIG S. HOLT
University of Wisconsin
Madison, Wisconsin

ABSTRACT

The computer has shown great promise for expanding educational and occupational opportunities for severely handicapped individuals. The greatest obstacle facing these individuals today is that they are unable to access computers through traditional keyboards or other types of terminals. This paper describes the three basic techniques which have been successfully used to allow the severely handicapped to communicate with other people and with their environment. A review of over 25 various approaches which have been developed around the world is presented, including a comprehensive bibliography of available information.

INTRODUCTION

For many individuals severe physical handicaps have completely cut off most avenues of personal development and employment. Their physical involvement bars them from any constructive or creative activities requiring physical or manipulative abilities. Moreover, their inability to speak, write or efficiently operate even simple communication devices severely impairs their ability to develop and exercise their mental capacities. This latter problem is basically an output problem in which a normally functioning intellect is trapped within a body having no effective means of communicating or interacting with the environment. Fortunately with today's technology, especially micro electronics and the computer, new avenues are being opened for these individuals which promise them not only a chance for a more effective education and a more meaningful mode of self expression, but also a means of self support through employment.

The major problem in trying to realize the full potential of these individuals is in finding efficient means of communication for them. Information output should consist of both written communication and discrete commands with which they can control certain elements or devices in their environments.

Two years ago we presented one approach for providing the severely physically handicapped with a means to control computers and other data and information processing equipment. The approach described was developed for individuals who had some pointing capability but who were physically unable to use regular keyboards in an effective manner. In this paper we will be presenting a summary of all of the different basic approaches which have been developed around the world to interface individuals with varying physical abilities. With these different approaches most any individual, no matter how severe his physical handicap, could be provided with an effective means for controlling communication and other interactive devices.

THREE BASIC APPROACHES

Although a great many different aids have been developed to provide the physically handicapped with a means of controlling other devices, their control schemes are all essentially variations on three basic approaches. These approaches are scanning, encoding and direct selection. Each of these approaches has different advantages and disadvantages and will work better with one kind of disability than with others. Some of the techniques such as scanning are much more powerful in that they can be used by even the most severely handicapped. Other techniques may be less powerful but more efficient, thus allowing individuals who have more control over their movements to be able to communicate in a faster manner by taking advantage of their better physical abilities.

THE SCANNING APPROACH

The definition of scanning aids which has been developed by the Trace Center (University of Wisconsin-Madison) is:

Any technique or aid in which the selections are offered to the user by a display and where the user selects the characters by responding to the display. Depending upon the device, the user may respond by simply signaling when he sees the correct choice presented or by actually directing the indicator (e.g. light or arrow) toward the desired choice.

One example of a scanning aid would be a simple rotating pointer (see Figure 1(a)). With such a system the individual could start and stop the arrow using some switch that was specially adapted to take advantage of some movement over which he had good control. He could then use the arrow to point to the various characters desired. An encoding wheel on the back could digitize the selection process for entry to the computer. This type of scanning is referred to as linear scanning. A more efficient technique which has been developed is a two-speed linear scan whereby the individual can operate one button which will cause the aid to scan rapidly until it approaches the correct choice. The individual then releases the button and the aid slows down to enable an accurate selection by the individual.

Another technique which can be used to increase the scanning speed is an XY or row column scan (see Figure 1(b)). Here the aid lights one entire row at a time until signaled by the user. The aid then lights up the entries in that row one at a time until the user signals it again. The character is then output and the aid resumes scanning.

For individuals who can control a joystick or other set of four switches, a directed scanning technique can provide an even more efficient scanning control system. With this system the individual can direct the lighted square up, down, left or right to move it to the desired character. He can then release the control switch allowing the light to remain on the square for a predetermined time interval after which it is output. This technique has also been implemented using switches where one is pushed alternately to control the up and down direction and the other is pushed alternately to cause the light to move left and right.

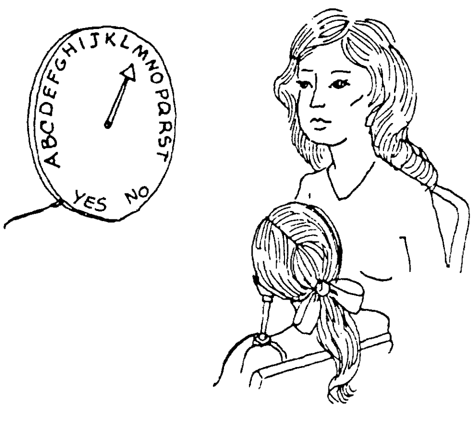

Figure 1(a)—Simple linear scanning technique

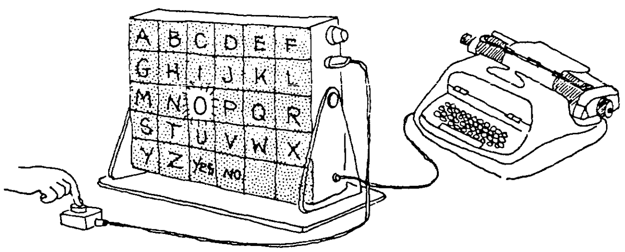

Figure 1(b)—Row/column scanning technique

The latest technique to be developed in the scanning category is the "anticipatory scan" or computer assisted scan. With this technique the aid looks at the last one or two letters which have been printed, refers to its programmed memory for the next most probable letters, and then displays those letters first. For example: if the last two letters printed by the handicapped individual were "...TH", the aid would present the letters E, A, SPACE, I... and then scan over the remaining letters afterwards. In this manner the letters which are most likely to occur next are presented to the individual first, increasing his speed for selection. Using this system the odds are about 80% that the next letter that the individual wants will be one of the first five characters presented by the anticipatory scanning aid.[7]

THE ENCODING APPROACH

The definition adopted for encoding aids is:

> Any technique or aid in which the desired characters are indicated by a pattern or a code of input signals, where the character codes must be memorized or referred to on a chart. Any number of switches may be used (e.g., 1, 2, 4, 7, 8, etc.). The code may involve activating the switches sequentially, simultaneously or in a specific time sequence.

One example of an encoding technique would be an aid where two numbers given in sequence are used to encode the desired characters. For instance, in the simplified example shown in Figure 2(a) a "2" and a "3" could stand for an "m" and a "4" and a "4" would stand for an "s". By using a larger number of encoding numerals (e.g., 10 or 12), larger numbers of characters and control commands can be encoded while keeping the number of keys relatively few.

For individuals who have very poor gross motor movement but who do possess some very fine motor control, techniques such as Morse Code may be more efficient. (Figure 2(b)). Here an aid can take advantage of a very small muscle movement or even a bio-potential to control a device which could decode

	1	2	3	4	5
1	A	B	C	D	E
2	F	G	H	I	J
3	K	L	M	N	O
4	P	Q	R	S	T
5	U	V	W	X	Y

Figure 2(a)—Simplified example of a two-number encoding scheme

his movements and in turn control some form of output or data processing equipment.

THE DIRECT SELECTION APPROACH

A direct selection technique is:

> Any technique or aid in which the desired output is directly indicated by the user. In direct selection aids there is a key or sensor for each possible output selection.

This is the most common form of control used in the computer industry. All keyboards would fall into this category. For the severely handicapped, a number of guarded and expanded keyboards have been developed (Figure 3(a)). For individuals who have some pointing abilities, but whose motions are too erratic to control even enlarged keyboards, other special techniques have been developed which can interpret even very erratic pointing motions. These techniques would also fall under the category of direct selection aids.

PROFILE OF EXISTING COMMUNICATION AIDS

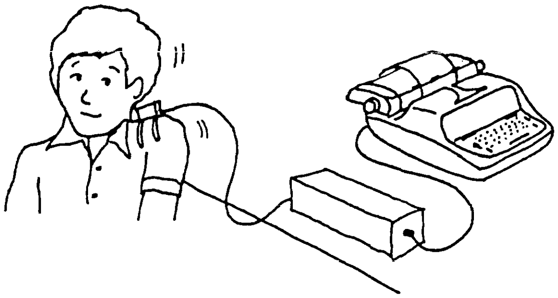

Figure 2(b)—Small muscular movement used to control output device via encoding technique

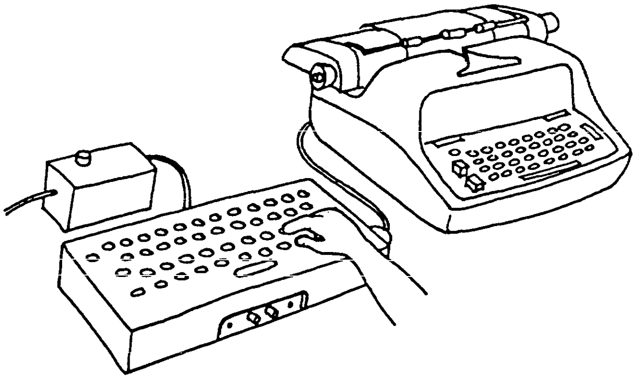

Figure 3(a)—A direct selection technique in the form of an expanded recessed keyboard

The following is a descriptive survey of aids currently available or under development in each of the above categories. This descriptive survey does not include all of the aids which exist in each of these categories. A more comprehensive listing and description of these and other aids is available from the Trace Center, University of Wisconsin-Madison. (See Bibliography).

SCANNING COMMUNICATION AIDS

The scanning type of communication aid is currently the most common form of communication aid available. The major advantages of these aids are: (1) they require little physical effort to operate and (2) they can be used by most anyone no matter how severe their physical disability.

The major disadvantage of these aids is their slow speed. The user must wait until the indicator stops at many unwanted characters before the aid will reach the desired character. The rate of scanning must stay relatively slow because the indicator must rest on each selection long enough for the operator to select it without error.

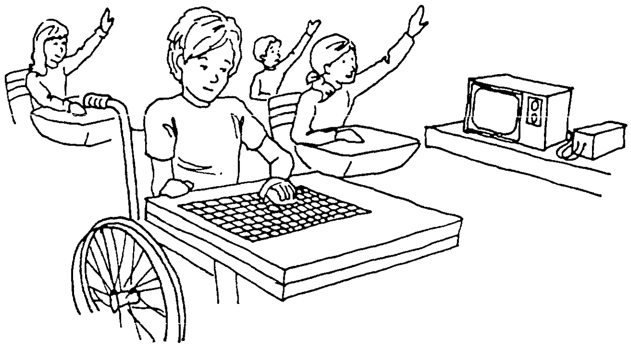

Figure 3(b)—Auto-monitoring technique; a direct selection technique which can be used by individuals having only very erratic pointing skills

Many different variations of this technique have been developed. A device which scans by eliminating the characters in a row column fashion was developed for use with severe myasthenia gravis patients by the Department of Surgery of the Royal Post Graduate Medical School, (London, England). Centre Industries, (New South Wales, Australia) also has an illuminated letter scanning device which uses a linear scan to control an electronic typewriter. A two-speed linear scanning aid is available from PMV (Stockholm, Sweden) which controls a standard IBM typewriter using a solenoid matrix positioned over the keyboard.

Several groups have developed aids which utilize the row column scanning pattern. With these aids a larger number of selections can be displayed without requiring great amounts of time to select them. The increased efficiency, however, requires two signals to be given for each letter selected. The Tufts Interactive Communicator (TIC) developed at Tufts University, (Boston, Massachusetts) uses the row column scanning technique and has a Burroughs display and strip printer as two of its output forms. Other versions of this aid have been adapted to work with a variety of outputs. The "Linguaduc Scanner" produced by Carba (Switzerland) uses one or two switches to control a Facit printer. POSSUM Controls, Limited (Aylesbury, England) produces the "POSSUM" device which uses an adapted typewriter as its output form, as does the Zambette Electronics (Essex, England) "System 8" unit. The POSSUM typewriter features a simple sip-puff switch and chin switch while the System 8 unit features a "magic" capacitance switch and projection system for displaying typewriter output on the wall or ceiling. The "Comhandi" produced by Physio-medical Systems (Montreal) is built into the base of a Teletype which it uses as its output form. The Cybernetics Research Institute (Washington, D.C.) also has a scanning communication aid called the Whispertype which controls a typewriter and can be used with a variety of input sensors. This aid has also been recently interfaced with a voice synthesizer. The Alphabet Message Scanner developed by Prentke-Romich (Shreve, Ohio) is a very simple row column scanning device which runs on batteries and has a data output jack on its back for control of other devices. A completely portable scanning aid has been developed by Vendacom (Brooklyn, New York) called the Porta Printer. This aid is built into an attaché case and weighs just 17 pounds. It uses a miniature strip printer as its output and can control two electrical outputs for the convenience of the user. The STRIP PRINTER is an aid which is very similar though lighter than the Porta Printer and is also marketed by Prentke-Romich (Shreve, Ohio).

Another fully portable scanning aid, which is built into a special lap board, has been developed by the Trace Center (Madison, Wisconsin). This aid has several output forms including typewriter, television display, teletype and voice synthesizer in addition to its built in strip printer and correctable alpha-numeric display.

As mentioned earlier, the anticipatory scanning technique was first introduced by the New England Biomedical Engineering Center at Tufts University (Boston, Massachusetts) and is now being incorporated into the newest version of the Tufts Interactive Communicator (TIC). A computer assisted anticipatory scanning system has also been implemented at Northwestern University, Rehabilitation Engineering Center (Chicago, Illinois) using a DEC mini computer.

One of the principal advantages of the scanning approach that has been mentioned is the fact that it can be used by almost any individual no matter how severe his handicap. This is due to the fact that the operator may use a single input switch to control the aid. In addition, any one of a large number of input switches or sensors could be used to provide the signal. Some examples of switches that may be used are breath switches, knee switches, impact switches, pull switches, proximity switches, whistle switches, the NASA Eye Movement Switch, eyebrow switches, muscle potential switches and brainwave sensors, to name a few. Thus, at least one switch could be found which could be operated by a given individual.

ENCODING AIDS

Because speed is so important when communicating (especially character by character) several research groups have developed devices that use encoding techniques instead of the scanning approach. The increased efficiency of signaling provided by the encoding approach increases the speed of communication. Here again, however, the increased speed requires a greater degree of control from the operator. More complex motions and sometimes more responses per letter are required. In addition, the encoding scheme must be learned before the device can be used. The greater the number of switches used in the encoding scheme, the simpler the code will be. However, an increased number of switches requires greater dexterity on the part of the operator. Thus, a compromise between the two factors, simplicity of code and number of switches, must be worked out. Different research groups have chosen different balances between the two factors in the design of their aids. The aid best suited to an individual is determined by his specific communication needs, and his physical abilities.

Centre Industries (Australia) chose a simple set of movements (two levels and a pause) as a Morse Code, to operate their COS unit which in turn controls a typewriter. Medicel (South Burlington, Vermont) also uses a Morse Code communication aid. This device, called the MC 6400, uses a television monitor as its output form. POSSUM Controls (Aylesbury, England) uses a three level code in one of their POSSUM units (sips, pauses, and puffs) which also controls a typewriter. The aid developed by Hengrove, Ltd. (Berkshire, England) uses a four level code (two degrees of sips and two degrees of puffs) which requires finer breath control but is faster. With the Electraid, 1, 2, 4 or 8 switches can be used to control a typewriter. The Cybernetics Research Institute (Washington, D.C.) uses a still larger number of switches in their CYBERTYPE device. The CYBERTYPE uses an encoding scheme which utilizes 14 switches arranged in two banks of 7. One switch in each bank must be selected to print a character. The aid may also be used with only 7 keys by just pressing two keys in succession. A portable independent encoding aid has been developed at the Trace Center (Madison, Wisconsin). This aid is built into a special wheelchair laptray and features correctability and the ability to print out words and phrases in addition to individual characters.

The basic advantage the encoding devices tend to have over scanning systems is the greater speed—a most important factor. Encoding devices do however require that the operator have considerably greater dexterity. They also require that the operator learn a code of some sort before operating the device. Those who have used encoding aids however report that the codes are usually easily learned and retained by the individuals using them.

DIRECT SELECTION AIDS

Communication aids in this category have the greatest number of switches; one for each symbol or character on the aid. To obtain a character the user simply operates the switch corresponding to that letter and that letter only. One obvious advantage with this type of aid is that its operation is very simple and straightforward. These aids also tend to be more rapid than the scanning systems since there is no need to wait for a scanning indicator to arrive at the proper letter. Speed of communication is limited only by the user's ability to activate one of the aid's switches. The major limitation of aids in this category is that they require increased dexterity on the part of the operator, who must have fairly good control of the gross motor movements of at least one of his extremities.

Some of the aids in this category are designed for persons with no arm or hand control but fairly good control of other portions of the body. MEFA GmbH (Bonn, Germany) makes an expanded four tier keyboard for operation with one's feet. Reva-Aids (Copenhagen, Denmark) makes an expanded proximity keyboard for use with cerebral palsied individuals. This keyboard can be operated by either foot or by headsticks. IBM makes special handrests and armrests which allow some weak and spastic individuals to operate standard IBM electric typewriters. When used with a correctable IBM Selectric typewriter these adaptations can provide the handicapped individual with a correctable communication aid. Furthermore a special "ORATOR" type-ball is available which can provide large and highly visible characters for the vision-impaired. Several special keyboards have also been developed by PMV (Stockholm, Sweden) to enable use of the typewriter by the severely handicapped.

A typewriter that is controlled by a light pen attached to the user's head has been developed by M. Soede and H. G. Stassen (Netherlands) and is called a LOT (light operated typewriter). Several telecommunication aids for the deaf can also be modified for the moderately involved individual, including the MCM Communicator marketed by SICO (Oakland, California) and the TV Phone marketed by TV Phone (Silver Spring, Maryland). A hand held communicator which can be worn on the wrist has been developed by Cannon, Incorporated (Japan) in cooperation with researchers in Holland. The aid is called the Cannon Communicator and uses a strip printer as its output. A portable direct selection communication aid which is built into a laptray has been developed by the Trace Center (Madison, Wisconsin). This unit, called the Auto Monitoring Communication Board (Auto-Com) has a special sensing system which allows the aid to be used by individuals having only very minimal pointing skills. The aid has a smooth, flat, hard surface and operates in much the same manner as a traditional communication board except that the user's output is automatically printed out for him on a self-contained strip printer or other output device such as a typewriter, CRT display or teletype. The Auto-Com is capable of printing entire words, phrases or strings of commands in addition to being able to print out individual characters.

CONCLUSION

It can be seen that a large number of devices have been developed for the physically handicapped, although only a limited number of these aids have been developed to interface with computers. All of the techniques described could be easily adapted to provide access to computers for the physically handicapped. It can also be seen that because of the diversity of approaches and specific techniques which have been developed by the various researchers, it should be possible to select an aid which could provide any particular individual with a control scheme which would take optimum advantage of his physical skills. Thus, the inability to control traditional data entry devices should no longer be a barrier to the use of computers by the severely handicapped. Moreover, two other features of the computer, remote terminals and time sharing, can help to overcome two other barriers, (transportation problems and the decreased work speed of more severely handicapped individuals) that may interfere with the physically handicapped individual's ability to participate in other types of endeavors.

The potential for the use of the computer in the instruction of the handicapped (particularly the more severely handicapped whose slower response time can make optimum use of the "patience" of the computer) should also not be overlooked.

FOR FURTHER INFORMATION

A master chart of communication aids listing the above communication aids and others in a chart form profiling their features, as well as an annotated bibliography of communication aids providing pictures, descriptive information and where to secure additional information on each of the aids, are both available from the Trace Research and Development Center for the Severely Communicatively Handicapped, University of Wisconsin-Madison, 922 ERB—1500 Johnson Drive, Madison, Wisconsin 53706.

ACKNOWLEDGMENTS

A special note of gratitude to Mary Jo Luster whose efforts are responsible for the location and classification of many of the aids contained in this summary. We would also like to thank the many individual researchers and groups who have assisted the Trace Center in compiling these summaries for use by other concerned professionals.

ABSTRACT

Spellex is a system developed to aid the blind in the use of computer and office equipment without sighted help. It consists of a digital spelled speech generator interfaced with a number of instruments by digital electronic circuits. Voice is produced by two specially programmed read only memory chips. Standard C-MOS components are used in the design of the spelled speech generator so that the processor can be easily implemented using the latest large scale integrated circuit technology. As it now stands, Spellex provides voice for standard input and output terminals, punch card reader, paper-tape punch and reader, calculator, electric typewriter and the Lexiphone reading machine for the blind.

INTRODUCTION

With the rapid progress in digital electronics and speech processing techniques, the field of aids for the blind has entered the stage of synthesizing voice by digital circuits as the output medium.[1, 3] This evolution of using spoken sound as output is logical because speech is one of the most common and natural media of human communication. Due to the decrease in price of electronic components, it is now possible to build intermediate types of speech aids at a reasonable cost. This paper deals with the application of the Spellex system for communication with the computer and its accessories.

Many job opportunities in our competitive society are not available to the blind because they cannot work without sighted help. However, with a multitude of aids now being developed using tactile and auditory feedbacks,[5] it is forecast that more blind people will be able to hold technical and professional jobs in the future. Indeed, during the past several years a considerable number of blind programmers were able to find employment in the field of data processing. There are also several good facilities for the training of blind programmers, both in North America and Europe.

In response to a questionnaire on their special needs, blind programmers indicated that they would like to see the following tools developed:[8] Braille terminals and printouts, reader for inkprint printouts, spoken input/output, card reader for verifications and corrections and Braille writer as an attachment to miscellaneous equipment. The development of the Braille line printer[4,6] has answered some of their needs and the development of the Spellex system will further resolve their problems related to reading and communication with the computer and its accessories.

The Spellex system depicted in Figure 1 is the result of several years of continuous research and development in auditory feedback. At the present stage of development, it can generate a synthesized spoken sound each time it receives an output signal in ASCII from the various machines. The spelled speech generator was initially conceived as an output device for the Lexiphone reading machine.[7,8] This enables a blind user to monitor the machines easily. At the present moment, the Lexiphone can read several type fonts.[2] A calculator has been interfaced to Spellex and an IBM electric typewriter is functional with an editor and enunciates the sound of all the keys. The system also

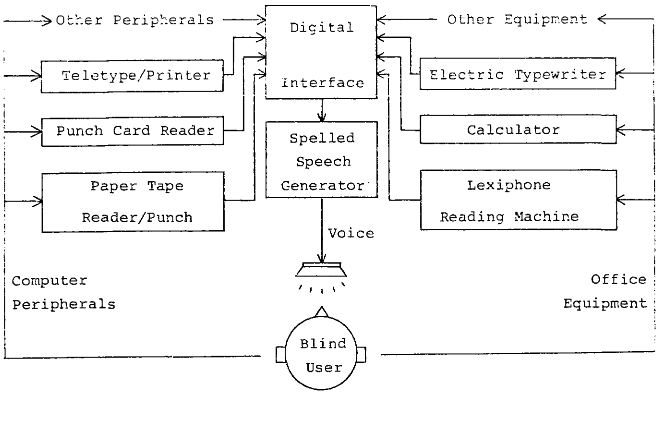

Figure 1—The Spellex system

operates a portable punch-card reader, teletypes and teleprinters.

THE SPELLED SPEECH GENERATOR

Spelled speech was synthesized by the concatenation of phonemes stored digitally in Read Only Memories (ROMs). In order to minimize the memory requirement, only 18 phonemes were chosen to synthesize the whole set of 64 ASCII characters.[7] They were extracted from recordings by the computer specially programmed for digitization and segmentation purposes. Although some of the sounds produced may be a bit artificial, extensive experiments proved that blind subjects could master them in a matter of just an hour or so after which they could "read" between 60 and 80 words a minute.[8]

The first version of the generator was developed on a mini-computer. Based on the principles of the computer program which generates the spoken sounds, a portable digital apparatus was subsequently designed and built. The circuit is relatively simple and can be easily converted to the current LSI computer technology. Its block diagram is shown in Figure 2. As the ASCII code of a character reaches the machine, a pointer is set to search its location in memory. By a table look-up technique, the phoneme combination for the corresponding sound is found. The phonemes are then generated through the digital to analog converter according to pre-programmed phonetic rules also stored in the ROMs. Thus, one hears the sound A (phonemes /e/ and /i/) when the ASCII code 301 reaches the machine. The current spelled speech generator will make any instruments talk as long as they give an ASCII output.

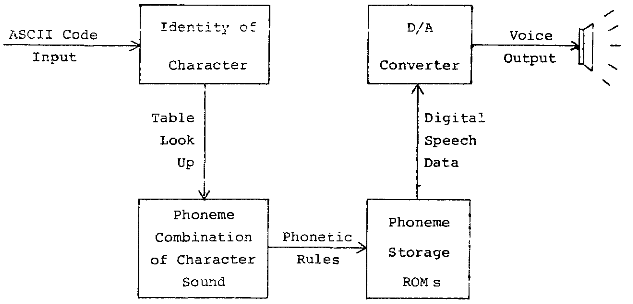

Figure 2—Block diagram of the spelled speech generator

COMMUNICATIONS WITH THE COMPUTER

Since ASCII codes are readily available from most computer terminals, the Spellex system enables blind programmers to hear what they command the computer to do. This mode of operation is desirable for mini-computers as well as big computers using remote terminals. Our system provides communication with the computer by telephone lines at remote terminals at three locations in Vancouver: the Jericho Hill School for the Blind, the Crane Memorial Library and the Vancouver branch of the Canadian National Institute for the Blind. An editor is also included in the programs so that detected errors can be removed immediately. Once the user is satisfied with the output, he can have it punched on paper-tape so that multiple copies can be made afterwards. So far, blind students have used the system for text editing and as a training facility for typing. They have used it to type theses, make copies, circulars, and even applications for jobs! Nearly everyone likes to play with the new machines. However, continued co-operation with blind people is needed to adapt the interface to new uses as they are discovered. Many suggestions have been received from users of these terminals, especially from the oldest installation (1972) at the Jericho Hill School for the Blind. The system has also been used by multiple-handicapped blind.

So far, we have answered the input problem. The output problem is more difficult to solve due to the fast speed at which characters are generated from the computer. Even with the slowest specified rate of 110 bauds, it represents an output speed of at least 100 words a minute, and the speed of line printers could be many times faster. Some blind people can listen to spelled speech at 100 words per minute if they have some ideas about the kind of output and the likely results, but not the others. To overcome this particular problem, we have programmed the computer to slow down its speed by the introduction of silent gaps between characters. To date, we have used this technique with success. Another alternative is to implement a memory buffer at the terminal so that the output can be slowed down to the programmer's desired speed. Of course one can also record the computer output on tape-recorders so that he can verify it when desired. The reading of paper-tapes follows the above pattern.

CARD READING

The one operation with which a blind programmer does not appear to be able to cope satisfactorily is the reading of individual punched cards for verification and correction. Braille printouts may be used to check a complete stack of cards, but there is a need to read cards singly for certain purposes. One device, which has been available for some time, requires the user to find each hole with a probe, but the procedure is too time-consuming for efficient operation.

To answer the above needs, a portable card reader was developed in the laboratories of the National Research Council. This device employed a tactile read-out with no form of code conversion. Appropriate tactile stimulators in a row of 12 were activated corresponding to the holes punched on the card. Recently we have modified this equipment to provide an ASCII output for the Spellex spelled speech generator. A block diagram of this new device is shown in Figure 3.

The card to be read is placed in a carriage that is movable from left to right. A small plastic key in the rear left hand corner assures correct orientation of the card. Only one column is read at a time and this is selected by moving the carriage manually. Column positions are identified by feeling the location of a pointer which moves along a raised scale. A row of twelve photocells under the moving carriage is fixed to the body of the instrument to detect light passing through the 12 possible punched holes in any column. A fluorescent lamp is used as the light source. ASCII codes of the punched characters are provided by an integrated circuit Hollerith to serial ASCII code converter. Thus, the operator hears the sound of the punched character each time its holes pass through the photocells. At present, the synthesizer is triggered at each column location by a pushbutton. However, it is planned to provide an automatic trigger so that each character on the card will be pronounced as soon as the column is properly aligned. An automatic drive for the carriage will also be added if field trials with blind programmers indicate that this is a useful feature.

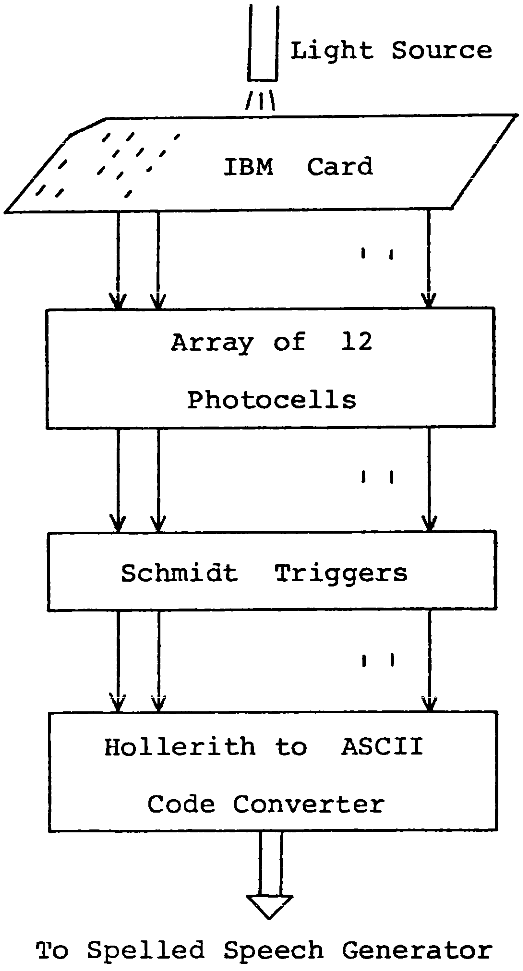

Figure 3—Punch card reader

CONCLUSION

The Spellex system does not only make office equipment such as the typewriters and calculators talk but also teletypes, card readers and some other computer peripherals. In sum, it can make any instruments talk as long as ASCII code is available. Although spelled speech is slower in speed than ordinary conversation, it is especially useful in such cases as reading computer programs, checking spelling errors and providing numerical output. It can also be employed in the mini-computer environment, on-line applications and satellite terminals for large computers. It has the potential of being manufactured by large scale integration technology. The cost of such a unit can be very low when large quantities are produced.

OUTLOOK FOR THE FUTURE

Over the past few years, numerous blind people have accepted the challenge of working in the field of data processing. While scientists and research workers have developed a number of tactile and auditory instruments to assist them, there are still some problems blind programmers are facing, in particular: faster means of reading computer output, flow-charting communication, means of getting information from books, manuals, periodicals, and other reference materials. It seems that the needs of blind programmers are many and can only be solved when a multi-media approach is taken, i.e., combining the use of both tactile and auditory feedbacks for adaptation to computer peripherals and other equipment. They could then use the appropriate type of sensory aid as required. Those who are poor in Braille and tactile senses (e.g., diabetes) could make use of auditory instruments to carry out their daily work. The converse is true for those who have a poorer auditory sense although statistically this condition is far less common than the former condition. While Braille seems to be more suitable for establishing permanent records of computer output and programs, spelled speech is more suitable for the input phase and on-line monitoring, and optical readers such as the Optacon and the Lexiphone are more suitable for reading materials already in print. A multi-media approach in a time-sharing mode seems ideal for the visually handicapped to choose the right equipment and feedback medium for each particular situation. The ultimate solution will be a low-cost multi-media system which can only be realized by greater efforts in research, development and evaluation.

ACKNOWLEDGMENTS

This work was supported by grants from the Medical Research Council and the National Research Council of Canada, the Mr. and Mrs. P. A. Woodward Foundation, the Vancouver Foundation, and the Department of Education of Quebec, Canada. The authors also wish to thank John Moon and Lloyd McSheffrey for assistance.

Development of a hand-held talking calculator for the blind

by R. E. SAVOIE, J. S. BRUGLER and J. C. BLISS
Telesensory Systems, Inc.
Palo Alto, California

ABSTRACT

This paper describes a project to develop a calculator for blind people. Based on the results of a survey of needs and an evaluation of various types of displays for the blind, spoken word output was chosen as the ideal display. The final product, hand-held and battery powered, incorporates a custom LSI microcontroller and a single 16K Read Only Memory to synthesize a vocabulary of 24 words.

INTRODUCTION

Small, lightweight hand-held calculators have become as standard a household item as toasters since Hewlett-Packard Company pioneered the HP-35. These electronic calculators are among the few truly innovative products of recent years and a success of American technology made possible by Large-Scale-Integration (LSI) electronic circuitry. New and improved calculators are being introduced almost daily by various manufacturers, with computation capability ranging from the basic four functions to programmable models which are essentially computers. All indications are that the prevalence of use of these calculators by working adults and school children is on the increase.

Thus far, the blind have largely not benefited from this technological advance because pocket calculator displays are visual. To overcome this lack, many organizations, including our company, have worked at developing special calculators suitable for use by the blind. The motivation for these efforts stems largely from the realization that an effective calculator for the blind would not only provide a quick and reliable means for doing calculation, but also would offer the possibility of increasing the mathematical skills of the blind. Mathematics has traditionally been a difficult subject for blind students, partly because of the complications of displaying mathematics in Braille.

The development described in this paper initially addressed several fundamental questions such as: How would the blind use a calculator? What features are required? How should the information be displayed? The answers to these and other questions led us to develop a talking calculator that provides to the blind user all the information and convenience that ordinary hand-held calculators provide to the sighted.

BACKGROUND

The traditional calculation tool for the blind has been the abacus, which performs simple computations adequately, but which requires great skill for more involved work. When electronic calculators became generally available, TSI developed a special lens module that allows an Optacon user to read many of these calculators without modification. The Optacon is an electronic reading aid for the blind that presents the user with a tactile facsimile image of an area about the size of a letterspace, selected by a small camera that is scanned by the user. By replacing the standard lens module used for reading inkprint with the special calculator lens module, the Optacon user can scan the calculator's visual display and feel the images of the digits displayed on his finger. A number of Optacon users own sophisticated, scientific calculators which they use routinely in their work. However, many totally blind or low vision people are not Optacon users, but have a need for a portable calculator which can produce the numerical display in a form that does not have to be read visually. To address these needs, TSI began to investigate the alternatives to the visual display readout which is standard on pocket calculators.

DESIRED FEATURES OF A CALCULATOR FOR THE BLIND

Blind persons' computational needs cover the same wide spectrum as that of the general public. In order to accurately assess interest from the blind community in an electronic calculator, we conducted an informal survey of 180 blind people throughout the country.[1] We found that 75 percent of those questioned expressed a desire to own an electronic calculator. The results of the survey, together with our own opinion, led to the following list of key important features needed in any calculator we should develop for the blind:

1. *At least four functions (add, subtract, multiply, and divide), floating point calculation plus automatic constant, memory and square root.* Nearly half of the survey respondents indicated that they would use a calculator primarily for personal use, and only 5 percent needed full scientific capability. The above features would therefore cover most of the expected usage.
2. *Easy usage by the sighted and partially sighted.* Many potential blind users have sighted spouses and children who would also use the calculator. The utility of a calculator would also be increased considerably if those partially sighted who cannot read ordinary calculators would be able to use it.
3. *Easy portability and battery operation.* About half of our survey respondents indicated a firm desire to have a portable unit as close as possible to pocket size.
4. *Immediate confirmation of keyboard entry.* The operator needs instant feedback to confirm each key-press to insure easy learning and fast, accurate computation.
5. *A display that is easily learned.* To enable widespread usage there should be no undue burden on the operator, other than learning how to operate the calculator. Additionally, the calculator should be easy to teach and demonstrate.
6. *Minimum human error in display readout.* Calculators do not make mistakes—human operators do. The display technique chosen should be sufficiently clear and unambiguous to minimize the inevitable human error.
7. *Low "user frustration."* This subjective parameter relates to the others, and means basically that the display is easy to use. The operator should be able to concentrate on the mathematical problem at hand, not on just reading the display.

A critical problem in meeting the above goals is to choose the proper display. The computation itself is easy, due to the recent availability of inexpensive LSI calculator circuits. Our initial work was therefore directed toward the display problem, with the hope that the same LSI technology could lead us to an effective display. Since we were searching for "pocket" calculator displays, we did not consider displays providing permanent hard copy.

DISPLAY ALTERNATIVES AND EVALUATION

Choice of a digital display for the blind is the subject of considerable effort throughout the world. A recent report[2] by J. M. Gill of the University of Warwick, Coventry, England lists 27 different digital displays either available or proposed. We encountered several additional displays during our investigations. Most of these displays, it should be noted, are useful for digital information whether from a calculator or not.

In Table I we present a listing of the important pocket calculator displays that we know, along with a comparison with respect to the important features we identified in our survey, plus calculation speed and cost. Displays are ranked within each category, with lowest numbers the best. To the right, scores of each column are added to give a rough ranking of the various display options. Our listing of the relative display merits is, of course, subject to debate, but the indication is that the most attractive display is speech.

One can appreciate that the display problem is really one of too many choices. All of these displays work. Undoubtedly, any one of them could be happily and successfully used by many people. Faced with this dilemma, we decided to construct or obtain several different calculators having the display techniques we liked the best, and conduct a comparative evaluation as objectively as possible. Following this plan, we evaluated four different calculators.

1. *An Audio-Matrix Scan Display*—a number of side-by-side columns of braille readout cells, one column for each display digit. The user scans each column of cells vertically with his fingertip. A tone is provided when the correct cell is touched.
2. *An Audio-Keyboard Scan Display*—the calculator keyboard itself is used to perform the digital readout. The user scans the keyboard by sequentially pressing the numeric keys. An audio tone is generated when the key corresponding to the

TABLE 1—Ranking of Calculator Displays

Display Type	Learning Effort Required	Sighted Use	Computation Throughput Speed	Portability	Confirmation on Entry	Overall Error Rate	Cost	User Frustration	Unweighted Total Score
Abacus	2	2	4	1	4	2	1	2	18
Optacon	5	1	1	2	3	2	5	2	21
Tactile-Parallel	3	3	1	2	2	2	4	2	19
Tactile-Serial	3	3	2	1	2	2	3	3	19
Audio Tones	4	3	2	1	3	4	2	3	22
Speech	1	1	2	1	1	1	4	1	12
Audio-Keyboard Scan	2	2	3	1	2	3	2	3	18
Audio-Matrix Scan	2	2	3	2	2	3	2	3	19

most significant digit is depressed. At successive scans, successive digits are determined on down to the least significant digit. Of course, the calculator itself is disabled during the scanning process.

3. *A Braille Serial Display*—a single braille display cell dynamically presents the digits, one at a time, from most to least significant digit upon user command.
4. *An Audio-Speech Display*—synthetic speech is the output code.

Our evaluation involved participation by almost two dozen blind subjects, many of whom were sophisticated in mathematics and had experience in evaluating sensory aids. The evaluators were shown the calculators and allowed to practice. Next, they were timed for speed and accuracy doing sample problems. Finally, their subjective preferences were solicited.

The Audio-Keyboard Display was eliminated early in the evaluation because we determined that it simply required too much effort on the part of the user. Of the seven evaluators who saw the remaining three displays, six preferred speech output, and speech proved to be the fastest and most accurate, as shown below.

Display Type	Av. Time/ Problem	Total No. Errors	Preferred by
Matrix Scan	66 sec.	13	0
Braille Serial	38 sec.	14	1
Audio Speech	26 sec.	0	6

A key finding was that quite commonly an error with the matrix or braille displays was the result of reading correctly a display that had the incorrect answer because the user had made a mistake entering the problem without knowing it. This problem was obviated with the speech display, which pronounced the name of each key as it was depressed.

Our evaluation thus led us to conclude that spoken speech is preferred using both subjective and objective measures. Speech, as the natural human communication means, uniquely needs no learning, can be used by the sighted, causes minimum user error and frustration, and provides immediate feedback identifying every key depression. Another advantage of voice for the calculator application is that additional required display parameters, such as "overflow," "minus" and "point" are provided in a natural way. All of the other display techniques become awkward when faced with these extra functions.

DEVELOPMENT OF SPEECH PLUS™ CALCULATOR

Based on the results of our survey and evaluations, we formulated the following product specifications:

1. Hand held and battery operated
2. Spoken speech for every key depression and for display on command
4. Cost effective and reliable.

One main effect of these constraints was to eliminate analog methods of producing speech, such as magnetic tape or optical film, which we felt could not compete with modern solid-state electronics in terms of size, cost and reliability.

At the time that these goals were written, we had a breadboard talking calculator (used in the evaluation) that comprised two large boxes full of electronics. One box contained a TTL prototype electronic speech synthesizer which employed a synthesis algorithm for which TSI subsequently obtained an exclusive license. The remaining electronics was required primarily to interface our speech synthesizer to an ordinary calculator chip. This interface proved to be surprisingly complex, because the high-speed, multiplexed, 7-segment signals used for the visual display are inappropriate for the slow-speed sequential readout required by the speech synthesizer. A possible solution to eliminating this interface would have been the use of a printing calculator chip, but there were none available that satisfied our computational needs. The major engineering tasks as we began the development can be summarized as:

1. Reduce the speech synthesizer (over 60 integrated circuits) to a small, cost effective size
2. Reduce the complexity of (or eliminate entirely) the interface between the calculator chip and the speech synthesizer
3. Design a convenient package engineered with the human factors of a blind user in mind.

To tackle the problem of the speech synthesizer, we engaged a consulting firm to evaluate the synthesis algorithm and recommend whether it could be implemented using a microcomputer. Their findings supported our feelings that microprocessors available then (April 1975) were inadequate in all of the following areas:

1. Speed
2. Size
3. Power consumption
4. Cost

We had previously confirmed the feasibility of executing the synthesizer design in a custom LSI microcontroller. With the finding that the microprocessor approach was not feasible, we began LSI development. The resulting custom MOS LSI program successfully reduced the 60 IC packages to a single microcontroller circuit and a single ROM.

The microprocessor approach, however, was the solution to reducing the interface complexity. We were able to identify a one-chip microcomputer that could be programmed to perform the computational algorithm we required and also to give the speech command signals required by the speech synthesizer.

The packaging problem involved innumerable details, but was centrally concerned with satisfying the following requirements:

1. Small and lightweight enough to be hand-held
2. Keyboard designed expressly for the blind.

The first problem was complicated by the presence of considerably more electronics than are in an ordinary calculator. The major contribution to size reduction was, of course, the use of LSI integrated circuits to reduce the package count. We also took care to assure low power consumption so we could obtain the required operating time with physically small batteries.

To find out as much as we could about the best keyboard design, we conducted an evaluation of twenty commercial keyboards using almost fifty blind subjects. We also tested several different formats of custom keyboard. For these, subjects were timed and scored for errors on sample problems with a simulation of a talking calculator. The general findings, which were incorporated into the calculator design, were:

1. Relatively large key tops were preferred
2. Relatively long keystroke was preferred
3. A tactile locating "bump" on the "5" key was preferred
4. Functional partitioning by spatial separation was more efficient than other tactile cues
5. A 6×4 horizontal key matrix was more efficient than a vertical or square format (because many subjects used two hands to input data)
6. The standard calculator arrangement of the number keys was disliked by many blind subjects. These subjects had experience using push-button telephones, which have an inverted arrangement. It would be confusing to a blind user to alternate between calculating and telephoning if the basic number matrices were different. We therefore decided to use the telephone arrangement for the number matrix of the keyboard

Figure 1 shows a functional block diagram of the talking calculator. It employs a "three-chip" architecture. On the left is the microcomputer, which implements our calculation algorithm, drives the visual LED display, services the keyboard, and sends speech command signals to the speech synthesizer portion on the right. The speech command signal is a 5-bit parallel code specifying one of the 24 words in the calculator's vocabulary, and a strobe signal to initiate speech.

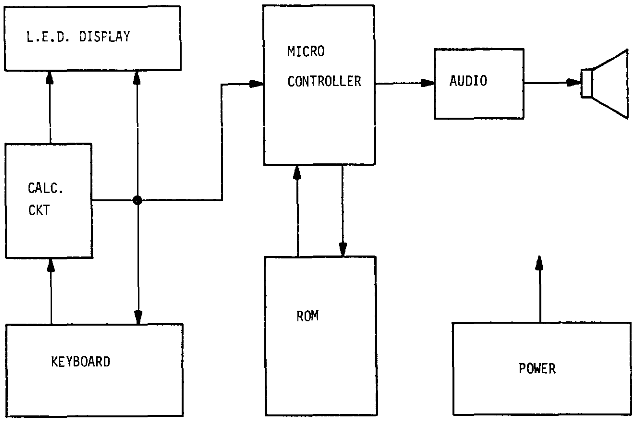

Figure 1—Functional block diagram.

The speech synthesizer uses two LSI integrated circuits, one of which is a commercially available 16-K n-channel MOS read-only-memory, mask programmed with our custom pattern. The second IC is our Custom MOS ROM Controller (CRC), a micro-controller which implements a proprietary algorithm for speech synthesis. Upon command of the calculator chip, the micro-control chip reads the outputs of the calculator chip. These signals are used to fetch control information stored in the read-only-memory (ROM) chip. The CRC also determines the addresses needed to access data stored in the ROM. From ROM information, the control chip determines how to say the word, the pronunciation, how long to say the word, and when to stop saying the word.

Sound is produced from data stored in the ROM. The micro-control chip selects the ROM addresses to be read and speech is produced from the data stored in a given location. Each speech sound is made up of many digital bits, each one making up an increment of the analog audio signal. The control chip also converts the digital information produced in conjunction with the ROM to an analog audio signal, via an on-chip D/A converter.

The division of labor between these two ICs is such that the vocabulary and language information reside solely within the ROM, while the controller is language- and vocabulary-independent. Thus, a change in the language of the calculator involves only replacing the "English" ROM with the appropriate foreign language. We are presently working on a German calculator.

APPLICATIONS

The Speech Plus™ calculator is expected to open whole new fields of application of math to the blind. We see imoprtant uses in the vocational, educational, and home areas.

Blind vending stand operators can use the calculator to figure prices and sales taxes, and also to do their own accounting. Blind salesmen can figure quotes, budgets, and the like. And scientists and engineers can use the calculator at their jobs.

In education, the calculator offers the possibility of improving the methods of teaching math to blind (and sighted) children, as the entire class can follow the calculation by sound. At higher grades, it offers a means for blind high school and college students to do assignments involving calculations.

In the home, the calculator can be used to reconcile bank accounts, figure taxes, do comparison shopping, and is useful in hobbies such as carpentry and electronics.

We intentionally structured the calculator so that the calculating portion and the speaking portion are relatively independent. The speech synthesizer can easily be expanded to a 64-word vocabulary with the addition of one more ROM. There are many applications for other devices for the handicapped which could benefit from the use of such a relatively small-vocabulary voice capability. These include talking voltmeters, talking clocks, talking typewriters, talking notetaking devices, talking computer terminals, and so on. The development of a speaking capability for the calculator thus opens the door to a wide variety of other possible applications.

SUMMARY

An extensive survey of blind people indicated that there is demand for a hand-held electronic calculator useable by the blind. An evaluation with blind subjects showed that audible speech is the best display modality for an electronic calculator for the blind. The principal drawback of speech is its cost, which has been effectively mitigated through LSI electronics.

Survey of public attitudes toward computers in society*

by DAVID H. AHL
AT&T and Publisher—Creative Computing Magazine
Morristown, New Jersey

ABSTRACT

There is no doubt that the computer will have at least as great an effect on humankind as any previous innovation, but today we can see just the tip of the iceberg. In the future the computer will be not merely in the realm of the scientist or data processing specialist but it will be available to everybody.

Do people understand the computer and what it can do? *Creative Computing* magazine conducted a survey in 1975 to find out. The survey was conducted in two highly computerized nations, the United States and Germany among both young people and adults and among people who had been exposed to the computer and those who had not. The sample of 843 was relatively balanced demographically.

This survey indicates that most people are remarkably optimistic about the benefits the computer can bring to society in a number of areas, for example, education, law enforcement, and health care. People feel they are unable to escape the influence of the computer and that it has some undesirable effects, however, they do not feel particularly threatened by it. Young people tend to be less optimistic and feel more threatened by the computer than do adults. A surprising two-thirds of the population have a fair understanding of both the role and function of the computer although there are a few misconceptions.

Compared to the 1971 AFIPS/*Time* survey, people have become more optimistic about the use of computers in most areas with the notable exception of credit data banks. Also, this *Creative Computing* survey identified the computer influence on elections as a real danger area—to our knowledge this has not been previously surveyed.

METHODOLOGY

During the 6-month period, February through July 1975, *Creative Computing* Magazine conducted a survey on people's attitudes toward computers and their role in society. Some 843 people responded in two highly computerized nations, the United States and Germany. About one-third of the respondents had been directly exposed to computers in some way; two-thirds had not. Thirty-six percent of the respondents were classified as young people (20 and under) and students; the remainder were a relatively balanced cross-section of adults.

The 17 questions in the survey fell in four major categories (although they appeared in random order on the survey instrument). The categories:

1. Computer Impact on the Quality of Life (4Q)
2. Computer Threat to Society (4Q)
3. Understanding of the Role of Computers (5Q)
4. Understanding of the Computer Itself (4Q)

In some cases where the questions were similarly worded, the responses to this questionnaire are compared to those from a 1971 survey jointly sponsored by AFIPS and *Time* Magazine.

SUMMARY

Computers are not only invading our lives along a multitude of directions—supermarkets, credit data, medical records, hobbies, etc.—but our society is becoming so dependent upon computers that it can truly be said that we live in the computer age. The computer will have at least as profound an effect on humankind as did the printing press some 500 years ago. In the Guttenburg Museum, a map plots the spread of printing out from Mainz to the rest of the world over scores of years. The computer invasion has taken place at an infinitely greater speed.

Now, some 30 years after its invention, what do people think of the computer. Monster or savior? Slave or dictator? Do people understand this awesome force?

This survey indicates that most people are remarkably optimistic about the benefits the computer can bring to society in a number of areas, for example, education, law enforcement, and health care. People feel they are unable to escape the influence of the computer and that it has some undesirable effects, however,

* For further information about this survey, please contact David Ahl, Editor, *Creative Computing*, P.O. Box 789-M, Morristown, N.J. 07960.

they do not feel particularly threatened by it. Young people tend to be less optimistic and feel more threatened by the computer than do adults. A surprising two-thirds of the population have a fair understanding of both the role and function of the computer although there are a few popular misconceptions.

Compared to the 1971 AFIPS/*Time* survey, people have become more optimistic about the use of computers in most areas with the notable exception of credit data banks. Also, this *Creative Computing* survey identified the computer influence on elections as a real danger area—to our knowledge this has not been previously surveyed.

COMPUTER IMPACT ON THE QUALITY OF LIFE

On the whole, respondents felt that the computer will improve the quality of life in four areas: education, law enforcement, health care, and prevention of fraud. Young people and students saw somewhat less improvement from the use of computers than did adults.

Computers will improve education—About 85% of all the respondents strongly or mostly agreed with that statement and only 5% disagreed. This was the highest positive (or negative) response to any single question and also the question which had the greatest agreement between adult and youth.

Computers will improve law enforcement—82% of the adults agreed with this and only 3% disagreed. The younger respondents were somewhat more cynical; 70% agreed and 10% disagreed.

Computers will improve health care.—On this issue, the young respondents had considerably more doubts than adults; about 79% of the adults agreed but only 54% of the youth. More than twice as many youth disagreed with the statement as adults—12% vs 5%.

Ranking lower on desirable uses of the computer is its use for *storing and checking credit rating data;* 64% of both adult and youthful respondents saw this as a worthwhile application. However, 13% of the adults thought this was a bad application for the computer perhaps reflecting previous hassles that they or friends had with computerized credit rating data. Most young people probably haven't been exposed to this malady; only 8% of them objected to this application. While substantial, the 64% of the people in favor of this application represents a substantial decline from the 75% recorded just four years ago in the AFIPS/*Time* survey.

THE COMPUTER THREAT TO SOCIETY

Respondents were mixed in their feelings about the threatening nature of computers. Most felt they were unable to escape the influence of the computer. Nearly half saw computer predictions influencing the outcome of elections. More than one-third felt that computers dehumanize society to some extent. About one-quarter saw the computer taking more jobs than it creates. And about one-fifth saw the computer having an isolating effect on programmers, operators, etc.

A person cannot escape the influence of computers—92% of the adults agreed with that statement, most "strongly" agreeing; only 4% disagreed. These percentages are virtually the same as those recorded in the 1971 AFIPS/*Time* survey. Reflecting a more optimistic, perhaps somewhat naive view that one can drop out and avoid anything one doesn't approve of, only 67% of the young people felt they could not escape the influence of computers and 18% strongly disagreed with the notion that computers couldn't be avoided.

Computer polls and predictions influence the outcome of elections.—About 46% of the respondents agreed with this statement and 27% disagreed. In a democratic society, this is truly of grave importance. If almost half the people, adult and youth alike, feel their voting behavior is in some way influenced by computer polls and predictions (join the bandwagon, we've lost so why bother voting, etc.) then we have a real problem.

Computers dehumanize society by treating everyone as a number.—Reflecting a rather positive shift in attitude, only 37% of the adult respondents agreed with this statement and 50% disagreed compared to the percentages of 54% agreement and 40% disagreement just four years ago in the AFIPS/*Time* survey. The younger respondents in the current *Creative Computing* survey were more pessimistic; 40% agreed that computers dehumanize and only 31% disagreed. (Youth were not included in the 1971 survey.)

Computers isolate people by preventing normal social interactions among users.—Computer bums and computer freaks are common around any school with a computer. Million dollar corporate computers have to be fed data around the clock to justify their investment and there is a growing army of midnight shift programmers and operators. Among the uninitiated, FORTRAN or COBOL are more foreign than French or German. Are computers really isolating segments of society? Maybe, but apparently it's not very noticeable since only 20% of the respondents agreed with the statement above. More revealing, however, is the fact that 63% of adults disagreed with the statement and only 43% of young people disagreed. Perhaps computer freaks, who tend to be among the younger cadre, *are* becoming more evident.

UNDERSTANDING THE ROLE OF COMPUTERS

This issue was examined from two directions: what types of jobs are suitable for a computer and what will be its effect on human employment (or unemployment)? For the most part, adults saw the computer as suitable for dull, repetitive tasks like a hammer or lathe while young people saw computers in much broader roles. Furthermore, adults saw computers replacing low skill jobs and creating just as many jobs as they eliminate; young people were not as optimistic.

Computers are best suited for doing repetitive, monotonous tasks.—Eighty percent of the adults agreed with this statement and 10% disagreed. Among young people, 57% agreed, 22% disagreed. In other words, young people see the computer doing a wide variety of things beyond simply data processing, numerical machine tool control, and telephone switching. But perhaps in some of these more sophisticated applications in which the computer takes over some of the human decision-making function, youngful respondents are more fearful of computers and less optimistic than adults.

Computers are a tool just like a hammer or lathe.—Again, adults are in considerably greater agreement with this statement than are younger respondents.

Computers slow down and complicate simple business operations.—Interestingly enough, most people seem to believe that computers are used reasonably well in business because 68% disagree with this statement and only 17% agree.

Computers will replace low skill jobs and create jobs needing specialized training.—Somewhat more adults agreed with this statement (71%) than did youth (62%). About 15% of both adults and youth disagreed. This implies that a substantial fear exists that computers will take a tremendous number of jobs and there will have to be a massive effort by society (retraining, welfare, or ?) to absorb the human beings put out of work by the computer monster. This leads to the next question.

Computers will replace as many jobs as they eliminate.—Again, somewhat more adults agreed (70%) than did youth (61%) and fewer adults disagreed (13%) than youth (23%). So we see that a large number of people believe the computer will replace low skill jobs, but furthermore, we see some question about the creation of new jobs by the computer to replace the ones eliminated and, as before, there is even more doubt expressed by youthful respondents.

UNDERSTANDING OF COMPUTERS

After looking at the various roles of the computer, one must ask, do people understand the computer per se by itself? And the answer is that a surprising number do. And quite a few don't. Indeed between one-quarter and one-third of the population believe the computer is beyond the understanding of the typical person. Also, many people have the wrong notion about who causes computer mistakes—machines or people.

Computers are beyond the understanding of the typical person—Are they? Well 25% of the adults and 31% of the youth think so. But 62% of the adults and 49% of the youth think they are within comprehension. Perhaps more revealing—among schools with a instructional computer program, nearly 80% of the students believe that computers are within their understanding.

Computers make mistakes at least 10% of the time—This statement must be coupled with the next one: *Programmers and operators make mistakes, but computers are, for the most part, error free.* FACT: Statement 1 is absolutely false, statement 2 is true. How did respondents do with these questions? Most answered "correctly"—about 68%, fewer youth than adults, but a fair number of people were downright wrong (13%). The rest of the people didn't know (19%). These percentages are similar to those scored on nationwide tests of scientific facts—about ⅔ of the people know the facts but the other third are wrong or just don't know. A happy situation? Not very.

It is possible to design computer systems which protect the privacy of data.—Not even the computer designer knows for sure, so what can we expect from the general public? Well, 61% of the adults think you can design a secure system and 26% think you can't; only 49% of the youth think you can and 16% think you can't. What does all this say? Probably nothing except that some people are optimists and some are pessimists, and at least on the data privacy issue, more adults are optimistic than young people.

APPENDIX—*Statistical Results of Survey of Public Attitudes Toward Computers in Society*

	ADULT (N=300)		YOUTH (N=543)	
	Strongly or Mostly Agree	Strongly or Mostly Disagree	Strongly or Mostly Agree	Strongly or Mostly Disagree
Computer Impact on the Quality of Life				
• Computers will improve education.	86.6%	5.9%	84.2%	4.5%
• Computers will improve law enforcement.	81.9	3.3	70.0	10.1
• Computers will improve health care.	78.6	5.3	54.1	11.9
• Credit rating data banks are a worthwhile use of computers.	64.2	13.4	64.0	7.6
Computer Threat to Society				
• A person today cannot escape the influence of computers.	91.6	4.0	66.6	17.7
• Computer polls and predictions influence the outcome of elections.	48.1	27.5	44.2	26.9
• Computers dehumanize society by treating everyone as a number.	37.4	50.3	39.9	30.6
• Computers isolate people by preventing normal social interactions among users.	18.7	62.5	20.9	42.5
Understanding the Role of Computers				
• Computers are best suited for doing repetitive, monotonous tasks.	80.0	10.3	57.0	21.6
• Computers are a tool just like a hammer or lathe.	72.6	14.7	61.3	23.4

Alexandria, Virginia

ABSTRACT

The Center for Inquiry and Discovery in Washington, D.C., is planning to establish a public computer center to be used primarily by school age children. A survey of existing public-access computing facilities throughout the country is being made in order to seek information and advice to assist in this planning. This paper describes the survey being undertaken, the institutions being studied and the findings to date.

SURVEY OF PUBLIC ACCESS TO COMPUTING

There is at present no public access computing facility in the Washington, D.C. area. Although universities and even some secondary schools have computers for student and faculty use, access to these systems is generally restricted. The Center for Inquiry and Discovery, a newly established institution in Washington, is planning to create a public computer center for a wide variety of uses.

The Center will organize computer-related workshops, classes, clubs and special projects for individuals, community groups and local schools. In addition, the computer will be used in the exhibit areas of the Center. There will be an exhibit devoted to computers, where the casual visitor will be able to learn something about the nature of computing and perhaps become interested enough to enroll in a class or workshop. The computer will also be used in some of the other exhibit areas to help to explain the subject matter using simulations or graphic displays where appropriate. Finally, a data bank describing community resources, available materials and upcoming events of possible interest to Center visitors will be available from terminals located throughout the exhibit areas.

In order to plan for this computer facility, a survey is currently being conducted by the Center to study similar programs at museums, science centers and other public institutions throughout the country. Also included in the survey are several research oriented labs (SOLOWORKS at the University of Pittsburgh, the LOGO project at MIT, Xerox PARC in Palo Alto) which have as a common goal the development of computer systems which can be used effectively by people having widely divergent backgrounds and interests.

Information is being collected about hardware, software, educational programs, staffing, types of users, costs and financing at these institutions. The following is a partial list of questions taken from a questionnaire being used in the survey.

Ties with other institutions

- What kinds of services are provided to local schools, colleges or community groups (e.g., field trips, classes during school hours, facilities for students to do individual projects, in-service teacher training)?
- Do students and teachers receive credit and release time for their participation?
- Does the center provide a time-sharing service for the schools or the community and, if so, what level of support is provided (e.g., development of curricular materials)?

Exhibits

- What philosophy about computing is shown to the one-time visitor?
- How are exhibits designed that are easy for visitors to use and understand, and which need minimal supervision?
- Is game playing the most effective use of computers in an exhibit area?

Educational programs

- What classes, workshops, and clubs are available for the public?
- Are educational programs provided for various age groups and levels of sophistication?
- How are educational programs, classes, workshops evaluated?

Equipment

- What kind of computer equipment (e.g., central system, terminals) is used?

- How is maintenance handled?
- What software packages are available for users?

Staffing

- What level of staffing is needed to support the computer center and its activities?
- To what extent does the center rely on students and other volunteers to perform staff functions (e.g., teaching classes, systems development, hardware maintenance) ?
- Are volunteers reimbursed in some way for their efforts (e.g., receiving school credit, revenue from sales of software) ?

Financing

- Is the computer center self-supporting or does it rely on general admission charges, grants or donations?
- Is the computer used to raise money by providing such things as mailing list and accounting services to other non-profit institutions?
- Is computer time sold to the public?
- Is tuition charged for classes and workshops?
- Are payments received for services provided to schools?

The following is a brief description of those institutions which have already been visited.

Lawrence Hall of Science on the University of California Berkeley campus is a science museum with a large staff of students. It has five computer terminals in the exhibit area running games and simulations and an extensive educational program of classes for school children and the public. Its three computers provide a low cost time-sharing service for over 35 educational institutions in Northern California.

Oregon Museum of Science and Industry (*OMSI*) in Portland has in addition to its exhibit area a community research center. The goal of this research center is to provide the community with access to otherwise unavailable scientific equipment. It has a PDP 11/45 that approximately 40 students per year use to do individual projects for which they receive high school credit. Advanced software development projects have earned revenue and equipment donations for the center.

Community Computer Center is a storefront computer center in Menlo Park, California, that offers the public access to recreational uses of computers. Their activities include a hardware club, classes for teachers, birthday parties, field trips, and game nights.

The Exploratorium in San Francisco is a large science center that hopes to use computers in the future to simulate scientific phenomena.

Pacific Science Center in Seattle is in the American exhibit building of the 1962 World's Fair. They are still planning their computer activities, but do have two terminals running games with time donated by various schools and businesses.

Boston Children's Museum has a computer, terminals, and calculators in an exhibit area for visitors and school children on field trips to use. They also use their computer for administrative purposes.

Boston Museum of Science has a large exhibit area with a computer and terminals donated by Honeywell.

Franklin Institute in Philadelphia has a terminal in the math area, running a demonstration package. Computer time is donated by businesses and schools. They also hold a summer computer workshop. They are planning to use the computer in a new Bicentennial exhibit.

Maryland Science Center is a new institution not yet open to the public. In a preview exhibit they used the computer-controlled turtle and music box developed at MIT's LOGO Project.

The LOGO Project at MIT has developed new ways for young children to learn mathematics and logical thinking using the LOGO language, computer-controlled devices and graphics.

SOLOWORKS at the University of Pittsburgh is working to develop the hardware, software, and courseware for an open mathematics laboratory. They use a wide variety of computer peripherals such as graphic displays, robots, and a pipe organ in their lab.

Xerox PARC has developed a computer system and a language called SMALLTALK which makes graphics and animation easy to use. They hope to open their own storefront computer center in the near future.

Other institutions which have been or will be contacted by telephone and visited in the future include: Ontario Science Center, Chicago Museum of Science and Industry, The Science Museum of Minnesota, Science Museum of Roanoke Valley in Virginia, Denver Children's Museum, Fernbank Science Center in Atlanta, and the Brooklyn Children's Museum.

While each site surveyed has its own unique features, certain ideas, programs and problems seem to be almost universal. Although the survey is not yet complete, a summary of the most common and most important points of information gives a picture of a "typical" public access computer center.

Coordination with local public schools is essential. The schools are the primary sources of users for a public access computer system. While the computer exhibit areas attract the attention of adult and child alike, the more in-depth behind-the-scenes activities such as workshops and computer programming classes, mainly attract school children. Many of these classes are official school functions, with the computer center being the site for repeated field trips from the schools. Payments from schools for use of the center's resources are often an important source of income.

Cooperation with local universities is important since college students are a valuable source of part-time or volunteer staff. The possibility also exists to offer in-service training for teachers in the computing center for college credit.

Most of the institutions visited have computer terminals in an exhibit area. Simple games are the main mode of initially presenting computers to visitors, however, neither staff nor user interest is sustained if the only computer activities available are games.

Cathode ray tubes (CRTs) or silent printer terminals are preferable in the exhibit areas to decrease noise. Since the majority of museum visitors tend to read little of the printed text accompanying exhibits, graphics displays are an additional advantage. Simplified or color-coded keyboards are sometimes used, particularly with young children.

The level of staffing at the centers surveyed varies from the Lawrence Hall of Science with over 30 part-time staff members, most of whom are Berkeley students, to other institutions with only one part-time person. It is important to have at least one paid staff member whose responsibility is to coordinate and provide direction for all the various activities in the center. High school and college students who develop a strong interest become a valuable, but temporary, resource as instructors, programmers, and maintenance engineers.

All the institutions surveyed have received loans or donations of either computer hardware, computer time, or terminals. One institution has traded marketable software packages to a computer manufacturer in return for equipment (e.g., a disc drive). Although donations and loans were instrumental in the development of the various centers, they also have disadvantages. Donations of computer time are often short-term commitments. Software packages developed for a borrowed computer system must either be re-implemented or discarded when the hardware base changes. Donated equipment often presents a maintenance problem since the equipment tends to be several years old. Maintenance contracts are, therefore, fairly costly and parts are more difficult to obtain.

None of the centers is totally self-supporting. Most rely on general museum admission fees, grants, endowments and donations. These revenues are often supplemented by income from school field trips, classes, workshops, and sales of computer time to individual community members and groups. Many of the museums also use their computers to do their administrative work and have expanded to provide these services to other cultural institutions at low cost.

When the survey is complete, our goal is to have developed a model of an ideal public access computer center. It is our hope to build this center in phases as we acquire the necessary funds, personnel and experience. We envision it to be a non-profit, self-supporting computer center which will be able to grow as community acceptance and demands increase.

Building your own computer

by STEPHEN B. GRAY
Amateur Computer Society
Darien, Connecticut

ABSTRACT

Microcomputer kits have changed the build-it-yourself hobby dramatically. Until the introduction of such kits, only about two dozen amateur computers of any real complexity were in operation; nearly all were built by engineers in the computer industry. Formidable problems exist when trying to use or rebuild obsolete vacuum-tube or transistor computers, such as the non-availability of schematics. Building from scratch is so complex that usually only electronics engineers achieve it. Building a machine that uses the instruction set of a commercial computer is popular. Microprocessors were introduced only a few years ago, and already two dozen microcomputer kits are available, ranging from inexpensive minimal machines using assembly language, to high-level-language systems costing several thousand dollars.

INTRODUCTION

Microcomputer kits have been available for only a little over two years, but they have changed the build-a-computer hobby quite dramatically. Up to the beginning of 1974, only about two dozen amateur computers of any real complexity were in operation, and nearly all had been built from scratch by engineers in the computer industry. Today two dozen different microcomputer kits are available, based on half-a-dozen different microprocessors, and about 7,000 have been sold, a great many to people with apparently little or no knowledge of electronics.

Despite all the activity in microkits, many computer hobbyists are still building machines of their own design, or copying a commercial machine (or its instruction set), or operating and/or rebuilding obsolete computers. Before looking at the microcomputer scene, let's first examine what can be done, and has been done, in the more individualistic areas.

USING OBSOLETE COMPUTERS

Vacuum-tube computers are occasionally available, but most of the drawbacks in using them are formidable: many are so large that a barn is required to store them, they need a great deal of air-conditioning and electrical power, and tubes can be expensive to replace.

Schematics are needed to get the computer working and maintained, but they are almost never available. Even with the older transistor computers, schematics (and especially updated schematics) are usually impossible to obtain. Now and then the prototype of a recent computer can be bought cheaply, but again, usually without schematics, so the buyer has two choices: take months or years to trace out every connection, or rewire most or all of the machine.

Several hobbyists who have bought obsolete computers with ailing or missing magnetic-drum or core memories have tried replacing them with semiconductor memory, quite a task even for an electronics engineer, which not all of them are.

Despite all the problems, many hobbyists are still operating an old computer, or trying to get it into shape, including machines such as the LGP-30, RPC-4000, LGP-21, and G-15. The CDC 160A appeals to a number of amateurs, but few if any are in the hands of hobbyists, because the machine is still relatively expensive, and it has 1700 discrete transistors, leading one California amateur to note, "I look at this number as an indication of the problem I would have in keeping it running or even getting it going." He bought an RPC-4000 "at a graveyard-type disposal sale," and later noted, "My RPC is working but I can't get an assembly program more than two-thirds loaded. This produces lots of messages telling me my programs are bad. I suspect some memory aberrations, but the memory print routine won't print either. So I have been trying to write a simpler routine of my own in machine language. That is a drag. It is amazing how many ways you can make mistakes with 32-bit instructions."

An Indiana hobbyist bought a Univac O File Computer as scrap, with arithmetic unit, program-control unit, 90-column reader/punch, sort-collate unit, tape-drive program controller, and six magnetic-tape units. The new owner says, "I had figured to use the outside winter air to get it turned on and see what I've got, and just close down in summer. As to space, not too bad:

only about 400 or 500 square feet, pretty compact. I'm presently having 220 V installed to begin to turn on some of it." The manufacturer told him they can't provide schematics for any machine this old. Each machine was somewhat different, various changes having been made to each during its life, and careful documentation had to be kept as to what was inside each. Many of the old schematics and documentation have been thrown out, and "no amount of money" could provide relevant schematics for most of these old machines, antiques at 19.

Manuals are (or were until recently) available for the Univac 1108: 20 to 30 of them, each costing $50. Some Univac Solid State computers were given away to schools; when the schools asked the manufacturer about documentation, the situation turned out to be "impossible," as there were no records available on updated blueprints. "Maintenance in those days was a tricky thing," said Univac, "and the man who did it has long since been assigned to newer equipment, so there is nobody available from us today who knows how to service the old machines."

One company was getting rid of its Univac I, and wanted to give it away. But Univac found that to take it apart carefully and reassemble it elsewhere would cost $100,000, so the machine was scrapped.

BUILDING FROM SCRATCH

As in amateur radio, many computer hobbyists would never think of buying a kit or an assembled machine; they must build one. Up until only a couple of years ago, this task was so difficult that only a couple of dozen computer hobbyists in this country had operating digital computers that could really be considered as computers, and nearly all were electronics engineers in the data-processing industry.

The main problem in building a computer from scratch, without resorting to a microprocessor, is that so many areas of specialization are involved: logic, input/output, memory, peripherals, and mechanical skills such as packaging, back-plane wiring, metalworking, plastics, and many others. To build one's own computer once required learning a great deal about each of these fields. Although some computer hobbyists are engineers who design their own circuits, most non-engineers must rely on published information, and although several dozen books and manuals contain computer schematics, they have serious limitations. A book may show schematics of various portions of a computer—arithmetic unit, memory, control circuits—but none show how to connect them together, and anyway, they are usually only partial schematics. Minicomputer manuals with full schematics can be bought, but many of the parts are identified only by the manufacturer's code number; copying such a machine would be no real hangup for a computer engineer, but it is indeed for the neophyte.

Even supposing that an amateur computer-builder did get hold of complete schematics and all the parts, the one big stumbling block that has thrown many is core memory. It is still expensive to buy when new, and when surplus it may contain broken cores, or perhaps it's surplus because it couldn't pass the manufacturer's quality control. Getting a core memory to work still separates the men from the boys, if there are still any who want to try it, now that semiconductor memory is so readily available and so cheap.

Surplus computer printed-circuit boards have been available for years, but most of them, especially the IBM SMS series, have had their "tab" ends broken off, to make sure the boards won't find their way back into commercial computers. Many of the 3800 different types of SMS boards are level-changing circuits, of little use to the amateur.

DESIGNING YOUR OWN

Computer engineers often like to design their own machines, perhaps for the challenge of making it work. One Pennsylvania engineer's pre-IC machine is 7 feet long, 1½ feet deep, and 6 feet high; it took a year to build and "will take 10 years to program," according to the builder, who used NOR gates from a process-control system declared scrap, mounted on 120 circuit boards with 35-pin connectors.

One North Carolina hobbyist built 75 percent of his computer with IBM SMS cards, the rest with home-built cards, an IBM 1620 core memory, Selectric typewriter and paper-tape reader/punch for input/output. The six-register machine has 16 instructions. "I/O devices available but not connected: 384K-word drum, two 7330 tape drives, two 100-cpm card readers. . . . A home-built line printer is ⅓ complete; 52-character chain, about 200 lpm."

A letter published in the April 1969 issue of the Amateur Computer Society Newsletter, from an ACS member now in Israel, said, in part, "In past issues of the Newsletter, some rather ingenious instruction sets have been devised which either simplify hardware, decoding or subsequent programming. It should be borne in mind, however, that the use of an instruction set which is already implemented on a commercial machine means a great reduction in problems with software, which would then be readily available. Remember that commercial manufacturers also look for instruction sets which tend to optimize both hardware and software, and many machines have instructions worth copying. If you've never written an assembler or Fortran compiler, don't just laugh it off as an easy project; it may well take you longer than to build the machine itself. Coming up with a new, unique instruction set may be a thrilling idea, but getting someone else's instruction set to function with your hardware is no small feat either."

COPYING A COMMERCIAL MACHINE

The computer amateur who wants to make things easier on himself by copying has two choices: he can obtain the schematics of his favorite computer and try to duplicate it, or he can build a machine of his own design that will use the instruction set of a commercial machine; the latter choice is the most common.

Most of those who have borrowed an instruction set already in use are copying that of the PDP-8 family, because of the variety of programs available, and a simple yet powerful set of instructions.

An Arizona hobbyist has built two computers from scrap parts. "Both are 12-bit, 2-μsec machines patterned after the PDP-8 instruction set. The first was built from second-generation discrete-component DTL NAND logic. The memory was of my own design. My second computer was built to get around the power dissipation problem (1.5W) of the first machine. It gets expensive to operate and refrigerate that kind of system in Arizona. The second machine is made out of 7400-series TTL and has an 8K x 12 main core memory. . . . All the PDP-8 software works on my system. This has saved considerable time, as you can well imagine. I have used the following DEC software: compilers (Focal—8K, Basic—Poly, Fortran—8K); assemblers (Macro 8, Pal III, Saber); maintenance programs, disk monitor systems (my 32K core memory looks like a DF32 Disk System). . . . I have devoted most of my spare time for the last four years in accumulating the parts and developing my software."

In Maryland, a computer amateur says, "Over the past four years, I have been in the process of building a computer. The actual hardware work got under way about three years ago. The machine really started working only a year ago. My machine uses the PDP-8 command set and runs at about the speed of a PDP-8/S (24-μsec cycle time). My memory is from an IBM 1620. . . . I have implemented only 4K at present, though I have designed the boards to allow easy expansion to 8K. . . . I have copies of the DEC software, which all seem to run: Focal, Editor, Pal III, etc. While I use the DEC sofeware, I have made a point of never looking at their PDP-8 hardware diagrams, etc. I'm sure I learned more this way. After all, I'm supposed to be an EE."

A Floridian built a "Mininova 721," which he designed "to be a miniature Nova 1200. . . . I wanted to have a Nova for my very own, but couldn't afford it. I thought 'someday when the price of ICs comes down I'll design and build my own minicomputer, a small-scale version of the Nova.' Well, the prices of ICs came down tenfold or more in 1971-72, and this made my dream practical. The rest was innovation, enthusiasm, and a lot of careful planning. . . . I've incorporated very carefully the best features of the Nova instruction set and programmer's console, and designed the circuits to make a true stored-program, programmable digital computer (complete wtih loads of integrated-circuit MOS-RAM memory) that would execute 16 different very carefully selected instructions. . . ."

TWO PRE-MICROPROCESSOR KITS

Back in the Sixties, the Tesla Research Foundation, with offices in Utah and Arizona, offered a variety of analog and digital computer kits, plans for digital gadgets, and home-study courses. The DI-TR5 digital computer, for instance, cost $365 in kit form, $440 assembled, used germanium transistor NAND logic and diode OR gates, and had two registers and 15 instructions. Input/output was with switches and lamps. The company didn't last long, and has vanished without a trace.

Beginning about five years ago, the National Radio Institute has been offering a course in computer electronics. The course includes building a simple desktop computer, which weighs 16 pounds. The Model 832 NRI Digital Computer contains 52 TTL ICs, 7400-type. The specifications include: 17 storage locations for 8-bit words, expandable to 32 words; over 15 basic instructions; input/output is with switches and lamps. For teaching purposes, the memory consists of slide switches.

THE MICROPROCESSOR REVOLUTION

All the previous quotes from amateurs building their own computers are from before 1974, the year in which hobbyist microcomputer kits first appeared on the market.

The avalanche started somewhat slowly, two years before, when Intel Corp. introduced two "Micro Computer Sets," the MCS-4 and MCS-8, sets of LSI chips for microprogrammable general-purpose computers. The MCS-4 was built around the 4-bit 4004 microprocessor, with 45 instructions; the MCS-8, around the 8-bit 8008, with 48 instructions. Although highly attractive to the hobbyist, both sets were expensive. The MCS-4 consisted of the 4001 programmable ROM memory, 4002 RAM data storage, 4003 I/O expansion, and the 4004 MPU. The last three were fairly cheap: $50, $10, and $100, respectively (in 1972), for 1 to 24. The catch was the 4001: the minimum order quantity was 25, at $25.50 each, plus mask charges of $600. The purchaser could have the ROMs programmed by Intel, or do it himself with the SIM-01 microcomputer (then $400), three control-program ROMs at $101 each, and an ASR33 Teletype.

The MCS-8 cost even more: the 8008 was then $200 for 1 to 24, and programming the ROMs required the SIM8-01 at $900, plus the control ROMs and Teletype.

Hobbyists soon seized upon these MPUs. A Connecticut computernik put it this way, "Enter the Intel 4004 and 8008 CPU on a chip! Both are complete

CPUs with quite a bit of power (45 instructions) and flexibility (internal address stack for subroutine nesting, etc.). The 4004 is not as desirable since it is more complicated to control and doesn't look as much like a typical computer. The 8008, however, is a beaut! . . . The only drawback I see on these devices is their slow speed (about 1 MHz), yielding about 75K instructions per second. For amateur (and many commercial) uses this should be no real problem. Whether we wait 1 sec or 3 sec for the answer does not really matter. But a cost of $5K or $1K does matter!"

MICROPROCESSOR HOBBY KITS

In early 1974, Scelbi Computer Consulting offered the Scelbi-8H modular computer kit, based on the 8008 MPU. There was a starter set of five cards—CPU, DBB (data bus buffer) and output, input, front-panel card, and RAM card (256 8-bit words)—at $440. One step up, the standard card set, with 1024 words of RAM memory, was $565. A standard computer, with cards, chassis (console switches, card sockets, input/output and power connectors), and separate power supply, was $795 in kit form, $950 assembled. The 8H deluxe had 4096 words of RAM memory, and a higher-rated power supply; $1400 in kit, $1600 assembled. The memory could be expanded to 16K words, for about $2760 more.

Peripherals for the 8H included an oscilloscope alphanumeric interface, audio cassette tape unit interface, ASCII keyboard, and bit-serial interface for Teletype.

The Scelbi 8H was manufactured from March 1974 to June 1975, and was superseded by the Scelbi-8B, manufactured from April to December 1975, and using Intel 2102 RAMs "which allow the 8B to be directly expanded up to 16,384 words of memory at a cost comparable to that of 4,096 words of memory in an 8H," which used the Intel 1101 RAM. The 8B kit, with 8008 MPU and 1K memory, was $499; empty 4K RAM card, $49; eight 2102 RAMs, $59. Scelbi provided extensive assembly-language software for their machines.

Scelbi got out of the hardware business at the end of 1975, and has since devoted itself exclusively to software, and to publishing books such as the $19.95 "Machine Language Programming for the 8008 (and Similar Microprocessors)." (The book could just as well have been called "Assembly Language Programming, etc.," but the author felt that people with little or no knowledge of computers would be more likely to understand the title the book was given.) At this writing, Scelbi is working on software such as BASIC for the 8008 and the 8080, and is considering what other MPUs to write software for.

The July 1974 issue of *Radio-Electronics* heralded the debut of the Mark-8 microcomputer kit, based on the Intel 8008 and using 7400-series TTL ICs. A minimum Mark-8, with 256 8-bit words, was about $300. The Mark-8 was available from June 1974 to December 1975, and will be superseded this Spring by the Dyna-Micro kit, an 8080 "microcomputer learning system, not a number-cruncher," with a 1702A PROM that loads on reset, and a memory of 256 words, maximum 512 words; about $200.

The January and February 1975 issues of *Popular Electronics* unveiled the Altair 8800 computer kit from MITS, based on the Intel 8080 MPU, an 8-bit-word/16-bit-address machine with 78 basic instructions. The 8800, through extensive advertising, has become the best-known and most widely sold hobby computer, with some 6,000 sold as of this writing. The basic Altair 8800, with CPU board, front panel, power supply and expander board, is $439 kit, $621 assembled. The 4k dynamic memory boards are $195 kit; the 2K static memory kit is $145; 1K static memory kit, $97; maximum memory is 65K. There are serial and parallel interface boards.

Altair hardware options include a terminal with built-in audio cassette interface, a floppy-disk system, and a line printer. Software includes 4K and 8K BASIC, 12K Extended BASIC, assembler, text editor, system monitor, debug and DOS.

Sphere, a Utah company, offers the 4K Sphere 1 computer kit, using the Motorola 6800 MPU, with 512-character TV terminal, keyboard and power supply, for $860 ($1400 assembled). Memory is expandable to 65K, at about $240 for a 4K board, $400 for 8K, $750 for a 16K memory-board kit. A mini-assembler, editor, debugger, and utility commands are built into 1K of PROM. Available software includes Extended BASIC (with string and matrix manipulation), machine-language subroutine calls, trig functions, and disk-file input/output, plus FDOS (flexible disk operating system). The Sphere 2 kit adds serial communications and audio-cassette capability, at $999. The Sphere 3 kit adds 16K more of memory, for $1765. The Sphere 4 kit includes a 65-lpm printer, two IBM-compatible floppy disks, and DOS, at $6100. Other Sphere products include a light pen, and both full-color and black-and-white video graphics systems.

The MITS Altair 680 kit, with the Motorola 6800 MPU, is less than a third the size of the Altair 8800. Software includes a monitor on PROM, assembler, debug and editor. The 680 has three interrupt levels (the 8800 has eight). A $345 kit includes 1K bytes of RAM; the price for the 12K RAM board kits has not been set as of this writing.

The SWTP 6800 kit, from Southwest Technical Products Corp., using the Motorola 6800 MPU, comes with serial interface, 128 words of static scratchpad RAM, and 2,048 words of main memory, at $450. Additional 4k memory boards are $125 each; interface cards are $35. The SWTP 6800 contains a "Mikbug" ROM with a program that allows data to be entered the moment power is turned on.

In addition to the Altair 8800 and 680, Sphere and

SWTP 6800 kits, over a dozen others are available, including the Mike 2 and Mike 3 (Martin Research), Mark 80 (E&L Instruments), MOD 8, MOD 80 and RM6800 (MiniMicroMart), 008A (RGS Electronics), "George" (Godbout Electronics), Micro 440 (Comp-Sultants), SRI-1000 (Systems Research Inc.), Imsai 8080 (IMS Associates), Jupiter II (Wave Mate), and Micro-68 (Electronic Products Assoc.).

Some kits are based on the Intel 8008 (Mike 2, MOD 8, 008A), or 8080 (Altair 8800, Mike 3, Mark 80, MOD 80, Imsai 8800), others on the Motorola 6800 (Altair 680, Sphere, SWTP 6800, RM6800), National Semiconductor PACE ("George," SRI-1000), or Intel 4040 (Micro 440).

Many microprocessors are available as part of a PC-board kit marketed for engineering evaluation, usually with a minimum of memory, and without power supply, chassis or case. Some of these are being bought by hobbyists, including the JOLT from Pehaco Corp., built around a MOS Technology 6502, at $249; a Mostek F8 Evaluation Kit, using the Mostek 3850; three evaluation kits from Cramer Electronics, based on the Intel 8080A, Texas Instruments 8080, Motorola 6800, $495 each. Cramer has planned later evaluation kits based on the AMD 9800, Mostek F8, RCA COSMAC, and bipolar MPUs such as the Intel 3001, AMD 2901, TI C400, Motorola 10800.

KIT PROBLEMS

Building a computer kit is not all that simple for a beginner. One kit manufacturer says, "For every person who can wire a computer kit, there are ten who can't." But those ten do try. Another manufacturer says, "Half the people buying kits are not qualified to build them. From the ones that are sent back, it's obvious that most people don't know how to solder, don't even know how to put components on boards. Even resistors get all jumbled up. Our literature says the builder should have a couple of years experience in electronics, but people just don't believe that."

Because of these problems, Sphere is now offering the Micro-Sphere 200, in assembled form only. Built around the 6800 MPU, the basic 200 comes with 4K RAM, cassette loader, cassette operating system, 12-line by 21-character alphanumeric character generator, and "Monte Carlo games package," at $860. A second 4K of memory is $180; an Extended Business BASIC ROM, $400; floating-point and trig ROM, $130.

The latest hobbyist computer offered by Systems Research is the SRI-F8, sold as a wired unit only, not a kit, because "too many people building computers have blown CPU chips. It's too dangerous." Quite a few beginners (and some professionals too) have destroyed sensitive ICs with static electricity, and have also put ICs in the wrong sockets or wrong-way-around, and burned them out. The SRI-F8, with the Mostek F8, 1K words, Teletype interface and debug program in ROM, is $325. Options are power supply, cassette interface, keyboard interface, video interface, keyboard, and enclosure.

Not all marketers of microkits are altruistic to the point of really trying to provide a top-quality product with adequate assembly and operating instructions. A few kits are little more than a box of parts, delivery of some kits is on an uncertain schedule, and some manuals that are supposed to be for beginners, would be understood only by a computer-design engineer. Surely many beginners are buying kits with no knowledge of what is involved in writing programs in assembly language, which many will find to be tedious, uninspiring and error-prone. And there are only a couple of books or manuals that teach the tyro how to use microprocessor assembly language; nearly all the manufacturers' publications are meant for the engineer or the professional programmer. Of course some computer enthusiasts thrive on assembly language, but many beginners are likely to soon find that what they really want is a high-level language such as BASIC. So far, BASIC is available on only a few hobby computers, including the Altair 8080, Sphere, and Jupiter II.

AMATEUR COMPUTER CLUBS AND PUBLICATIONS

A variety of amateur computer clubs and newsletters exists. The Amateur Computer Society, the oldest, has been publishing a newsletter since 1966 (all the quotations regarding hobbyist computers are taken from the ACS Newsletter). The other newsletters, and the clubs, came into being after the introduction of microprocessor kits, and include the Micro-8 Newsletter (Lompoc, Calif.), Homebrew Computer Club Newsletter (Menlo Park, Calif.), Interface (Studio City, Calif.), and The Computer Hobbyist (Cary, N.C.). The Amateur Computer Club Newsletter first appeared in England in March 1973; the newsletter of the Association Francaise des Amateurs Constructeurs d'Ordinateurs was first published in the Spring of 1974.

THE LAST QUESTION

One big question remains for the amateur: after you've gotten tired of playing games on your kit computer, what are you going to do with it? The discussion of this question opens up a whole new area, so large that another paper should be devoted to it.

THREAD (Three-dimensional Reconstruction And Display) with biomedical applications in neuron ultrastructure and computerized tomography

by JOHN C. MAZZIOTTA and H. K. HUANG
Georgetown University Medical Center
Washington, D.C.

ABSTRACT

THREAD is a computer system capable of displaying three-dimensional images from serial two-dimensional sections. The serial two-dimensional input images can either be in the format of 35 mm films or in digital cross sectional pictures of live patients generated by the ACTA (Automatic Computerized Transverse Axial) Scanner. The hardware components of the system consists of FIDAC (Film Input to Digital Automatic Computer), MACDAC (MAn Communication and Display to Automatic Computer), and the Display Subsystem of the ACTA-Scanner. The software includes such features as segmentation, rotation, hidden line removal, shading plane definition, shading and display. Two examples, one from serial electron micrographs of a neuron and the other from serial ACTA, live patient, scans are given to demonstrate the capability of the system.

INTRODUCTION & BACKGROUND

The study of tissues in the biomedical sciences is most often in the form of two-dimensional cross sections. This is especially true of microscopic data obtained from both the electron and light microscope. The recent advent of computerized tomography, whereby computer generated cross-sectional tomograms are produced anywhere in the whole living human body, provides a new additional source of two-dimensional serial images.

Three-dimensional reconstruction of this data has for the most part been avoided because of the difficult and time-consuming techniques involved. However, the added insights and the additional qualitative and quantitative data that can be obtained from three-dimensional studies, prompted investigators to undertake three-dimensional reconstructions using graphic art techniques. These reconstructions took the form of wax and plexiglass models as well as artists' drawings.[1-11] Although these methods produced some elegant results, they were quite costly in terms of artists' fees, time-consuming and lacked simple means to obtain quantitative data such as volume, shape and surface area.

To obviate these disadvantages, computer graphic systems were employed to provide semi-automatic three-dimensional reconstructions of microscopic data.[12-17] Most of these systems required some type of photographic manipulations of the input data in order to transform the information into digital format. These procedures included tracing photographic prints with light pens or cursors,[13,14] the use of a camera lucida followed by tracing on a data tablet [15] or manual tracking of cell outlines using the computer as a notebook for coordinate points.[16,17] Output from these earlier systems was in three forms, purely quantitative data such as perimeters and surface area,[15] schematic diagrams of reconstructed images[12,16,17] or line drawings depicting the contours of the section outlines which in most cases served as a guide for artists who then drew shaded three-dimensional images of the structure.[12,13,16,17] Most of these earlier systems provided the important advantage of image rotation so that any surface of the reconstructed object could be visualized.

In the field of computerized tomography, cross-sectional tomograms are taken allowing for the visualization of the internal anatomy of the living patient in the horizontal plane. Consecutive scans obtained at fixed intervals along the patient's longitudinal axis provide serial cross sections of the patient. Methods exist for the alignment of such data and the display of other (sagittal, coronal, or arbitrary) planes obtained from the original cross-sectional scans.[18-20] Three-dimensional imaging of selected structures, however, allows a specific object (bone, organ, tumor, etc.) to be displayed as an isolated image which can be rotated to allow visualization of all surfaces. This display is analogous to the situation encountered with microscopic serial cross-section reconstruction and is the logical next step in computerized tomography data display.

The three-dimensional reconstruction and display of nonbiomedical data has been an active field in computer graphics. The work of Roberts, Warnock, Sutherland and others demonstrates the excellent results that have been obtained in the three-dimensional reconstruction of geometric and architectural structures.[21-28] However, the reconstruction and display of three-dimensional biomedical data of the type described above, differs from geometric data in two specific ways: (1) algorithms to reconstruct biomedical serial section data can take advantage of the initial condition that all two-dimensional sections are aligned with respect to their X and Y axes and that these sections follow each other sequentially along the Z axis prior to rotation, and (2) biomedical data reconstruction in three-dimensions is complicated by the lack of any geometric assumptions about individual section outlines, since they may assume any random shape and are often quite complex.

The THREAD system allows for the three-dimensional reconstruction of biomedical data in the form of serial cross sections, using existing hardware devices and methods analogous to earlier three-dimensional geometric or architectural reconstructions. The system locates objects of interest in each section automatically, thereby eliminating time-consuming manual outline tracing. THREAD can rotate objects to any viewing angle and the system generates both contour-grams (line drawings), as well as fully shaded, three-dimensional images in both color and black-and-white in a fast and highly automated fashion.

The major hardware subsystems of THREAD include: FIDAC[29,30] (**F**ilm **I**nput to **D**igital **A**utomatic **C**omputer) a flying spot scanner for 35 mm film, MACDAC[30,31] (**MA**n **C**ommunication and **D**isplay to **A**utomatic **C**omputer) an interactive computer graphics terminal, and the video graphic display subsystem of the ACTA-Scanner.[32] The software subsystems include: programs to digitize 35 mm film negatives, find boundaries of objects of interest in each section, align section outlines, erase hidden lines and programs to rotate and shade the completed three-dimensional object.

The THREAD system can accept input data in two forms, either 35 mm film negatives of serial sections photographed from any source or serial computerized tomograms generated by the ACTA-Scanner which are stored on magnetic tape. Figure 1 depicts the complete THREAD system.

In this paper we present a detailed discussion of the use of the THREAD system using two examples: reconstruction of images from electron micrographs recorded on film and macroscopic structures recorded *in vivo* from serial computeriezd tomograms obtained with the ACTA-Scanner.

HARDWARE DESCRIPTION OF THE THREAD SYSTEM

The hardware of the THREAD system was already in existence and consists of three major components, all of which convert digital information into graphic displays in an interactive manner. Input data can be digitized from 35 mm film negatives, as is the case with photomicrographs or if the input data is already in digital form as is the case with ACTA-Scanner output tapes, this information can be directly read by the computer from a magnetic tape unit. Data is processed by an IBM 360/44 computer equipped with disc storage for intermediate results.

Film input

Serial sections of structures can be recorded on 35 mm film and converted to digital form by the FIDAC device (Figure 2). Film is positioned in this device and a flying spot scan is generated whereby the image on the film is digitized into 16 grey-levels, the value of which is proportional to the relative translucency of the film at each particular spot. The scanner can sample some 450 rows of spots with 672 spots per row, converting a standard 35 mm film frame into a grid of 450 x 672 numerical values. This data is then transmitted on-line to the computer, the whole process requiring ⅓ of a second.

The FIDAC device can also send the digital signals of its scan to the MACDAC display device (Figure 3) without storing them in the computer memory so the

operator can see the image and make adjustments prior to computer data acquisition.

MACDAC

The MACDAC device is an interactive computer graphic system which provides for CRT display of digital information transmitted to it by the computer or FIDAC. In addition to display, the device has the capability of transmitting coordinates from its circuitry to the computer allowing the operator to interact with and modify the image on the CRT.

The operator may point out objects using MACDAC by positioning a light spot on the screen by means of a joystick controller and pressing a "Read" button on the device which sends the point's coordinates into the computer.

Video display

Output in the form of two 160 x 160 matrix pictures is generated by the THREAD system and stored on magnetic tape for viewing on the display processor of the ACTA-Scanner, Figure 4. The output portion of the ACTA-Scanner is usually employed in the display of computerized tomograms but also provides a flexible graphics display system for information which can be stored on magnetic tape as 160 x 160 or 320 x 320 matrices.

The components of the ACTA display system include: a magnetic tape unit (Figure 4-2), a preprogrammed video display processor called the RAMTEK (Figure 4-3,4), a 19-inch color TV monitor (Figure 4–5), two 12-inch black-and-white TV monitors (Figure 4-6), a mini-computer (Figure 4-7) and a teletypewriter console (Figure 4-1).

Two 160 x 160 matrix pictures (or a 320 x 320 matrix picture) are simultaneously displayed side-by-side on all three monitors. The display system has the

capacity of distinguishing 2048 discrete intensities which are viewed as sixteen grey-levels.[33] For our purposes, the 2048 possible intensities are equally divided into the sixteen grey-levels, each with a range or width of 128 intensity values. These grey-levels may be assigned a continuous gradient of black to white or color codes may be selected for some or all of the individual grey-levels.

In the final display, a heading appears along with the two reconstructed images. The heading contains information describing the object and its orientation (Figure 13). A grey-level reference is also provided where the sixteen grey-levels are displayed as individual blocks along with the maximum and minimum intensity values represented by that particular grey-level.

The ACTA display system provides for automatic color coding, image enlargement and various photographic formats which the operator can request by means of selecting the appropriate code word on the teletypewriter.[34]

SOFTWARE DESCRIPTION OF THE THREAD SYSTEM

All driver programs are written in either FORTRAN IV or Assembly and interact with the operator in everyday language via typewriter console.

Data gathering phase

Film input data is received from the FIDAC device one frame at a time and the portion of the frame which contains the objects to be reconstructed is stored in sixteen grey-levels in the computer memory. Digital input from magnetic tape is handled in a similar fashion. Any single grey-level or composite of grey-levels may be displayed on the MACDAC monitor.

The operator is asked for information pertaining to each section including: its thickness and magnification. The operator is also instructed to point out, using the MACDAC light spot, the left-most boundary of an object of interest and three alignment points to be used later for orienting all sections in the series relative to one another. Automatic boundary location commences once the above information is obtained by the program.

Standard boundary detection methods are used: boundaries or section-object outlines which differ from their surroundings by one or more grey-level can be automatically located by the program.[35] This process is initiated in the memory when the operator points out an object of interest and types the object's grey-level into the console. The coordinates of the light spot serve as a pointer or bug which moves to the right until contacting a grey-level which equals or exceeds the threshold set for this object. The program then moves the bug clockwise around the object boundary, recording the coordinates in a 4 x 1000 element array where the first two columns represent the boundary point's X and Y coordinates, the third column represents the Z coordinate (proportional to section thickness) and the fourth column is used for later coding of selected points. The boundary processing terminates when the starting point is again located by the bug. All points are plotted on the MACDAC monitor and the operator may choose to manually edit the result if the object outline was indistinct. Up to nine objects may be located and stored for each section.

The above procedure is repeated for each section in the series and once completed, all sections are aligned using the alignment markers previously obtained for each section. Alignment is obtained by a best-fit approximation. When all objects in the series are aligned, the lists of their boundary points may be stored on magnetic tape and a new series of sections can be processed.

Reconstruction phase

The reconstruction phase of the software package is divided into six distinct steps. These six steps are preceded by the acquisition of the object boundary point lists from magnetic tape and are followed by display of the completed image.

1. *Segmentation:* Each object outline in the series is subdivided into segments of equal length, the end points of which will later be connected between adjacent sections to facilitate shading. These segment end points are assigned consecutive code numbers termed segment marker numbers. As will be seen later, the higher the number of segments chosen, the greater will be the detail of the final image.

Segmenting begins by determining the section-object outline which contains the greatest number of boundary points. This number represents the greatest possible number of segment markers available for this object. The operator is then asked what percentage of this maximum should be used in the reconstruction. For example, if the maximum segment number equals 100 and the operator chooses to use 50% of these segments, a section through this object which contained 50 boundary points would have the fourth column of its 4 x 1000 boundary point array filled with consecutive numbers from 1 to 50. If the section outline had greater than 50 boundary points, zeroes would be inserted between segment marker numbers at regular intervals (e.g. 1,2,0,3,4,0, . . ., 50) and if the object had less than 50 boundary points, segment marker numbers would be evenly deleted (e.g. 1,6,11,16, . . ., 50).

2. *Rotation:* Section object outlines are rotated by selecting two rotational angles, one about the vertical Y axis and one about the horizontal X axis. These angles are substituted in a rotational transformation

matrix and the X, Y, and Z coordinates of all object boundary points are transformed by matrix multiplication.[24] All rotated points must be checked to insure that they are positive values and if negative values are encountered, the entire list of boundary points for the object must be shifted into the positive domain by addition of a constant to the appropriate coordinate set.

3. *Hidden Line Removal:* Hidden lines are defined as portions of section-object outlines which are overlapped by the addition of a new section on top of it. Other authors have used a variety of techniques to remove hidden lines during reconstruction,[22,27,28] but solutions were directed at objects or groups of objects composed of plane polyhedra. These algorithms perform depth sorts along the Z axis at critical points and reject lines that would not be visible in the final image. However, input data for three-dimensional reconstruction from serial sections is already depth sorted, each section lying sequentially in front of the previous section. One merely examines the rotational angles to determine the forward-most section and the sequence will be known for all remaining sections. We define the forward-most section as the section last digitized unless the object is rotated greater than 90 degrees about either the horizontal or vertical axis in which case the first section to be digitized is defined as forward-most.

The procedure for hidden line removal amounts to stacking each section upon the previous section starting with the back-most and erasing any lines which fall within the area inside the forward-lying section. The process begins by initializing a region of memory to zero. This region of memory is the same size as the completed picture (160 x 160) and is called the contour-gram matrix. Processing begins by "drawing" the back-most section on this matrix, this is accomplished by locating, on the contour-gram matrix, the X and Y coordinate of each boundary point for this section and inserting the value of that point's Z coordinate in the matrix. The Z coordinate is used later in processing and serves as a code for that particular point.

Following this step, the same procedure is carried out for the next forward-lying section. This is followed by erasure of overlapped boundary points lying inside the newly added section. Erasure is accomplished by a line-by-line examination of the matrix points lying within the confines of the forward-lying section. Each point lying within these confines, regardless of its value, is replaced by a negative number, the magnitude of which is equal to the section's number in the serial set (e.g., the area inside the outline of section number 5 is coded with -5's). The use of a special negative number serves two purposes: (1) it defines areas of the matrix as within the confines of a specific section outline (a code used later in processing), and (2) it allows for simplified display of the complete contour-gram by lighting only those points on the MACDAC monitor which have positive values (i.e. the unerased Z coordinates). All sections are processed in sequence from back to front in this way.

4. *Plane Definition:* Planes are defined as rectangular areas lying between visible portions of adjacent sections and are formed by connecting corresponding segment markers. Starting with the forward-most section, a search is made of the boundary point list for the lowest segment-marker number. Once found, a similar search is made for the same number in the boundary point list of the section immediately behind the first. If either marker is missing, the program moves to the next marker number and the search is repeated.

If both segment markers are found in the arrays, the contour-gram matrix is examined to determine if these points (represented by their Z coordinates) appear in the picture or if they have been erased during hidden line removal. Three possible outcomes exist: (1) if both points are located, they are connected by a line and the program moves to the next marker number; (2) if neither point is located, the line is ignored and the program moves on; (3) if one of the two points is missing, it is dealt with as a special case.

In the special case of a missing point in the forward-lying section (Figure 5a), a line is drawn connecting the located back segment point and the expected position of the missing forward marker point. Points along this line are tested from back to front and the line is terminated when it encounters a positive number. The case is similar for a missing back segment marker except that the points along the connecting line are tested from front to back (Figure 5b).

Finally, a case exists where both segment marker

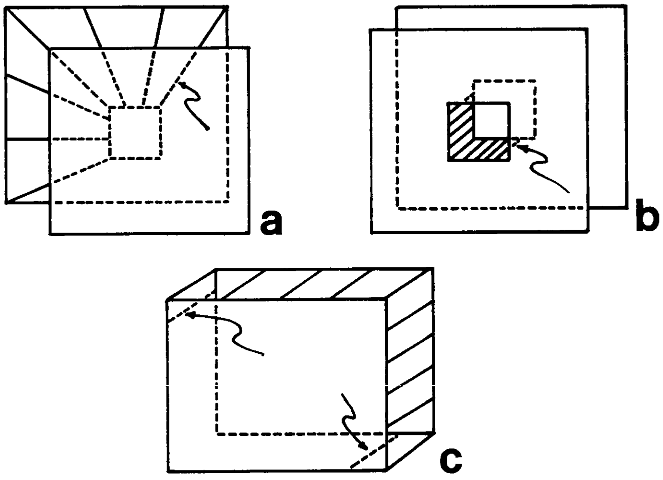

Figure 5—Special cases in "plane" determination described in text, (a) arrow shows partial line drawn in case of missing segment marker point in the forward-lying section, occurring with two large sections straddling a smaller section, (b) arrow shows partial line drawn in case of missing segment marker in back-lying section, (c) arrows show potential erroneous lines with both segment marker points visible in contour-gram (dotted lines indicate hidden lines not seen in final image)

coordinates can be located in the contour-gram but the connection of these points would be erroneous (Figure 5c). To eliminate this possibility all connecting lines are always tested to insure that their points never enter an area coded with the negative value of the forward-most section. When this occurs, the line is discarded.

After all segment markers in each section pair have been processed, adjacent connecting lines are grouped in pairs resulting in planes lying between the two sections. The program examines all sections in the series, defining planes between them and generates a list of the vertices of all planes.

5. *Shading Values:* Shading values or the light intensity assigned to each plane are derived using the methods described by Bouknight.[25] The light source and the viewer are defined as being in the center of the viewing screen and at an arbitrary distance from it. Since the graphic display system can distinguish 2048 intensities, this defines the range of shading values available. Each plane is assigned a shading value proportional to the angle it makes relative to a normal to the viewing screen. Those planes lying perpendicular to the normal are brightest and those parallel to it are darkest.

6. *Shading:* Using its respective vertices, each plane including the surface of the forward-most section is essentially "colored-in" with its assigned shading value on the 160 x 160 contour-gram matrix. The completed image and the image of the contour-gram generated for this object at the selected angles are then stored on magnetic tape for display.

RESULTS

Microscopic structures

Three-dimensional reconstruction on an ultrastructural level is demonstrated for a nucleolus obtained from cross sections through a neuron of the cat brain (Figure 7). This cell was serially sectional and photographed in the electron microscope at a uniform magnification.[36] Six equally spaced sections through the cell's nucleolus were used as input data for the reconstruction process. The physical time required to position the film in the FIDAC device, digitize the picture and locate the nucleolar outline was approximately two minutes.

As was previously described, varying the number of segment markers alters the degree of detail in the final image. This can be seen in Figure 8 where the contour-gram of two sections through the nucleolus is seen with varying numbers of segment markers connected. Image 8a was produced using only 10 percent of the available segment markers. Image 8b uses 50 percent, while Image 8c uses 90 percent of the markers. The number of planes produced in the image as well as the processing time required to generate these planes increases as the number of segment markers increase. The difference in processing time is significant and is demonstrated by the fact that Image 8c required approximately two minutes of processing time while Image 8a required only 15 seconds.

Contour-grams of this nucleolus at four different rotational angles can be seen in Figure 9. Contour-grams such as these can be displayed along with the shaded three-dimensional image at the end of processing or can be visualized during processing on the MACDAC monitor.

Figure 10 shows the final shaded image of the neuron nucleolus at two rotational angles varied with respect to the vertical axis. The structure is tapered at one pole and is slightly constricted at the center. Processing time for this image was slightly under five minutes. Image quality was consistent throughout a wide range of rotational angles.

Computerized tomography

A patient with a biopsy-proven brain tumor was referred for computerized tomography of the head. A serial set of ten ACTA scans was obtained at 1 cm intervals beginning at the level of the external auditory canal. Contrast material was used since it enhances tumor visualization in the brain. The tumor was present in five of the ten scans (Figure 11).

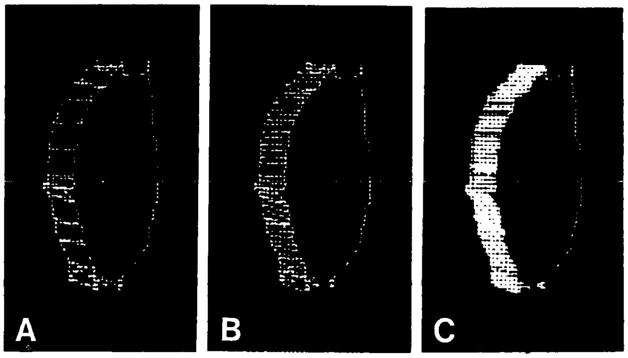

Figure 8—Contour-gram of sections through a neuron nucleolus showing the effects of varying the percentages of segment marker points used in the reconstruction, (A) 10 percent, (B) 50 percent, (C) 90 percent

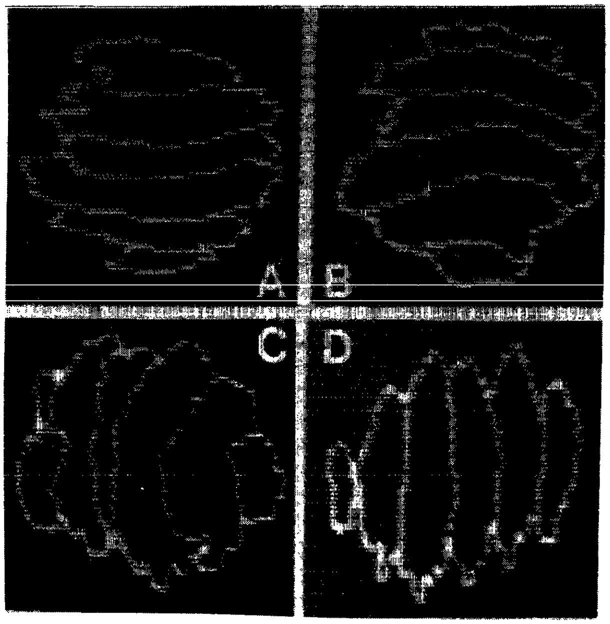

Figure 9—Contour-grams of the nucleolus seen in Figure 7 at four rotational angles

The five sections showing the tumor were recorded on magnetic tape and served as the input data to the THREAD system. Processing resulted in the shaded three-dimensional views of the isolated tumor mass seen in Figure 12. Since no tumor was seen above or below the 5 input sections, the resultant image is truncated at both poles. Thinner input sections would provide a more detailed view of these regions. Each individual picture point on the viewing monitor represents 1.5 square millimeters for surfaces parallel to the viewing screen.

Figure 13 shows the standard display format of the THREAD system including: date, object orientation and composition in coded form and the grey-level block display with reference numbers described earlier. Usually, a contour-gram and a shaded image or two shaded images at different rotational angles are viewed side-by-side on the screen. Figure 13 shows the automatic enlargement feature of the system with which the operator can type a code word into the console and have either the left or right image enlarged on the opposite side of the screen. Color formats are also available as is the capability for Polaroid photography from the monitors.

SUMMARY AND FUTURE BIOMEDICAL PROSPECTS

The THREAD system represents an effective and highly automated method for three-dimensional reconstruction and display of biomedical data from many

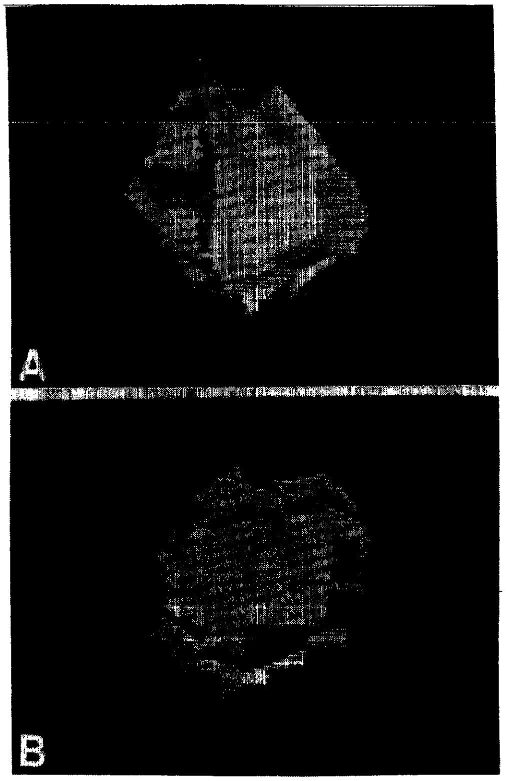

Figure 10—Shaded three-dimensional image of a neuron nucleolus generated at two rotational angles by the THREAD system: (A) right lateral view, (B) left lateral view. The program assumes viewer and light source are directly in front of monitor and assigns the brightest shades to planes lying parallel to the viewing screen

sources. It has a number of advantages over previous three-dimensional reconstruction methods, particularly the ability to automatically locate object-boundary outlines and to produce shaded three-dimensional images of the reconstructed data.

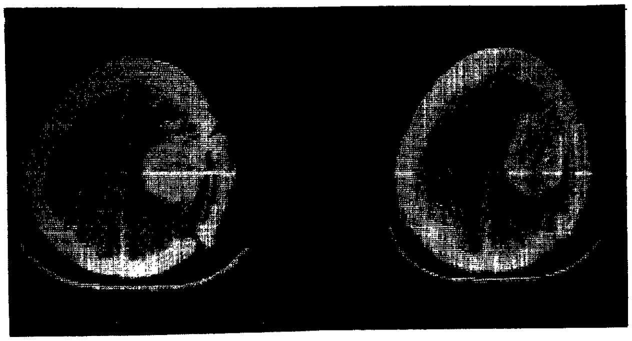

Figure 11—Two adjacent computerized tomograms produced by the ACTA scanner from a patient with uptake of contrast material by a brain tumor in one cerebral hemisphere. Skull defects are the result of previous surgery

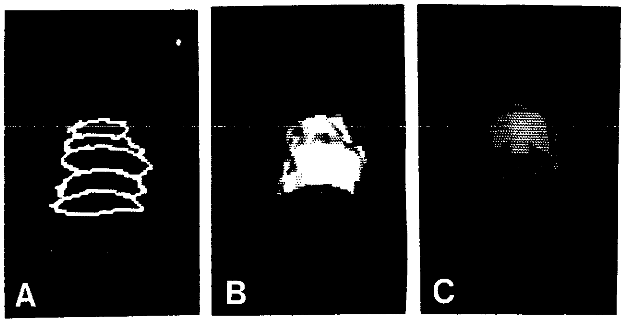

Figure 12—Three-dimensional reconstruction of brain tumor by the THREAD system, (A) Contour-gram of inferior and medial surfaces of tumor mass, (B) Shaded image of A, (C) Greater rotation of same tumor about the horizontal axis, showing more of the inferior surface

The shaded image might be further enhanced by a number of techniques to reenforce the three-dimensional illusion created by the shaded image. Smoothing of the shading planes by performing successive linear interpolations in both the X and Y direction will result in a more continuous shading gradient.[37] Stereo pairs can be generated, side-by-side, on the viewing screen with each image symmetrically rotated with respect to its vertical axis and by adjusting the relative X-axis spacing of the two images to accommodate for differing interocular distances in the viewer. In addition, movies could be made of the object at consecutively varying rotational angles thereby allowing for rapid viewing of all object surfaces.

Finally, quantitative data such as volume, shape, and

surface area may be readily calculated for individual objects.[38] Comparison of this type of data are important in the study of changing cell morphology during experimental manipulations. Similarly, quantitative data obtained from reconstructed computerized tomograms can be used to study normal anatomy *in vivo* and to examine the effects of various treatment modalities on the size and morphologic characteristics of tumors and other pathological entities.

ACKNOWLEDGMENTS

The authors wish to thank the staff of the National Biomedical Research Foundation for their assistance and the generous use of their facilities. In particular we appreciate the initial interest and continued support of Dr. Robert S. Ledley in this project and the programming assistance of B. Shiu. We thank Dr. Betty Hamilton and the Department of Anatomy, Georgetown Medical School for their encouragement and guidance.

Regional kidney transplant matching—The RENTRAN interactive approach*

by DAVID J. MISHELEVICH, PETER STASTNY, R. GAIL ELLIS and SUSAN G. MIZE
University of Texas Health Science Center at Dallas
Dallas, Texas

ABSTRACT

An interactive on-line computerized renal transplant matching system called RENTRAN which serves the Southwest Kidney Transplant Region is described. The region consists of one transplant center in Arkansas, two in Oklahoma, and six in Texas. The computer used is the DECsystem-10 located in the Medical Computing Resources Center at the University of Texas Health Science Center at Dallas. RENTRAN participants have remotely located standard interactive computer terminals and gain access to the computer by dialing over normal telephone lines. Functions provided by RENTRAN include obtaining instructions, performing a donor-recipient match, obtaining a list of potential recipients, making a user comment or adding, updating or deleting a patient record. Either long or short dialog forms are available for inexperienced and experienced users respectively. In the time period since August 1, 1973 when the system went into production, there have been in excess of 100 matches attempted and approximately 50 kidneys have been transplanted according to RENTRAN results. There are about 350 recipients currently on the data base. The system was developed with funds provided by the Texas Regional Medical Program and operational expenses and enhancements are provided through a $25 per year potential-recipient patient charge for being listed on the data base.

INTRODUCTION

Success in renal transplant matching can be increased by enlarging the pools of potential recipients and donors. With this in mind, the Southwest Kidney Transplant Region maintains an interactive on-line computer-based matching system called RENTRAN in collaboration with the Medical Computing Resources Center (MCRC) of The University of Texas Health Science Center at Dallas (UTHSCD).

The network is shown schematically in Figure 1 and includes one center in Arkansas (Little Rock), two centers in Oklahoma (V.A. Hospital in Oklahoma City and St. Anthony's Hospital) and six centers in Texas (Austin, Dallas, Galveston, Houston and two in San Antonio). The latter two are located at Lackland Air Force Base and The University of Texas Health Science Center at San Antonio. The three states comprise the Southwest Kidney Transplant Region and maintain common tissue typing standards including the holding of typing workshops, use of a common tissue typing tray and exchange of sera from sensitized recipients for cross-matching.

This paper describes system capabilities, including sample computer terminal interactions. The results for the first year and one half of operation are presented

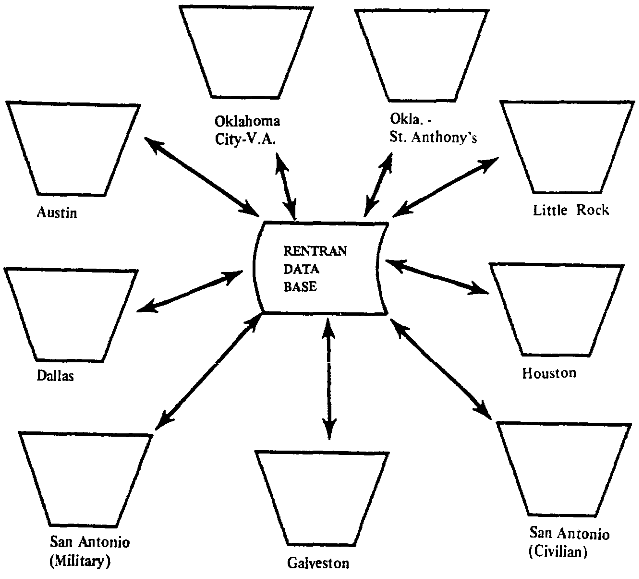

Figure 1—Overall threetate RENTRAN network

* The major portion of financial support for RENTRAN came from the Renal Program, Texas Regional Medical Program.

and a comparison of features with the SEROP system[1] is made.

SYSTEM DESCRIPTION

The interactive on-line computerized system replaced a previous batch system whose major defects were relatively infrequent updating (monthly) of potential recipient data and the necessity for human determination of matches based on scanning lists of potential recipients comparing the blood types and up to four HL-A values. The current system went into production on August 1, 1973 with development occurring earlier that year. A prototypical demonstration version was programmed in the BASIC language in two months, beginning in December 1972. The production version of the RENTRAN program was begun in March 1973 in the COBOL computer language using the ISAM (Indexed Sequential Access Method) file structure and runs on the DECsystem-10 computer located in the MCRC. The MCRC is an academic and scientific computing facility that serves some administrative functions as well.[2]

A prime objective in the system design was to put the computing power where the users are. The computing system has a number of dial-up lines and supports a variety of interactive computer terminals. The transplant centers in the three-state region communicate with the MCRC DECsystem-10 over normal telephone lines at rates of 10 or 30 characters per second. The terminals are equipped with acoustic couplers for digital to analog sound signal conversion and vice versa to permit the communication. Data confidentiality is maintained by the use of account numbers and passwords on the time sharing system.

The RENTRAN data base is a file of potential kidney transplant recipients currently numbering about 350. The following items of information are kept for each patient:

Registry number
Name
Age
Sex
Race
Blood Type (ABO)
HL-A Antigens
Location Center
Source of Reference
Presence or absence of antibodies
Number of acceptable mismatched antigens.

This information is maintained daily on disk storage in the computer system and on back-up magnetic tapes. In addition, monthly printouts are made of the file for comparative and back-up purposes.

The user has a choice of the following functions:

Obtain instructions
Perform a donor-recipient match
List potential recipients
Make a user comment
Add, update, or delete a patient.

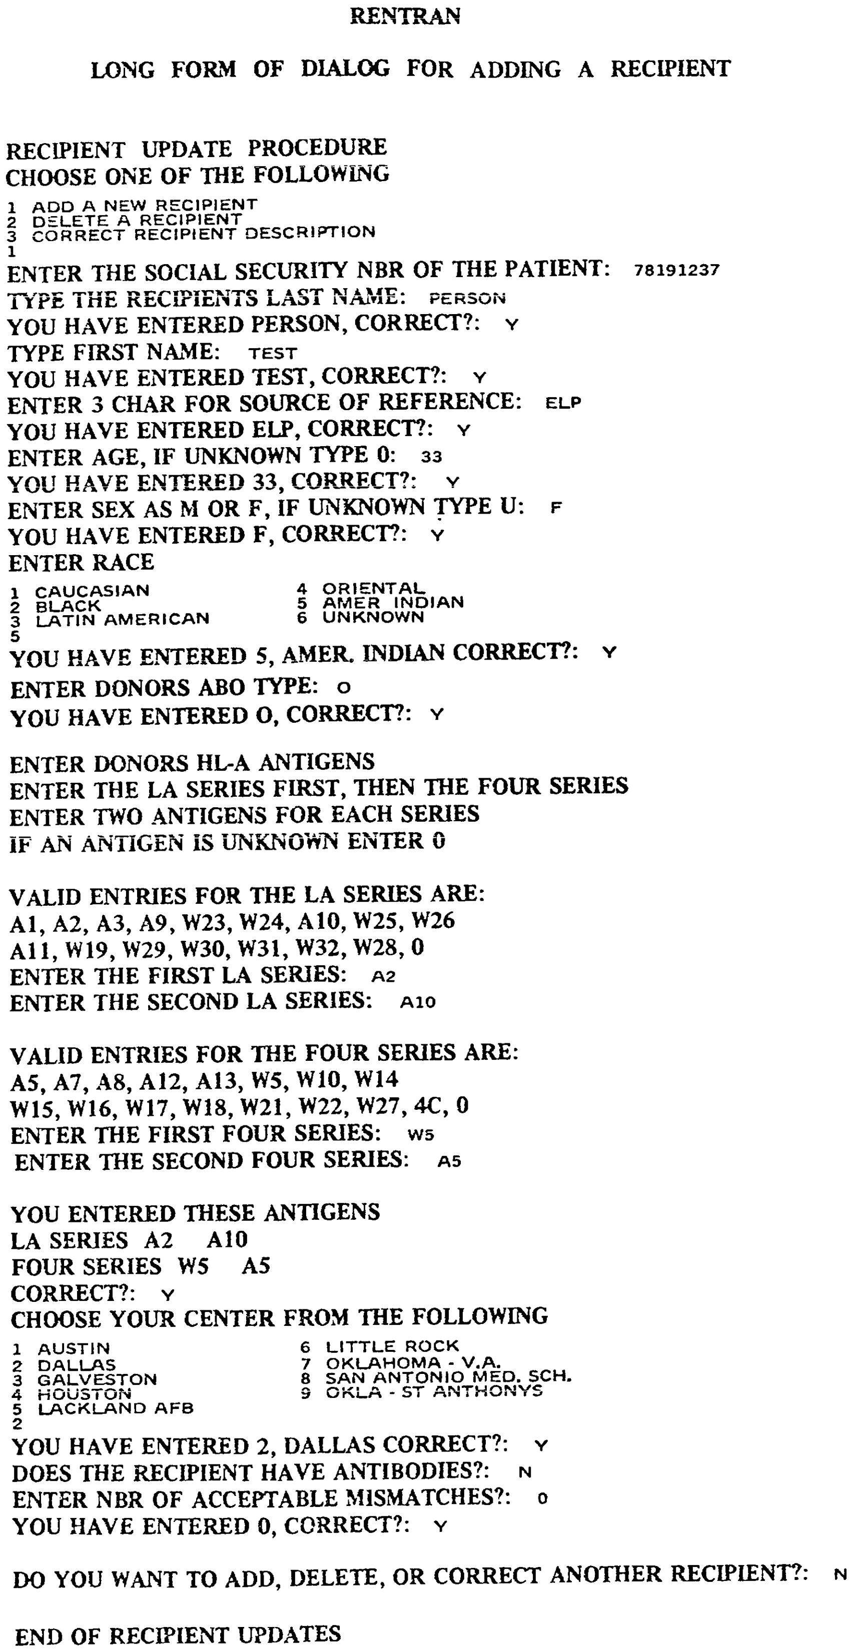
Since the system is designed to minimize typing at the computer terminal, the choices for these and other multiple choice items are numbered. Thus the user simply has to type in the appropriate number and press the carriage return to enter the selection into the computer. A sample update procedure demonstrating the addition of a patient is shown in Figure 2. This interaction was human engineered to make RENTRAN easy to use by an individual without computer experience. Each user entry is edited for consistency and the user is obliged to enter a meaningful response before proceeding to the next entry. Because more experienced users found this dialog with its many checks to be long and tedious, a short dialog version was developed. The same process in short-dialog form is shown in Figure 3. In this format if the user forgets the possible values in a multiple choice question, he or she can type in a 0 (zero) followed by a carriage return and the possibilities will be typed out to prompt the user. Editing for consistency also applies to the short dialog.

Updates are actually stored in a temporary file and once a day the added, changed, or deleted data is checked for consistency and processed by a maintenance program to bring the master RENTRAN file up to date. This indirect approach was selected to protect data integrity by avoiding problems with users of varied experience making changes directly to the master data bank.

A sample patient listing with the names removed appears in Figure 4. The primary listing choices are all patients or those within a given center. Once a specific center is designated, the variety of lists that may be obtained for that center includes the following:

All potential recipients having a certain blood type
All those with a specified number of HL-A antigens
All those with a certain number of acceptable mismatches
All those who have developed antibodies
All those with a specific source of reference
All patients for the center listed alphabetically
All patients for the center in registry number sequence.

Two additional listing capabilities which are independent of the center are obtaining the data for a single patient provided the registry number is known and listing those patients who have been added as potential recipients during the current month.



```

Figure 3—Sample update procedure demonstrating the addition of a patient using the short dialog

The dialog associated with a matching procedure is shown in Figure 5. It is important to note that cross-matching of antigens is permitted. For example antigen designation 4C will show matches to A5, W5, and W18. Each time a match is performed, a follow-up form is mailed to the donor center to determine the disposition of the kidneys.

The user of RENTRAN can get minimal instructions for system use on the terminal even though full user documentation is supplied to each center. This permits the system to be usable even if the documentation is mislaid. A telephone reference is given for special problems that might arise.

An important capability is the user comment facility. Problems, general questions or other items of interest are input by the users and reviewed on a daily basis when the updating of the master file is done. Changes may result from these comments, such as the provision of an abbreviated as well as a long form of the dialog to expedite interaction by the experienced users.

The DECsystem-10 is available 24 hours per day, 7 days per week except for an average of 2½ hours of preventive maintenance and rare episodes of unscheduled down time. In almost two years there has been no time when a match could not be done even if some delay was necessary. Periodically a printed listing of all potential recipients on the data base is distributed to each member center to be used for backup in case of emergencies. It is still, however, the objective of

the MCRC to develop a fully redundant fail-safe system to further increase availability for such critical activities.

RESULTS

Some basic statistics of RENTRAN since initiation of the production system on August 1, 1973 are demonstrated in Table I. As of March 1, 1975 there were 356 potential recipients on the file and 108 donor-recipient matches have been performed. The data gathered by analysis of the follow-up forms mailed after each attempted match or deletion of a recipient from the data base are shown in Table II. In some cases a kidney was transported to an area outside the regional membership. RENTRAN results were used in over 50 cases to identify the appropriate recipient.

Figure 5—Interactive dialog demonstrating the matching procedure

Another area of interest involves reasons for the permanent or temporary removal of potential recipients from the data base. The information is shown in Table III. There were 263 permanent removals (142 because of transplantation, 51 because of death, and 70 because of miscellaneous reasons as analyzed in the figure) and 26 temporary removals (of which 5 were due to infection).

FINANCIAL ASPECTS

The development of RENTRAN began in December of 1972. The initial development cost was approximately $9,000 with roughly four-fifths coming from the Texas Regional Medical Program. The computer terminal and telephone costs are borne by the individual transplantation centers. Operating expenses and

periodic RENTRAN enhancements are provided by a $25 charge made once during a September to August fiscal year to each potential recipient listed on the file irrespective of the length of time on the file during the year. Patients are not charged twice if they are temporarily removed and then reinstated during the same fiscal year. Patients are individually billed through their respective centers for RENTRAN via a computerized billing system.

DISCUSSION

The system is much more successful than the preceding batch system. The concept of using a centralized up-to-date file with access over telephone lines has proven to be quite reasonable. There are other such computerized systems in existence, a major one being the SEROP (Southeastern Regional Organ Procurement Program) system.[1] A detailed comparison of its characteristics with those of RENTRAN is shown in Table IV. SEROP currently covers a larger area with its 30 participating institutions. While there is no practical limit to the number of centers or potential recipients which could be supported by RENTRAN, the Southwest Kidney Transplant Region has developed on the basis of geographic proximity and cooperation among the physicians involved. It must be stressed that most of the decisions are medical ones and therefore are made by the medical group which oversees RENTRAN activities. A somewhat more mathematical approach to computerized donor-recipient matching has been developed by the Department of Immunohematology, University Hopital, Leyden, the Netherlands.[3] A key to the success of RENTRAN and a main objective in its design was to make the system easy to use for those trained or untrained in its use.

CONCLUSION

Renal transplantation is the most successful of all internal organ transplantation procedures. Pooling of recipients in regional exchange groups allows more efficient utilization of available cadaver kidneys. The computer-based regional approach such as that of RENTRAN which provides an accurate and up-to-date file of a fairly large size to maximize the probability of finding a likely potential recipient and which is accessible via telephone lines from essentially any distance has proved to be a viable one. The RENTRAN system, which is readily available and easily used, is successfully utilized by the participating transplant centers.

TABLE IV—Comparison of RENTRAN features and information to those of the system supported by SEROP.

A COMPARISON OF RENTRAN TO THE SEROP TRANSPLANT SYSTEM

SYSTEM FEATURE	AS USED BY SEROP SYSTEM	AS USED BY RENTRAN
Recipient Identification	includes # of transplants, RH factor, antigens against which patient is sensitized	social security #, source of referral within center
Donor Identification	Basic ID - Name, age, location, etc.	None
Update Technique	Direct to files. Brief & succinct but requires training in format program expects.	Indirectly, once per day for file protection. Verbose or abbreviated form user's choice. Training not necessary.
# programs	Separate program for each function (update, list, etc.)	One user program combining functions
Patient protection within center	Password method	None
Matching criteria	(1) HL-A compatibility (2) presensitization (3) waiting time	HL-A compatibility
Billing capability	None	Basic monthly audit trail
24-hour availability	Network of 8 GE Mark III's available. Maximum of 30 minutes downtime guaranteed	When possible
Instructions for use	None programmed	Programmed with telephone reference
User comment facility?	No	Yes
Follow-up after match	None described	By mailout
Cross-matching of antigens	None	Extensive
Statistics	3½ years implementation 6 major revisions 800 recipients on file 30 participating institutions 10 states	2 years implementation 1 major revision 356 recipients 9 participating institutions 3 states
Cost	R & D = $20,000 over 4½ yrs. maintenance = $550 per month for 800 patients	R & D = $9,000 over 1 year Maintenance and enhancements $25 per patient per year

ACKNOWLEDGMENTS

Thanks are gratefully given to the members of the Southwest Kidney Transplant Region, the Texas Regional Medical Program, Dr. Garabed Eknoyan of the Baylor College of Medicine who headed the renal section of the Texas RMP, Mr. Stephen B. Brewton who programmed the original prototypical demonstration program in BASIC, Ms. Linda Firnberg who participated in the systems analysis and training, and Mr. Michael Blaylock who programmed many of the later changes to RENTRAN.

Data base for protein sequences*

by M. O. DAYHOFF, W. C. BARKER, R. M. SCHWARTZ,
B. C. ORCUTT, and L. T. HUNT
National Biomedical Research Foundation
Washington, D.C.

ABSTRACT

Proteins are linear polymers synthesized in living organisms from twenty different kinds of amino acids according to the message carried in the chromosomes. Typically, they have evolved by natural selection over hundreds of millions of years through many small changes in sequence. The present computerized data base includes 77,267 amino acid residues from 767 sequences. We believe that all of the protein structures occurring in living organisms can be combined into fewer than 1,000 groups containing proteins of similar sequence. Each group can be characterized by a few sequences that are known exactly and by a number of evolutionary parameters. The rest of the structures, occurring in organisms not examined, can be described with estimated precision in terms of the number of differences from a known sequence or from sequences inferred to have been present in ancestral forms. The following kinds of information are needed: sequences of proteins from each group, the phylogenetic tree of biological species, a list of protein groups and the gene duplications in each, a description of the quantitative parameters of the evolutionary processes affecting proteins, and methods of estimation of sequences in ancestral species and in living forms phylogenetically close to those investigated. The conceptual tools and the computer programs necessary for the prediction of all of the 10^{10} to 10^{11} protein sequences in living species are described. One can readily visualize the separate parts operating as an integrated interactive computerized data base that could predict sequences for specified organisms with an estimated precision based on the collection of known sequences.

Proteins are the most interesting of all of the biochemical components of living organisms because of their potential for diversity in structure and function, their key positions in the cellular fabric, catalysis, and control mechanisms, and their great conservation of structure, which provides information about biological evolution. Sequence studies have been carried out for various reasons in a number of disciplines: structural chemistry, crystallography, enzymology, genetics, evolution, systematics, physiology, immunology, pharmacology, virology, and bacteriology, to name a few. In many of these disciplines, the protein sequences and associated data are essential for an understanding of the fundamental concepts and for a parsimonious organization of the knowledge.

Proteins are synthesized by complex cell machinery according to the information in the deoxyribonucleic acid (DNA) template, which is replicated in cell division or reproduction. There are 4 kinds of nucleotides in the linear DNA chain and there are 20 kinds of amino acids in the linear chain of the protein. Some proteins are functional as initially polymerized; some undergo subsequent chemical modification.

Occasional errors are made in the copying of the DNA from generation to generation. When such errors are beneficial or neutral, the new sequence may eventually replace the original as the predominant form in the species. The main kinds of errors reflected in the protein sequences are point mutations (the exchange of one amino acid for another) and insertions or deletions of one or a few residues in the chain. Although errors occur in many individuals each generation, it may be millions of years before a change in any one protein permeates the whole population.

PRESENT AND ULTIMATE SIZE OF THE PROTEIN SEQUENCE DATA COLLECTION

We maintain a reference data collection of protein sequences embodied in a series of books entitled *Atlas of Protein Sequence and Structure*,[1,2,3] in computer tapes containing the sequences,[4] and in derivative data such as a key-amino-acid-in-context dictionary.[5] Over 3,000 experimental scientists have elucidated the 77,267 amino acid residues in the 767 sequences currently on our sequence data tape. These sequences represent only a small sample of the entire data base that could

* This work has been supported by NIH Grant GM-08710 from the National Institute of General Medical Sciences and by Contract NASW2546 from the National Aeronautics and Space Administration.

be compiled from the 10^{10} or 10^{11} different protein sequences from the approximately 2 million living species; in humans alone between 10^5 and 10^6 different proteins are thought to be expressed.

We believe that it will be possible to combine all of the naturally occurring protein structures into fewer than 1,000 groups containing proteins of similar sequence.[6,7] Each group (or superfamily) can be characterized by a sampling of sequences that are known exactly and by a number of evolutionary parameters. The rest of the structures, occurring in organisms not examined, can be described with estimated precision in terms of the number of differences from a known sequence or from sequences inferred to have been present in ancestral forms on the basis of the data from extant species. Thus, virtually the entire collection of proteins of living organisms can be described with useful precision by the elucidation of only a limited number of sequences and parameters for each group.

Procedures for organizing and estimating the chemical structures of proteins in living organisms require the following kinds of information:

1. The phylogenetic tree describing the evolution of extant biological species
2. The organization of sequences into superfamilies
3. A tabulation of the gene duplications that have occurred in each superfamily
4. The frequency of occurrence of point mutations and insertion-deletion events for each superfamily
5. A method for the estimation of protein sequences that occurred in ancestral species from those found in living organisms
6. A method for the estimation of a protein sequence in a living organism based on related sequences in other organisms and on inferred ancestral sequences

THE PHYLOGENETIC TREE OF LIFE

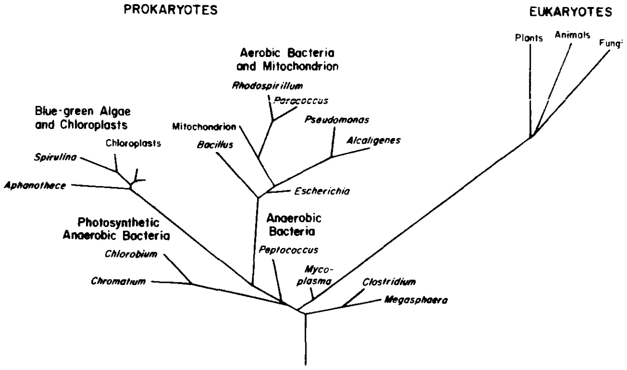

Figure 1—Phylogenetic tree of living organisms. The major groups of bacteria and blue-green algae as well as the eukaryote host and its endosymbionts are represented. Spirochaetes that may be the endosymbiotic ancestors of flagella and the mitotic apparatus are not pictured, as no sequence information from them is yet available. The topology and branch lengths were approximated from sequences of c-type cytochromes, ferredoxins, plastocyanin and azurin, and 5S ribosomal RNA. The position of *Mycoplasma*, estimated from transfer RNA sequences, is only tentative. The lengths of the branches reflect the amount of change that has taken place in the sequences of the various organisms

From fossil evidence and from biological and protein sequence evidence[3,8–11] an outline of the phylogenetic tree of life is emerging, as shown in Figure 1. About 2.8 billion years ago there were at least two morphologically distinct types of organisms already living on earth: one was filamentous and the other spherical. Presumably the genetic code and a rudimentary metabolism had already developed. Highly conserved descendants of these forms may be the filamentous and coccoid blue-green algae and the anaerobic bacteria such as clostridia. About 2.0 billion years ago, when an oxidizing atmosphere began to develop, a large number of different morphological types of prokaryotes abounded, presumably including the beginnings of the rest of the 19 major groups of bacteria found today as well as a proliferation of blue-green algal types. It is thought that one of the bacterial lines, possibly mycoplasma, gave rise to the host cell of the higher organisms, or eukaryotes. Another bacterial line invaded the host, developed a symbiotic relationship, and gave rise to the mitochondrion, in which the oxidative reactions of the cell take place. By a similar mechanism, blue-green algae gave rise to plant chloroplasts, in which photosynthesis takes place. The host cell and its endosymbiont(s) have evolved together in most of the multicellular forms.

About 1 billion years ago the lines that have since evolved into the present-day fungi, plants, and animals diverged from each other (see Figure 2).[12–16] Proceeding along the animal line leading to human, the insect line diverged first, followed by the annelid and mollusc lines and then, about 400 million years ago, by the line to the fishes. More recently the amphibians branched off, then the reptiles and birds. Finally, about 75 million years ago there was a rapid proliferation of mammalian species into some 19 orders. Among the primates the line to monkeys separated early, followed by the divergence of the great apes from the human line.[17] On many of the other branches of the tree there has been a comparable proliferation of groups. It seems reasonable to suppose that the major branches, representing biological orders, classes, and phyla, along with their approximate times of divergence and average amounts of evolutionary change, will soon be fitted into place, largely on the basis of sequence evidence. Much is already known from morphological evidence about the connections of species, genera, and families in the terminal portions of all of the branches, which represent the 2 million living species. At present it suffices to consider in our tree the few hundred species for which we have sequences and the approximately one thousand intermediate groups, such as families, about which most inquiries would be made.

The topology of this tree, the names of the species or groups on all of the branch tips, and the lengths of the branches, which reflect average evolutionary change of the proteins in the species, can all be stored in the computer. The same manipulative programs now used in deducing the phylogenetic tree from the data can be turned to the automated retrieval of sequence data.

METHODS FOR RECOGNIZING DISTANTLY RELATED SEQUENCES

At present the sequences of almost 500 proteins more than 5 percent different from one another are known.[3] These proteins can be clustered into 116 superfamilies by using statistical methods to recognize their similarity.[18]

A comparison of sequences is based ultimately upon the sum of scores derived from comparisons of an amino acid in one sequence with one in the other sequence. The contribution for each pair of amino acids is specified in a matrix of amino-acid-pair scores. The simplest such matrix counts 1 for amino acid identities and 0 for nonidentities. A very sensitive matrix, derived from the large body of protein mutation data, has proven to be most satisfactory for detecting distantly related sequences.[19]

The most useful computer algorithm for detecting distant relationships[3,19,20] determines the highest possible score for any alignment (including gaps) of two protein sequences. The score for a pair of real sequences is compared with the distribution of scores obtained by aligning 100 pairs of randomized sequences having the same amino acid composition as the two real sequences. This distribution is close to normal. The difference between the score obtained with the two real sequences and the mean score from the randomized sequences is divided by the standard deviation of the random scores to give the "alignment score" in standard deviation units. Comparisons of real sequences that are unrelated give an essentially normal distribution of scores. Probabilities derived from a normal distribution are associated with the alignment scores. When a pair of sequences gets an alignment score of 4.8 SD units or more, we feel quite confident of a relationship ($P<10^{-6}$), presumably by descent from a common ancestor. Because over 6,600 comparisons between superfamilies are necessary for the organization of the presently known data, the standard is set sufficiently high to eliminate false-positive results. Alignment scores are shown in Table I for representatives of the various families of the globin superfamily. The α and β chains form the hemoglobin molecule of vertebrate red blood cells whereas myoglobin is found in vertebrate muscle. The lamprey and annelid globins are also found within blood cells. The insect globin, on the other hand, is dissolved in the body fluid of larval forms. The plant globin is found in the root nodules of a legume.

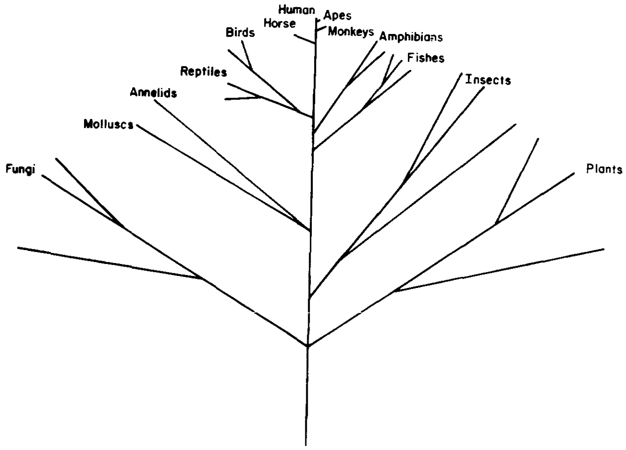

Figure 2—Phylogenetic tree showing the divergences of selected kingdoms, phyla, classes, orders, and families from the human line. The lengths of the branches have been drawn proportional to time without regard to the change in the proteins. The plants, animals, and fungi diverged from each other about 1 billion years ago

EVOLUTIONARY TREE OF A PROTEIN SUPERFAMILY

Each point on the evolutionary tree of a superfamily of related proteins represents a time, a biological species, and a protein structure. There is a point of earliest time on such a tree corresponding to the species ancestral to all of the others represented and within which the ancestral protein sequence for the superfamily was found. Sometimes during evolution a gene

TABLE I—Alignment Scores for Representative Sequences of the Various Globin Families (in SD units)

	α chain	β chain	Myoglobin	Lamprey	Annelid	Insect	Plant
Human Hemoglobin α chain		15.8	8.0	4.9	6.3	2.2	4.7
Human Hemoglobin β chain	15.8		7.6	3.8	6.0	2.9	4.2
Sperm Whale Myoglobin	8.0	7.6		3.6	5.7	3.7	2.7
Lamprey globin	4.9	3.8	3.6		1.2	3.5	1.4
Annelid globin	6.3	6.0	5.7	1.2		3.3	5.3
Insect globin	2.2	2.9	3.7	3.5	3.3		3.1
Plant globin	4.7	4.2	2.7	1.4	5.3	3.1	

is added within an ancestral species through the duplication of a gene already present. Two related proteins, frequently designated by Greek letters such as α and β, may then be found in all descendants. At each point of duplication, the phylogenetic tree of species must be modified to represent the evolutionary tree of the superfamily. The tree of descendant species is duplicated; one subtree represents the α protein and the other, the β protein. There may also be ancestral organisms that have lost genes. The branches for descendant species would then be deleted from the tree. Figure 3 shows the globins to be found in selected vertebrates. The duplication of the tree when the hemoglobin-myoglobin duplication occurred and again when the α-β gene duplication occurred can be seen. The γ chain has been found only in primates and must have been lost in the horse line.

FREQUENCY OF ACCEPTED POINT MUTATIONS

From the number of differences between homologous sequences in biological lines for which divergence times are known from the fossil record, the average rate of change due primarily to point mutations can be derived for each group of proteins. In Table II the average rates of mutation acceptance within selected protein families are shown. Observed changes have been corrected for inferred superimposed mutations. Most values are based on the time interval to 75 million years ago estimated for the mammalian radiation. Although there is more than a 500-fold difference in rates between the slowest and the fastest changing families, the rate of change of proteins within a family seldom varies by more than a factor of 2 or 3, particularly when the proteins fill the same functional niche in different organisms. In the presently available data, the most strongly conserved family is eukaryote histone IV; only two differences in 102 residues are found between the pea and the bovine sequences. The most rapidly changing protein family is amyloid A; its normal function, if any, is unknown, but its abnormal production and deposition is pathological. Even its rate is only one point mutation/100 residues/2 million years. This rate of change is so slow that homologues of all such proteins that were present in the first ancestral vertebrate should still be recognizable in living vertebrates as members of the same protein superfamily. Proteins within a few superfamilies, such as cytochrome c, have changed so slowly that members are recognizable in the whole world of living organisms.

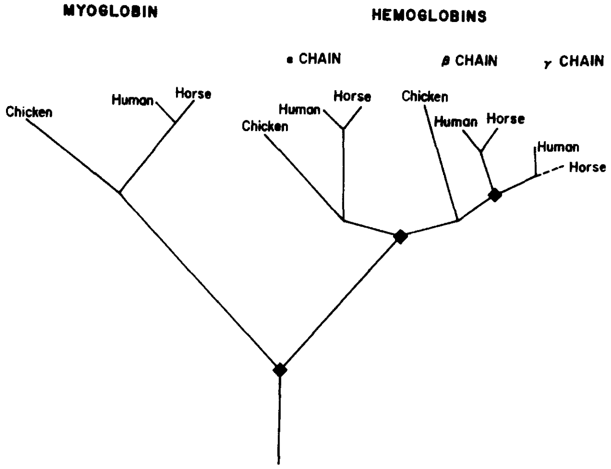

Figure 3—Evolutionary tree of the globin superfamily sequences from vertebrates. The lengths of the branches have been drawn proportional to time without regard to the change in the proteins. Diamonds mark the places where gene duplications have occurred in ancestral forms. The phylogenetic tree of descendant species is repeated at each of these points. The hemoglobin γ chain has been lost in the horse

TABLE II—Average Rates of Mutation Acceptance

Protein Family	PAMs/ 100my*	Detection Range
Amyloid A	48	All vertebrates
Growth hormone	32	
Immunoglobulin C and V regions	32	
Luteinizing hormone β chain	26	
Luteinizing hormone α chain	20	All eukaryotes
Hemoglobin chains	14	
Myoglobin	13	
Animal lysozyme	10	
Thyrotropin β chain	7	All organisms
Trypsinogen	5	
Cytochrome c	2.3	
Glyceraldehyde 3-PO$_4$ dehydrogenase	2.1	
Glucagon	1.1	
Glutamate dehydrogenase	0.90	
Histone IV	0.09	

* *Accepted point mutations per 100 residues per 100 million years*

NOTE: Observed changes have been corrected for superimposed mutations. In most cases estimated rates are based on the divergence of the mammalian orders 75 million years ago. For some proteins the estimated divergence times of other lines were used: amyloid A proteins from man and rhesus monkey, 20 mya; glutamate dehydrogenase from chicken and bovids, 300 mya; cytochrome c and trypsinogen from fish and mammals, 400 mya; glyceraldehyde 3-PO$_4$ dehydrogenase from pig and lobster, 800 mya; histone IV from plants and animals, 1,000 mya

The detection range is inferred from a model of the point mutation process, without insertions and deletions, using the average mutation rate shown. If such a conservative process has always obtained, all of the proteins in the last group could be detected in all living organisms in which they occur. Sequences of trypsinogen, cytochrome c, glyceraldehyde 3-PO$_4$ dehydrogenase, and glutamate dehydrogenase from prokaryotes and eukaryotes are detectably related. Homologues of thyrotropin β chain, glucagon, and histone IV have not been reported from prokaryotes.

For all sequences so far reported, related forms are found in other species. It is expected that related forms of virtually all human sequences would be recognizable in other vertebrates.

FREQUENCY OF INSERTION-DELETION EVENTS

The successful insertion or deletion of one or a few amino acids in a sequence is much less frequent than the acceptance of a point mutation. An average value of one insertion-deletion event per 42 point mutations has been derived from the evolutionary trees of 14 different groups of proteins.[21] It is possible to estimate this frequency with more precision in protein superfamilies, such as eukaryote cytochrome c, for which there is extensive sequence data.

ESTIMATION OF ANCESTRAL SEQUENCES AT THE NODES OF A TREE

Good computer algorithms are available for determining the ancestral sequences at the nodes of an evolutionary tree of protein sequences.[13,16,22] For each possible set of nodal sequences, the tree size is determined by counting the total number of differences between each pair of nodal and terminal sequences that are connected. The one (or set of alternative) nodal sequence(s) that corresponds to the minimum tree size is generated. Sequences along a branch can be predicted as an average of the sequences inferred or known for the two ends of the branch. For the cytochrome c sequence at the divergence of plant, animal, and fungal lines, 86 percent of the positions can be uniquely predicted (with >50% probability of being correct); and for the hemoglobin α chain at the divergence of the chicken and mammalian lines 84 percent of the sequence can be inferred.[1]

ESTIMATION OF PROTEIN SEQUENCES IN ORGANISMS NOT STUDIED

From the phylogenetic tree of living organisms, modified for the gene duplications within the protein superfamily under consideration, a subtree can be abstracted containing the branches for which sequences are known and the branch for which a sequence is sought. The elapsed time corresponding to this latter branch is also known and hence the number of point mutations and gap events expected to occur on it can be calculated from the rate parameters. The inferred ancestral sequence to be thus modified can also be estimated as described above.

Consider as an example a tree involving five species and the first six residues of their hemoglobin α chains, as shown in Figure 4. It is required to estimate the corresponding sequence in the cat. The minimal size tree has the ancestral sequence VLSAAD at all three nodes and also along the branch to which the cat line is connected. There has been one change on the branch to human and two on the branch to the mouse. These three mutations have occurred in the 415 million years of evolutionary time represented by all of the branches on this tree. If the sequences have been equally mutable during this time, then one would predict, using the binomial distribution, that, following the 75 million years represented by the dashed branch to the cat, there is a probability of 0.58 that the cat sequence has remained VLSAAD, a probability of 0.32 that there has been one change, and a probability of 0.10 that there have been two or more changes in the sequence.

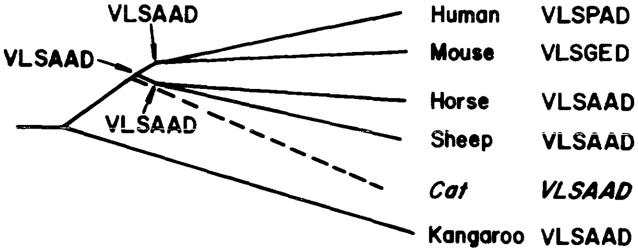

Figure 4—Prediction of the first six residues of the hemoglobin α chain in cat from sequences observed in a marsupial and in four other mammals. The ancestral sequence at all of the nodes is VLSAAD for the most parsimonious tree. The cat sequence is also possibly VLSAAD, although there is a probability of 0.55 that at least one residue has changed

In this procedure there are two major contributions to the error in the estimates, the error in the estimate of the mutation rate and the prediction error of the model. In this example, the standard deviation of the count is approximately $\sqrt{n}$, corresponding to a probability of 0.58±0.18 that no change will be found in the cat sequence. The precision of the model, which is derived from proteins in all superfamilies, is difficult to estimate from the data now available, but it seems close to the expectation for independent events. Additional parameters can be included as more data accumulates.

CONCLUSION

The conceptual tools and the procedures necessary for a prediction of all of the 10^{10} or 10^{11} protein sequences in living species are already highly developed. One can readily visualize the separate parts operating as an integrated interactive computerized system that could predict sequences for specified organisms with an estimated precision from the collection of known sequences.

From text to structured information—Automatic processing of medical reports*

by LYNETTE HIRSCHMAN, RALPH GRISHMAN and NAOMI SAGER
New York University
New York, New York

ABSTRACT

This paper describes the analysis and processing programs for a set of natural language texts in a medical area (x-ray reports on patients with breast cancer). The programs convert the information in the text into a tabular form suitable for further automatic information processing (e.g., editing of records, question answering on the data collected, or statistical summaries of the data). To set up a tabular form appropriate for the data, we first perform a manual linguistic analysis on a sample of the texts. From this we obtain the word classes and the form of the table (called an information format) for this type of material. We then apply the series of processing programs to the sentences of the texts. Each sentence is parsed with the Linguistic String Parser English grammar in order to obtain its grammatical structure; certain standard English transformations are then applied to regularize the grammatical form of the sentence; and finally a set of "formatting transformations" map the words of the sentence into the slots of the format or table, in such a way that the sentence is reconstructible (up to paraphrase) from its representation in the table. The results of applying these programs to a corpus are described. This procedure enables us to convert a natural language corpus into a structured data base.

INTRODUCTION

An essential part of the effective management of scientific and technical information is the efficient retrieval of information from a large body of text. One example of this is the retrieval of documents from a large collection of scientific articles, in response to a user's request. Another example of the same problem is the extraction of data from medical reports for statistical purposes, or for fact retrieval.

The key to efficient retrieval lies in the appropriate structuring of the information. For document retrieval, this may involve the extraction of key terms for each document. For medical records, it may involve transferring the most essential information into separate tables. These tasks pose a considerable burden on the preparer of the document. In addition, each such structuring will be appropriate only for the retrieval of certain types of information from the data base.

What is required therefore is a procedure for the automatic structuring of the natural language material itself, in such a way that all the information is preserved. The Linguistic String Project of New York University has been engaged in a long-term effort to develop techniques for processing textual information. These techniques are based on distributional analysis and computerized parsing of English texts. We intend in this paper to give an overview of our approach and to describe briefly our latest experiments.

OVERVIEW

Since we are dealing with textual data, structuring the information means, first of all, structuring the sentences. The question then is: what sort of structure should be assigned to the sentences? One alternative is some kind of surface parse tree. PROTOSYNTHEX I,[1] one of the earliest systems for information retrieval from natural language texts, attempted to use dependency analysis to match requests for information with sentences in the data base. However, surface analysis alone is inadequate for such information processing; one limitation is that it does not take into account possible differences between data and request due to grammatical paraphrase. For ex-

* This investigation was supported in part by research grant 1-RO1-LM-02616 from the National Library of Medicine, National Institutes of Health, DHEW, in part by Public Health Service Research Grant No. CA-11531 from the National Cancer Institute, and in part by research grant SIS75-22945 from the National Science Foundation, Office of Science Information Service. Development of the program for transformational analysis was supported in part under Contract No. NOOO14-67A-0467-0032 with the Office of Naval Research.

ample it would fail to match a request stated as an active sentence with an otherwise identical sentence in the data base which was in the passive voice.

It has long been recognized[2] that the effects of such paraphrastic variation can be overcome by performing some type of transformational analysis on the sentence. Transformational decomposition, following the theory of Harris, or deep structures, following the theory of Chomsky, can be used to reduce grammatical paraphrases to a standard form. A Linguistic String Project study in 1970 showed that Harrisian transformational decompositions could be useful in matching technical articles with information requests.[3] Such techniques can be used to structure a variety of texts; however, the resultant structures provide only general grammatical relations (subject, object), which are not directly related to the semantic or informational classes in a specific scientific subfield. In other words, the categories of English grammar are too general for information structuring.

It is possible to write a grammar specific to the use of language in a particular subfield of science, employing the same methods used to write descriptive grammars of whole languages. The resulting sublanguage grammar yields structures suitable for information processing: the word classes of this grammar are the word classes of semantic interest in the subfield; the overall arrangement of classes provides a format for the information content of subfield text sentences. For example, the grammatical structure of medical reports includes categories for patient, type of test, body organ tested, date of test, etc. Such an organization can greatly facilitate information retrieval or statistical manipulation of the data. On the other hand, each scientific field and type of text has its own structure. This means that a detailed linguistic analysis is required every time a new class of text is to be handled.

In this paper we describe an experiment in the computer formatting of material from medical records. Our previous papers have described the method of sublanguage analysis and information formatting for more complex textual material,[4,5] as well as the battery of programs which have been developed for text processing.[6,7] Here we focus on the problem of mapping text sentences into information formats. In the sections which follow, we will describe how the format for a particular type of medical narrative was derived, and how sentences are automatically transformed into structured information, as specified by the format. We will also indicate how the process of deriving formats may be automated or partially automated, and how the structured information of the formatted sentences can be used.

THE TEXTS

For our initial experiment in the computer formatting of texts, we chose to work on medical records. A set of follow-up reports on patients with cancer was provided to us in machine readable form, as part of a collaborative research project with Dr. I. D. J. Bross of Roswell Park Memorial Institute. The reports included laboratory tests, pathology reports, radiology reports, records of treatment, and discussion of medical problems. A linguistic analysis of some of these reports was done at Roswell Park.[8] We chose to process one particular type of report, identified as "Findings R(adiology)." This material was selected because it contained both full sentences and sentence fragments, a combination typical of the compressed note-taking style of much medical narrative (e.g., *x-rays not taken,* or *nothing to indicate metastasis*). The limited vocabulary of Findings R and the frequent paraphrasing of the various types of medical information made it possible to define valid word classes and formats on a limited corpus.

The corpus consisted of 159 Findings R reports on 11 patients, containing a total of 188 sentential units.* Due to frequent repetition of certain formulaic expressions, such as *x-rays negative,* only about half of the sentential units (86/188) were distinct, ignoring differences in date.

CREATION OF SUB-LANGUAGE FORMATS

To convert the medical information contained in a sentence into tabular form, we create a table (or format) with slots for each class of relevant information. The definition of a set of formats for a particular sub-field is done in two steps: first we perform a distributional analysis on the parsed sentences to obtain the sub-language word-classes; we then use the distribution of the word-classes to define the formats.

Distributional analysis involves classifying together words which occur in the same syntactically defined environments; for example verbs which occur with the same subjects and objects would form a word class. We begin building each class by finding a few words which occur frequently and share a number of environments. These words form the "core" of the new class. We then enumerate the environments in which these core words occur, and look for other words which share some of the same environments. If these other words occur primarily in the same environments as the core words, we add them to the class. This process can be illustrated with the NTEST (Noun TEST) class. The words *x-ray* and *film* share many environments, and are thus selected as the core of a new class. The characteristic environments in which they occur are:

* A sentential unit is a word sequence ending in a period; a sentential unit may contain more than one sentence or sentence fragment: *chest x-ray unchanged, nothing to indicate metastatic disease.*

$$(1)\quad [\text{chest}]\begin{Bmatrix}\text{x-ray(s)}\\ \text{film(s)}\end{Bmatrix}[\text{RN}]\begin{bmatrix}\text{show}\\ \text{--}\end{bmatrix}\; [\text{LN}]\begin{Bmatrix}\text{change(s)}\\ \text{metastasis}\\ \text{metastases}\end{Bmatrix}[\text{RN}]$$

$$(2)\quad [\text{chest}]\begin{Bmatrix}\text{x-ray(s)}\\ \text{film(s)}\end{Bmatrix}[\text{RN}]\begin{bmatrix}\text{be}\\ \text{--}\end{bmatrix}\; \text{negative } [\text{RN}]$$

Here braces enclose alternative elements and brackets enclose optional elements; LN and RN designate left and right adjuncts (modifiers) of the noun. Note that the dash is treated as a word of the sentence. Looking for other words which appear in these environments, we find:

(a) *Mammograms* no change. . . .
(b) Metastatic *series* showed extensive osteolytic metastases. . . .
(c) Metastatic bone *survey* -- negative.
(d) Flat *plate* -- mild degenerative changes. . . .
(e) Flat *plate* of abdomen -- shows lumbar spine to be riddled with multiple metastatic areas.

Since the environments of *mammograms, series, survey,* and *plate* match either environment (1) or (2) of the core words, they are added to the NTEST class.

We have implemented this approach to word classification in a computer program, although using a somewhat different procedure than that described above.[9] The program has been applied to the Findings R data and to other texts. Both the manual and computerized methods successfully classify all of the frequent words and some of the infrequent words.

To capture more of the infrequent words, we use a second-order distribution analysis procedure. In the characteristic environments of each class, we replace each word which has already been classified, by the name of its class. Consider the two environments of *x-ray* and *film* given above. At this point *chest* has been assigned to the NBODY class; *x-ray* and *film* to the NTEST class; *show* to the VSHOW class; *be* to the VBE class; *change* to the NCHANGE class; *metastasis* (*-ses*) to the NCONDITION class; and *negative* to the NONPATHADJ (non-pathological adjective) class. Replacing each word in the environments listed above by its class name, we get:

$$(3)\quad [\text{NBODY}]\ \text{NTEST}\ [\text{RN}]\begin{bmatrix}\text{VSHOW}\\ \text{--}\end{bmatrix}\; [\text{LN}]\begin{Bmatrix}\text{NCONDITION}\\ \text{NCHANGE}\end{Bmatrix}[\text{RN}]$$

$$(4)\quad [\text{NBODY}]\ \text{NTEST}\ [\text{RN}]\begin{bmatrix}\text{VBE}\\ \text{--}\end{bmatrix}\; \text{NONPATHADJ}\ \ [\text{RN}]$$

In similar fashion, we take the environments of each unclassified word and replace the words by class names where possible. For instance, there are two occurrences of *scan*:

(f) The liver scan was normal.
(g) Brain scan shows midline lesion.

Replacing words by class names, we obtain:

(h) NBODY scan VBE NONPATHADJ
(i) NBODY scan VSHOW LN CONDITION

Since these two sentences match the environment for NTEST words, we add *scan* to the NTEST class.

There are some words which occur so infrequently (once or twice in the corpus) that we cannot rely on distributional analysis to classify them. However these words must be assigned to a sublanguage class if the sentences in which they occur are to be correctly formatted. (Words are assigned to format slots on the basis of membership in a word class.) In these cases we either extend the criteria of a sub-class in reasonable ways, or if all else fails we use our knowledge of the meaning of a word to fit it into a subclass. On this basis we add to the NTEST class the words *auscultation, percussion, urinalysis,* and *view,* each of which occurred only once in the corpus.

Once we have defined the sublanguage word classes, we can use the word classes to define the sublanguage formats. A format is constructed so that:

1. equivalent pieces of information in different sentences will map into the same format slots;
2. each informationally significant word in a sentence is mapped into a separate slot of the format;
3. in each sentence, certain slots of the format may be empty, if the sentence does not contain that particular type of information;
4. not every word in a sentence will receive its own format slot: certain modifiers (e.g., *the*) are simply left as adjuncts on their head noun, if they contain no sublanguage information, or if they never occur independently of a particular word class;
5. *all* the words of the sentence are mapped into the format, preserving their original order of occurrence, with the exception of certain allowable paraphrastic permutations.

Once the sentences are formatted, we know exactly where (what slot or slots) to check, in order to find any particular type of information, in any sentence. However the formatted sentence will resemble the original unformatted sentence very closely, since no words are lost, and word order is preserved up to paraphrase. It is surprising that the sublanguage sentences are so highly structured that an information format can be constructed in this way, but it is just this structure that makes it feasible to do natural language processing on these texts.

We begin to build the format by taking a sentence of the corpus:

(a) Chest x-ray 12-6 shows no evidence of metastasis.

We replace the words by their sublanguage classes:

$$\text{(b)}\ \underset{\text{subj}}{\begin{bmatrix}\text{NBODY} & \text{NTEST} & \text{DATE}\\ \text{chest} & \text{x-ray} & \text{12-6}\end{bmatrix}}\ \underset{\text{verb}}{\begin{bmatrix}\text{VSHOW}\\ \text{shows}\end{bmatrix}}$$

$$\underset{\text{obj}}{\begin{bmatrix}\text{NEGATIVE} & \text{NSHOW} & \text{P} & \text{NCONDITION}\\ \text{no} & \text{evidence} & \text{of} & \text{metastasis}\end{bmatrix}}$$

Each significant word gets its own slot. Of these words, only P (preposition) has no significance beyond its role as syntactic marker; it is therefore included as an adjunct of NCONDITION. We can now write our first tentative format. The format slots are given names related to the type of information they will contain. The gross syntactic structure of the parsed sentence provides some additional groupings of the format slots into TEST (subject) and FINDING (predicate). In Table I words in () are adjoined to the main word in the slot.

Next we take another sentence and again replace the words by their word classes:

$$\text{(c)}\ \begin{bmatrix}\text{DATE} & \text{NTEST} & \text{P} & \text{ADJSPINE} & \text{NBODY}\\ \text{10-26} & \text{film} & \text{of} & \text{lumbar} & \text{spine}\\ \text{subj} & & & & \end{bmatrix}$$

$$\begin{matrix}\text{--}\\ \\ \text{--}\end{matrix}\begin{bmatrix}\text{NEGATIVE} & \text{NCHANGE}\\ \text{no} & \text{change}\\ \text{obj} & \end{bmatrix}$$

The subject of sentence (c) contains the word classes DATE, NTEST, NBODY, but in a different order than sentence (b). However there are paraphrastic transformational relations that allow the date (a time expression) to be on either side of the subject; and a paraphrastic transformational relation between the two noun phrases:

$$\begin{array}{ccccc} N_1 & N_2 & \leftrightarrow & N_2 \text{ of } & N_1\\ \text{chest} & \text{film} & & \text{film of} & \text{chest}\end{array}$$

Since the subjects of sentences (b) and (c) contain the same kinds of information, this information must be mapped into the same format slots in both cases. Changing the word order of sentence (c) for formatting is permissible, since it only involves paraphrastic permutations. Therefore *10-26*, *film*, and *spine* map into the format slots TESTDATE, TESTN, and TESTLOC as set up in format #1. *Lumbar* is not assigned a format slot of its own, but is left as an adjunct on *spine*, because ADJSPINE adjectives occur only on *spine* in this corpus; that is, they have no independent status and do not get a separate column of the format.

Next we must decide what to do with the symbol "--" which appears between subject and object in sentence (c). Should it be assigned to a new format slot, or can it be mapped into the VERB category? If we examine its distribution, we find that it has the distribution of VSHOW in certain cases, and of VBE in others, e.g., *Chest x-ray -- no evidence* and *Chest x-ray -- negative*. It is therefore appropriate to map it into the VERB slot. Finally, we must decide where to put NCHANGE in the format. Its distribution differs from NSHOW and NCONDITION; in particular it can occur in the same sentence with words from these two classes:

(d) No evidence of recurrence
NSHOW NCHANGE

(e) No callus formation
NCONDITION NCHANGE

Clearly the class NCHANGE is not in complementary distribution with either NSHOW or NCONDITION. We must create a new slot in the format between INDICATION and MED-FINDING to house it. Our revised format #2 is shown in Table II with formatted sentences (b)-(e):

In this manner we build up the format on the basis of a limited number of sentences. The adequacy of the format created can be tested by using it in the formatting of a different set of texts. The x-ray format made up from part of the Findings R data has been tested both against other Findings R data and against a different set of x-ray data from patients with sickle cell disease. In both cases it was found adequate to format the radiology material.

TABLE I

FORMAT #1

TEST			FINDING			
TESTLOC	TESTN	TESTDATE	VERB	NEG	INDICATION	MED-FINDING
NBODYPT	NTEST	DATE		NEGATIVE	NSHOW	NCONDITION
chest	x-ray	12-6	shows	no	evidence	(of)metastasis

TABLE II

FORMAT #2

	TEST			FINDING				
	TESTLOC	TESTN	TESTDATE	VERB	NEG	INDICATION	CHANGE	MED-FINDING
	NBODYPT	NTEST	DATE	VSHOW --	NEGATIVE	NSHOW	NCHANGE	NCONDITION
b)	chest	x-ray	12-6	shows	no	evidence		(of)metastasis
c)	(of) (lumbar) spine	film	10-26	--	no		change	
d)					no	evidence	(of) recurrence	
e)					no		formation	callus

Not all the entries in Findings R report the results of a test. There are a few sentences that refer directly to the patient:

(g) Patient given penicillin for 9 days.

(h) Patient to return in one month for repeat x-ray.

Clearly these sentences require a different format from the one being developed above. Since there are so few sentences of this type, a much larger corpus would be required to define a format for sentences (g) and (h), but as these sentences illustrate, even in a restricted subfield of a medical report, several formats may be needed to represent the different types of information encountered.

FORMATTING THE TEXT

Once the format is defined, the sentences must be mapped into the format. As before, it is important to have a procedure which can be generalized to texts in other subfields. Our procedure is built around the Linguistic String Parser, a powerful system for language analysis which provides the mechanism for parsing sentences with a context-free grammar augmented by restrictions;[7] it also provides the machinery for performing transformations on parsed sentences,[10] and a higher level language (the Restriction Language) for writing restrictions and transformations.[11]

Sentence formatting is done in three stages:

1. determination of sentence structure by linguistic string analysis;
2. regularization of certain sentence structures by use of general English transformations;
3. mapping of transformed parsed sentences into format slots, using specialized "formatting transformations."

We will briefly consider each stage in turn.

Linguistic string analysis

Linguistic string analysis provides a structural description of the sentence in terms of a specified set of linguistic strings. The assignment of a word to a format slot depends on its role in the sentence structure, as well as on its word class, so that a determination of sentence structure is a prerequisite to formatting. For example syntactic analysis resolves part-of-speech ambiguities, so that the word *left* is identified as a verb in

(a) The patient left the hospital.

but as an adjective in

(b) X-ray of the left lung showed metastasis.

The LSP string grammar was originally designed to handle only complete English sentences; it provides a broad coverage of English syntactic constructions and together with its associated word dictionary, has been used to analyze English scientific texts. In order to process the note-style and incomplete sentences of the medical reports, we made four changes in the grammar.

First, the grammar was expanded to handle the sentence fragments by adding a small number of new productions to the context-free component. Five types of fragments were allowed.

1. A sentence with subject and object but either without verb or with a dash (--) in place of a verb: *Chest x-ray -- no change., 10-6 x-ray negative.*
2. An adjective with its adjuncts: *Negative for metastatic disease.*
3. A noun with its adjuncts: *No evidence of change.*
4. A passive sentence without subject or *be*: *Not done on previous exam.*
5. A sentence preceded by a noun phrase. *Chest x-ray 4-6-71 chest film shows no evidence of fluid.*

Second, one restriction in the grammar was removed in order to accommodate the note-taking style of the text: this was the count noun restriction, which requires that a singular count noun have an article or some other appropriate form of modifier before the noun. For example, the Findings R text contains sentences like *X-ray shows lesion,* whereas in normal English both *x-ray* and *lesion* must be preceded by an article: *The x-ray shows a lesion.*

Third, certain constructions that were unlikely to occur in this type of text were eliminated from the grammar, for example, the question constructions. This pruning of the grammar speeded up the sentence analysis considerably.

These first three changes were designed to accommodate texts in a note-taking style and would be applicable to any subject area. A fourth change, needed to handle certain types of ambiguity, required the use of word classes and selectional restrictions specific to the sublanguage grammar of radiology reports.

One such type of ambiguity is a predictable structural ambiguity, which must be resolved in order to format the sentences correctly. This type of ambiguity can arise from modifiers on conjoined material. For instance, the sentence

(c) X-rays of lumbar spine and chest showed lesions.

may be analyzed as any one of the following:

(d) X-rays of lumbar spine showed lesions and chest showed lesions.

(e) X-rays of lumbar spine showed lesions and x-rays of lumbar chest showed lesions.

(f) X-rays of lumbar spine showed lesions and x-rays of chest showed lesions.

Such ambiguity is inherent in the syntactic construction, and has nothing to do with the particular words involved. Only sublanguage selectional restrictions can resolve it. In this example, *lumbar* is an ADJ-

SPINE which modifies only the noun *spine*, eliminating reading (e). Since *spine* and *chest* are both NBODY, it is more likely that they are conjoined than words of different classes (e.g., *x-ray*, an NTEST and *spine*). This eliminates reading (d) leaving the correct reading (f).

Another type of ambiguity arises from an "over-rich" lexicon--a lexicon for all of English, containing possible uses of words that would never occur in this sublanguage. The sentence

(g) No report of x-rays being taken.

received a parse in which *being* was taken to be a noun (as in *human being*) which was the object of a missing verb *be* or *show* derived from a sentence:

(h) No report of x-rays shows a being which has been taken.

There were several ways to deal with this kind of ambiguity. We could have used selectional restrictions on the subject and object of *taken*, or we could have placed tighter restrictions on the construction with an omitted verb. However we chose what seemed the simplest and most direct approach for such cases: we created a special x-ray dictionary, by editing the general English dictionary to remove word classifications (e.g., *being* as a noun) which would never occur in the Findings R text.

English transformations

In the Linguistic String Parser, the transformations are applied to the output of the string analysis. The function of the transformations is to regularize the parse trees, reducing the variety and complexity of structures present. For example, the sentences

(i) X-rays of chest and pelvis negative.
(j) X-rays of chest negative and x-rays of pelvis negative.

contain the same information. By transforming the parse tree for the first sentence into the tree for the second sentence we produce a more regular set of structures in which only full sentences (or sentence fragments) are conjoined. We also transform relative clauses into complete sentences; for example, we would convert

(k) X-rays showed a lesion which may be metastatic.

to

(l) X-rays showed a lesion such that the lesion may be metastatic.

The gain achieved in performing this transformation is that the complete sentences derived from relative clauses can then be formatted in the same way as any other sentence; no special process for formatting relative clauses is required.

These transformations are written for all of English; they do not make use of any information specific to the Findings R sublanguage. There are a large number of English transformations, but only a very few have been used in this application. This is because transformations expand compressed material into a more regular form by filling in certain pieces of redundant information, or information retrievable from context (like the verbs *be* or *show*). If a particular type of information is always omitted in a certain class of texts, no regularization is achieved by trying to fill in this missing information. For example, the word *x-ray* can be used both as a verb and as a noun, so we could have an English transformation to convert sentences with the noun to sentences with the verb; in Findings R, however, *x-ray* is used only as a noun, and no regularity would be gained. Moreover, the verb requires a subject--the taker of the x-ray--which is never present in this text. As a result, the only two English transformations used are the conjunction expansion and relative clause expansion described above. However, in more syntactically complex material or less abbreviated material, there might be a real benefit from a greater regularization of the syntax (via transformations) before attempting to format it.

Formatting transformations

The formatting transformations transfer the words from the parsed sentences to the appropriate slots in the format. They use the same transformational mechanisms built into the Linguistic String Parser to handle the English transformations. Because these mechanisms are set up to map trees into trees, the format is first created as a tree; after it has been built, it can be written out in the tabular form shown in Tables I-III. Formatting transformations move the words from the original ASSERTION or FRAGMENT node in the parse tree into the format slots. As a result, at the end of the formatting process, the FORMAT has the words of the sentence in it, while the original ASSERTION or FRAGMENT node is empty. This provides a check on the completeness of the formatting process.

Three kinds of transformations can be distinguished. The first type of transformation sets up the format slots under the node FORMAT. For sentences which contain a verb or adjective connecting two findings or pieces of data (e.g., *related to, compatible with, typical of*), the format is augmented with a CONNECTIVE slot and an additional set of FORMAT slots. It is necessary to add this new FORMAT to provide an empty set of slots for the second finding. Relative clauses are treated similarly: a CONNECTIVE slot is added, with a relative clause marker placed in the CONN slot under CONNECTIVE; and the assertion contained in the expanded relative clause is mapped into the new set of format slots.

Once the format slots have been set up, the remaining transformations each map words of one class into the appropriate format slot. These transformations fall into two groups. One type requires little if any syntactic or co-occurrence information; it simply searches the parse of the sentence for a word having both a particular syntactic category and a certain sublanguage word class, and then maps the word into the format slot associated with that word class. For example, the T-NTEST transformation looks for a NOUN of class NTEST. When it finds such a word in the sentence being formatted, it moves the word, together with its adjuncts, into the appropriate format slot (TESTN).

A different type of formatting transformation is required for a word that can go into one of several slots depending on what it modifies (e.g., negative and indefinite words). This class of transformations relies heavily on the availability of syntactic information from the parse. For example, *not* can go in any one of three slots, depending on what kind of verb it negates. Therefore the T-NOT transformation must apply before any of the verb transformations have moved the verb into its format slot: co-occurrence relations must be checked in the parse tree, where the syntactic relations are still explicit. Once the verb has been moved into the format, the syntactic relations have been translated into informational relationships and are no longer explicitly expressed. When the T-NOT transformation finds a *not*, it checks the main verb occurring in the same string with *not*. If the verb is VSHOW (e.g., *X-rays do not show metastasis.*), the *not* goes into NEG in FINDING. If the verb is VDONE (as in *not done*) the *not* goes into the NO-TEST slot, under TEST, because the class VDONE occurs only with NTEST nouns; if *not* occurs with VDONE, it necessarily negates the existence of a test, even if no NTEST word occurs in the sentence. Finally if the *not* negates a word that connects two findings (e.g., *is not related to, is not compatible with*) it will go into the NEG-CONN slot under CONNECTIVE.

The set of formatting transformations can be viewed as a set of special sublanguage transformations which reduce various sublanguage paraphrases to a standard representation in the format. For example, to find out if a test was performed, we need only inspect the NO-TEST column of the format. If it is empty, a test has been performed and we can find the type of test by looking in the NTEST slot. Or if we want to know when the first abnormality is seen in a patient, we look for the first sentence where both (1) FINDING is not empty and (2) the columns NEG and STATUS in FINDING are both empty. This is because all the "normal" findings are expressed either by NON-PATHADJ (*negative, normal*) formatted in the column STATUS or by expressions like *no change, no metastasis, no evidence of metastasis.* If one of the slots in FINDING has an entry other than NEG or STATUS, then it must be an INDICATION, a CHANGE, or a MEDical-FINDING (PART-OF-BODY words will not occur by themselves in the FINDING slot). The format thus standardizes the representation of the important medical information in the sentence, so that this information can be further processed.

RESULTS

To each sentence of our corpus we applied the formatting program, which parsed the sentence, performed certain English transformations on it, and then mapped this structure into the format. This program successfully formatted 176 of the original 188 sentences (94 percent). Table III presents the full format and several examples of formatted sentences.

The full format contains sets of slots for OBSERVE (for doctor+verb: *radiologist noted*), TEST and FINDING. For those sentences that require more than one set of format slots to accommodate their information (e.g., sentences 4 and 5 in Table III), additional sets of format slots are added, each linked to the preceding format by a CONNECTIVE:

FORMAT			CONNECTIVE	FORMAT		
DATA				DATA		
OBSERVE	TEST	FINDING		OBSERVE	TEST	FINDING

In Table III, each row represents a set of format slots; a sentence that requires three sets of format slots (e.g., sentence 5) will therefore occupy three lines of the table.

CONCLUSION

The formatting procedure enables us to convert a natural language corpus into a structured data base. Given a set of x-ray reports in machine readable form, the formatting program maps the input sentences one by one into the tabular format structure. This data base can be used in a variety of ways; we are currently at work on a program to extract various medical statistics from the data base (e.g. number of patients with recurrence of metastasis; time from operation to time of first suspected recurrence of metastasis; location of new metastasis, etc.). It should also be possible to use the data base with a natural language front end to process questions and answer them with information from the data base.

The formatting program is able to convert the natural language material into structured information partly because the material chosen for processing is itself highly structured; however, the formatting relies heavily on a linguistic analysis of each sentence, in order to handle such informationally complex structures as relative clauses, negation, and conjunction.

TABLE III

THE COMPLETED FORMAT: OBSERVE and TEST columns, with examples of formatted sentences.

Labels of the format slots:

NOTE: in the formatted sentences, adjuncts are placed in (); left adjuncts appear above the main word, right adjuncts below it.

Findings R sentences, formatted in the columns to the right:

	FORMAT								
	DATA								
	OBSERVE		TEST						
	MD	REPORT	NO-TEST	TEST-VIEW	TESTN	TESTLOC	VERB-DONE	OCCASION	TESTDATE
1. Chest film 6-5 shows enlargement of lesion on right hilum since film of 4-17					film	chest			6-5
2. X-rays taken 3-22-65 reveal no evidence of metastatic disease.					x-rays		taken		3-22-65
3. None this examination			none					(this) examination	
4. Nothing definite is seen that indicates tumor.		(is) seen							
5. The heart, lungs, and bony structures are intact.									

Without a stage of syntactic processing, it would not be possible to determine the scope of negation, the appropriate expansion for conjoined elements, or the referend of the relative pronoun. Because we can process these linguistic structures we can go beyond document retrieval; we are now able to "get inside" the text, to process the actual content.

Our formatting experiment was conducted on a rather simple set of reports which had little paragraph structure and contained specific limited kinds of information. A text that contained several different types of information (requiring several different formats), or had a more complex paragraph structure, with a corresponding increase in intersentential reference, would pose somewhat greater difficulties than the type of material discussed here. Nonetheless there are many instances of natural language material that is both restricted and highly structured (different types of medical reports; weather reports; program specifications in natural language), where this type of procedure would be successful in structuring the information.

Although the specific program described here will process only x-ray reports, the techniques that have been used to obtain the program are general. The string grammar parses English sentences; a few changes enabled it to handle fragmentary note style. The procedure for defining word classes (and selectional restrictions) is based on distributional analysis and can be applied to any language or sublanguage. Part of the procedure for obtaining word classes has been automated in the clustering program;[9] one of our next projects is to complete the automation by adding a program that will convert the parsed sentence into co-occurrence patterns suitable for clustering. The definition of the format was a general technique,

originally developed on a corpus from pharmacology.[4] An overall strategy for mapping parsed sentences into a sublanguage format has been defined, although the transformations themselves are dependent on the target structure (the format) as well as the type of sentence structures in the input. Because each step of our procedure has been based on general linguistic techniques, it should be possible to apply this procedure to convert natural language texts of any sufficiently structured subfield into a structured data base.

Design considerations of a database system in a clinical network environment

by SHI-KUO CHANG, M. O'BRIEN, J. READ, R. BOROVEC, W. H. CHENG and J. S. KE
University of Illinois
Chicago, Illinois

ABSTRACT

A database system designed in the context of a clinical network incorporating small computers, automated clinical instruments, and a variety of terminals is described. The database system is used for clinical data acquisition, research support, and clinical decision making support. The database system is based upon the relational approach, with important modifications to meet above design objectives and provide means for dynamic database reconfiguration. Its characteristics include: definition of elementary files as tables, a database skeleton describing the structure and contents of files in the database, a low-level database manipulation language based upon the Relational Algebra, and a frame-oriented user interface for high-level database manipulation.

INTRODUCTION

The Medical Information Systems Laboratory is developing a database system in the context of a clinical network incorporating small computers, automated clinical instruments, and a variety of terminals. The database system is intended to support patient care, clinical research, and research in advanced techniques of automated processing of medical information. The major support functions of the database system are summarized in Table I.

The primary functions of the clinical network include clinical knowledge acquisition, clinical research support, and clinical decision making support. Clinical data are collected from several sources: laboratory technicians, clerks, physicians, and automated clinical instruments. Clinical data should be checked for errors, formatted, and appropriately compressed, before being stored in the database. Moreover, database consistency and integrity should be maintained by the database system.

The clinical database is manipulated by local physicians for research purposes, using terminals connected to the clinical network. Another research use of the database is the sharing of clinical information via the Artificial Intelligence in Medicine (AIM) network. In the future, the clinical network could become a local node in a nationwide computer-communications network, so that outside physicians can conduct clinical research by gathering information from the databases at various local nodes.

The clinical database can also be used for clinical decision making. To aid clinical decision making, statistical information can be collected from the database, histograms can be plotted, using various mundane application programs. Data reduction and meaningful data manipulation capabilities are other useful features which can be provided by the database system. The database system should also facilitate the application of advanced artificial intelligence techniques such as automated inference and pattern recognition, so that such techniques can be explored as possible clinical decision making aids. Finally, since the clinical network will be used primarily by the Department of Ophthalmology of the Eye and Ear Infirmary, Uni-

TABLE I—Support Functions of the Database System

1. Clinical knowledge acquisition
   1.1 Data collection
       Technician Input
       Clerk Input
       Physician Input
       Automated Instruments
   1.2 Error control, data formatting and data compression
   1.3 Database consistency and integrity
2. Clinical research support
   2.1 Local physician research
   2.2 Outside physician research
   2.3 Artificial intelligence in medicine (AIM) research
3. Clinical decision making support
   3.1 Statistical information, graph plotting, and other mundane applications
   3.2 Data reduction
   3.3 Display and manipulation of stored information
   3.4 Automated inference aid
   3.5 Pattern recognition aid
   3.6 Graphics aid

versity of Illinois Medical Center, some interactive graphics capabilities are needed to present graphical information collected by some of the automated clinical instruments.

With the above objectives, we are designing a database system having the following characteristics:

1. Definition of elementary files as relational tables.
2. A database skeleton describing the structure and contents of files in the database
3. A low-level database manipulation language based upon Codd's Relational Algebra
4. A frame-oriented user interface for high-level database manipulation

In designing the clinical database system, we are heavily relying on the relational approach to database system design,[1-4] because we feel that the relational approach provides a unified, simple viewpoint to the user and at the same time also supports complicated deductive reasoning as exemplified by the first-order predicate calculus. The relational approach is also of interest from a methodological viewpoint, when we consider the problem of designing knowledge-based systems. Database systems are now being designed primarily for commercial applications in data processing. In order to extend the capabilities of database systems to support more sophisticated information processing applications such as automated inference, automated problem solving, and complex decision making, knowledge-based systems are needed. The relational approach offers possibilities of being extended to the design of knowledge-based systems.

The clinical database system is based upon the relational approach. However, important modifications are made to (a) meet the above mentioned design objectives, and (b) provide means for easy database reconfiguration, so that the database can be dynamically reconfigured for efficiency reasons. In what follows, the design of this database system will be described in some detail.

HARDWARE AND SOFTWARE ENVIRONMENT

The selection of hardware for the clinical network was based primarily on the availability of software tools for the development of the database system and other network control programs. The choice of Bell Laboratories UNIX operating system constrained our selection to PDP11-compatible machines. The clinical network includes a host computer, a number of satellites, a database module, and a number of terminals.

Host

The host system consists of a DEC PDP11/40 with 48K words of core memory, each word being two bytes long; two RK05 1.2 million word cartridge disk drives; two industry compatible magnetic tape drives; one Versatec electrostatic printer/plotter; and one high speed paper tape reader/punch which is used primarily for maintenance purposes. Communications with the satellites are via standard asynchronous serial lines. Initially these will operate at 9600 baud. As the final form of the clinical network takes shape, the lines and interfaces will be upgraded, and the old interfaces will be used for remote terminals.

Satellites

The four satellites are identical (at this time) and consist of a California Data Processor's 1/35 with 16K words of core memory, two serial I/O interfaces, and a bootstrap loader, mounted in a stand-alone cabinet which is converted to a desk when appropriate.

The choice of the CDP machine over a comparable DEC PDP11/35 was based primarily on price and flexibility. It is totally compatible with the DEC PDP11 and is based upon a fast, versatile microprocessor which will allow enrichment of the instruction set if necessary.

Each interface to clinical instruments will be a custom design tailored to make the data available in the most useful format. Preliminary specifications for each of the clinical interfaces have been completed. It is anticipated that some satellites (most notably the satellite for Glaucoma Clinic) will require more computer resources (more core memory and perhaps a local disk). These will be provided as the need arises.

Database module

The database module consists of front-end processor, a disk controller and disks. The processor and controller comprise a dual CDP 1/35. This configuration currently contains 32K words of core memory, memory management and an RK05 disk. Facilities for microprogramming consist of 256 words of alterable control store and a microconsole for debugging and maintenance.

The disks consist of four 80 megabyte Control Data Corporation 9762 Storage Modules giving a total storage capacity of 300 megabytes (after necessary formatting). The actual control of the disks is performed by a CDC CU/33 formatter which moves the heads, reads and writes the disks and performs error checking and correcting.

We plan to initially use the disks with a small interface which will make them look like DEC RP03 disks to the host machine. This will allow us to do most software development in the C language provided by the UNIX operating system.

Terminals

Three types of terminals are in use. The principal terminal in each clinic will be a modified Owens-Illinois

CVG-II plasma panel terminal with associated touch panel, both being outgrowths of the PLATO project.[5] Teleray 3700's and Infoton Vistar II's constitute the rest of the terminals for general use.

The system at this time (January, 1976) is partially operational. Six terminals are in use on the host system for database and operating system development. Links to one satellite and the Television Ophthalmoscope System[6] have been installed. The database module front-end is operational, and the disk components are being assembled.

In addition to the internal clinical network, a direct host/AIM link will be provided for access to the clinical database and for continued modelling of ophthalmic diseases, when AIM upgrades its 300 baud links to 1200 baud.

The selection of the UNIX operating system is made, primarily for the ease of software development under UNIX. The prototype database system is written in the above mentioned C language.[7] When the database module becomes operational, we also intend to run a stripped-down version of UNIX on the dual CDP 1/35. The lowest level database operations will later on be rewritten in microcode.

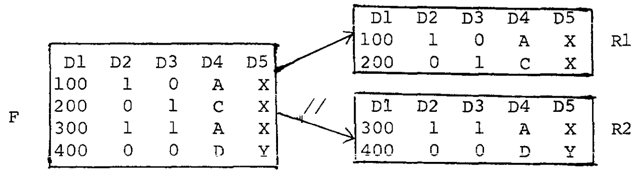
THE DATABASE

The clinical database comprises a collection of files. There are three types of files in the clinical database: *elementary files, composite files,* and *raw files.*

Elementary files

An elementary file is a *relational table** in Third Normal Form.[4] In the database, all composite files must be composed from elementary files. Since an elementary file is a relational table, all valid relational algebraic operations can be applied to an elementary file to extract the desired information. An elementary file is associated with a *descriptor set.* Each *descriptor* in the descriptor set has a name (usually a string of characters), a descriptor type, a format specification, and a descriptor domain. The descriptor types are as follows:

1. *Interval descriptor*—The descriptor domain is a linearly ordered set, with a minimum as well as a maximum element.
2. *Nominal descriptor*—The descriptor domain is an unordered set. Descriptors with values as character strings are regarded as nominal descriptors. So are logical descriptors which take on the logical values 0 or 1. However, there is usually an implicit collating sequence for character strings, so that they still can be sorted into a collating sequence.
3. *Structural descriptor*—The descriptor domain has a specified mathematical structure, such as a tree, a lattice, a semi-lattice, a directed graph, etc.



F

D1	D2	D3	D4	D5

200	0	1	C	X

R2

D1	D2	D3	D4	D5
300	1	1	A	X
400	0	0	D	Y

Figure 1—Vertical concatenation

The format of a descriptor is usually specified by a *picture* of the format, such as X(3), 9(5), which mean a character string of length 3 and a numeric string of length 5, respectively. In the current implementation, only the first two types of descriptors are allowed.

An elementary file consists of a number of records (or rows, tuples), each record being of the form $(d_1, d_2, \ldots, d_n)$, where d_i belongs to the descriptor domain of descriptor D_i.

Composite files

A composite file is a relational table which is defined in terms of other relational tables using certain *composition rules.* As an example, R1 and R2 are two constituent files. A composite file F can be defined as the *vertical concatenation* of R1 and R2, or

$$F=R1//R2$$

where // is the vertical concatenation operator, provided that R1 and R2 have similar descriptor sets, as illustrated in Figure 1. Similarly, a composite file F can be defined as the *union* of two constituent files R1 and R2, or

$$F=R1+R2$$

where + is the union operator, provided that R1 and R2 have similar concatenated keys, as illustrated in Figure 2, where D1 is the common key, and – denotes an undefined entry in the relational table.

A *concatenated key* is a subset of the descriptor set, which takes on unique values for each record in a file. If the concatenated key comprises one descriptor, that

R2

D1	D4	D5
300	A	X
400	D	Y

Figure 2—Union

descriptor is called a *key,* such as D1 for file F in Figure 2.

A third composition rule is *qualified vertical concatenation,* which can be used to combine files by adding an extra descriptor to indicate the individual identities of constituent files. An example is illustrated in Figure 3, where $F denotes the new descriptor for identifying constituent files. The composite file F is the qualified vertical concatenation of R1 and R2, or

F=R1(//$F)R2

The above example illustrates the composition of F from R1 and R2. Conversely, F can also be decomposed into several smaller files, as illustrated in Figure 4, where the decomposition is made with respect to descriptor D1, and

F=$F1(//D1)$F2(//D1)$F3

where $F1, $F2 and $F3 are new names for the constituent files.

Similarly, another composition rule is *qualified union,* which can be used to combine files with different descriptor sets by adding an extra descriptor to indicate the identities of the constituent files.

The last composition rule is the *horizontal concatenation* rule. A composite file F can be defined as the horizontal concatenation of constituent files R1 and R2, or

F=R1(*D1)R2

by equijoining the two relational tables on descriptor D1, where * denotes the *equijoin operator,* and D1 must be the key for both R1 and R2, as illustrated in Figure 5.

In horizontal concatenation, the constituent files can be joined on any common concatenated key, in which case the concatenation operation is written as (*D1,D2,...,Dn), where {D1,...,Dn} is the common concatenated key.

Raw files

Raw files are files not in the form of relational tables. In clinical data collection, data entered by human users could be appended to relational tables which have already been defined by the users previously. Some data collected by clinical instruments, however, will not be suitable to be stored in relational tabular form directly. Graphical information such as visual field charts, pictorial information such as those provided by the Television Ophthalmoscope System (the TVO System), are examples of nonrelational data. It will be wasteful to store such information in relational tables. Moreover, in the intended applications, such graphical and pictorial data will invariably be processed by special application programs. Therefore, they should be stored in raw files, with no restrictions on format, record length and file size.

$F3

D2	D3	D4	D5
5	1	B	X

Figure 4—Decomposition of F

Raw files can also be used for input/output purposes. After an elementary file has been defined, the following statement

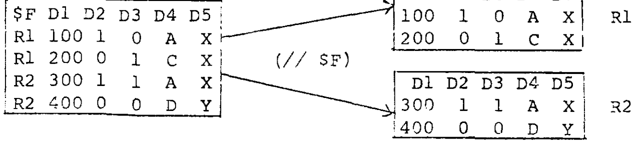
READ R1 FROM U1

can be used to transform a raw file U1 into an elementary file R1 in relational tabular form. Similarly, the statement

WRITE R1 TO U1

will transform R1 into a nonrelational format and store it in U1. If the phrase "FROM U1" is omitted the standard input file is assumed, which is normally taken to be the user terminal. Similarly, the omission of "TO U1" causes output to be directed to the standard output file, and the output normally appears at the user terminal.

The above input/output mechanism is very useful for the clinical research applications. For example, a file in relational tabular form may first be transformed into a raw file. A data reduction program based upon Variable-valued Logic Reduction[5] can then be applied to the raw file. Finally, the resultant raw file can again



$F	D1	D2	D3	D4	D5
R1	100	1	0	A	X
R1	200	0	1	C	X
R2	300	1	1	A	X
R2	400	0	0	D	Y

300	A	Y

Figure 5—Horizontal concatenation

be recast into relational tabular form. Similarly, picture processing applications are also applied to raw files, with subsequent transformation into relational tables, after extensive preprocessing has been made.

A final use of raw files is to *equate* a raw file to an elementary file (see later section). Any database operations to be performed on the elementary file will be actually performed by a special program associated with the corresponding raw file. For example, file U2 is a raw file with an inverted file structure. The associated special program is in a UNIX file P2. File U2 is equated to an elementary file R2. Whenever a database operation is to be performed on R2, the operation command and arguments are passed to P2, which then performs some operation on U2. In this way, files with different file structures could be treated as part of the relational database and at the same time still retain their idiosyncratic structures. It is thus unnecessary to transform all files into relational tubular form, which may not be economical either in storage or in speed, or both.

DATABASE SKELETON

With the above described three types of files—elementary files, composite files, and raw files—a database can be structurally characterized by a hierarchical schema, called a *database skeleton*. Here we will restrict our attention to one user's view of the database. Multiple user's views can be accommodated by having multiple database skeletons. An example is shown in Figure 6.

In the database skeleton, U1, U2, U3 and U4 are raw files. U1, U2 and U4 have associated application programs P1, P2, and P4. The composite file F1 is defined as the equijoin on D1 of two elementary files R1 and R2. The composite file F2 is defined as the vertical concatenation of an elementary file R3, and another composite file F3, which in turn is the equijoin on D2 of three elementary files R4, R5 and R6. The elementary file F4 is equated to raw file U4, whose associated program is P4.

From the user's viewpoint, he need only be aware of the existence of U1, U2, U3, F1, F2 and F4. The structures below composite files could be opaque to him.

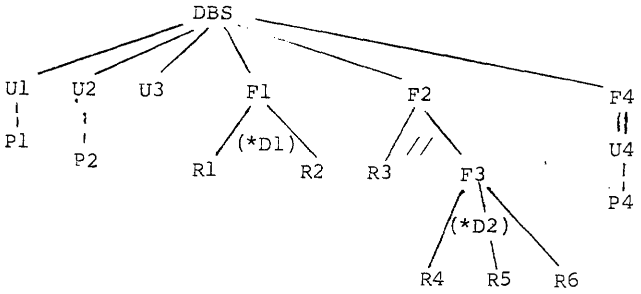

Figure 6—A database skeleton

He also may not know that F4 is equated to U4, and the relational table is in reality implemented as an inverted file.

Every file in the database skeleton also has an associated logical expression called the file *characteristics*, which characterizes the contents of this file. For composite files and elementary files, every record in a file must satisfy the characteristics logical expression. For raw files, the characteristics clause can be used to register typical samples, or prototype records, of a raw file.

A more detailed discussion of the database skeleton, together with its formal model and some theoretical results, can be found in Reference 9. Intuitively, the database skeleton serves the function of a structured file directory, similar to UNIX's tree directory. However, it is also a model of the database, with information on file size, file contents, and database operation statistics. Such information could be used (a) to optimize the performance of database operations, and (b) to dynamically restructure the database to improve system performance. These topics are also treated in Reference 9.

To illustrate how the database skeleton can be used for efficient searching, consider the case of a composite file F which is the vertical concatenation of R1 with the characteristics $(D1 \leq 200)$, and R2 with the characteristics $(D1 > 200)$. If it is intended to find all records in file F with $D1 \geq 300$, then the constituent file R1 need not be searched, because no record in R1 satisfies the search condition. This is discovered when the expression $(D \leq 200) \wedge (D1 > 300)$ is reduced to a logical zero. Therefore, a structurally organized database skeleton could help reduce database processing time.

DATABASE MANIPULATION LANGUAGE

The database manipulation language is based upon Codd's Relational Algebra.[3] An algebraic language is chosen for two reasons. First of all, an algebraic language is flexible and can easily be extended. The language is easily embedded in a host language, in our case the C language, so that the powerful instruction set of the host language can be used to write application programs or to design flexible user interfaces. In fact, the database manipulation language is considered to be a low-level language for internal use. The end user will communicate with the database system via the user interface described later.

The second reason for choosing an algebraic language is that it permits easy definition of structurally composed files. Although relational tables are useful as a unifying viewpoint for the end user, in implementing a realistic database system on a small computer, performance considerations cannot be overlooked. When a database grows larger and larger, the efficient storage and retrieval of possibly very large files becomes the primary concern of the system designer. In such cases, it is natural to consider breaking up or decomposing a large file into smaller pieces. The algebraic database manipulation language can be used to define structurally composed files and to dynamically restructure the files, so that storage requirements and processing time can be reduced.

The basic commands** of the database manipulation language are summarized in the Appendix. Several examples will be given in this section. The vertical concatenation of files, as illustrated in Figure 1, can be defined as follows.

```
DEFINE CFILE F(D1,D2,D3,D4,D5)
    STRUCTURE (//)
DEFINE EFILE R1(D1,D2,D3,D4,D5)
DEFINE EFILE R2(D1,D2,D3,D4,D5)
INCLUDE (R1,R2) IN CFILE F
```

Similarly, the horizontal concatenation of files, as illustrated in Figure 5, can be defined as follows.

```
DEFINE CFILE F(D1,D2,D3,D4,D5)
    STRUCTURE (*D1)
DEFINE EFILE R1(D1,D2,D3)
DEFINE EFILE R2(D1,D4,D5)
INCLUDE (R1,R2) IN CFILE F
```

In the definition of elementary or composite files, a *characteristics* clause can be included to describe concisely the contents of this file. Access and update can also be controlled by other clauses, as illustrated in the following example.

```
DEFINE EFILE R1(D1,D2,D3)
    CHARACTERISTICS (D1≤200)
    RETRIEVAL (D4='X')
    DELETION (USERID='SMITH')
    MODIFICATION (USERID='SMITH')
```

The above example provides the following information: name of elementary file is R1, with descriptors D1, D2, and D3; every record in R1 has D1 less than or equal to 200; all records with D3 equal to 'X' can be retrieved by any user; only user allowed to delete and/or modify records is 'SMITH'. (USERID is a global keyword. Other such keywords are PASSWORD, GROUPID, CLINICID, etc.)

A composite file can be dynamically restructured, as illustrated in the following example.

```
DEFINE CFILE F(D1,D2,D3)
    STRUCTURE (+)
DEFINE EFILE R1(D1,D2,D3)
DEFINE EFILE R2(D1,D2)
INCLUDE (R1,R2) IN CFILE F
.....
DELETE R2
.....
DEFINE EFILE R3(D1,D2)
DEFINE RFILE U3(P3) EQUAL TO EFILE R3
INCLUDE (R3) IN CFILE F
. . . . .
```

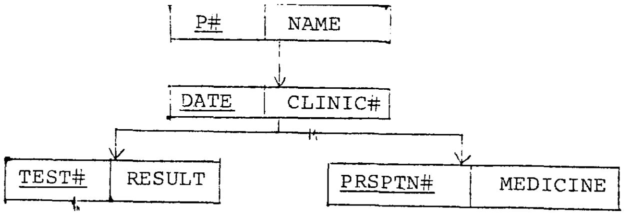

Figure 7—Hierarchical patient record structure

In the above example, F originally is the union of R1 and R2. Later on, R2 is removed from F. A *virtual* elementary file R3 which is equated to a raw file U3, is added to F. Thus, F is the union of R1 and R3 (which is really U3). U3 might have a file structure more efficient for certain retrieval operations, so that database operations performed on F can be processed more efficiently.

Hierarchical record structures, such as those used in IMS,[10] occur quite frequently in practice. Hierarchical structures can easily be represented using composite files and the horizontal concatenation rule, as illustrated in the following example. The hierarchical patient record structure is shown in Figure 7.

In Figure 7, the underlined fields are the key fields. This hierarchical patient record can be defined in our database as in Table II.

Suppose a composite file Fi has descriptor set Si and concatenated key Ki for horizontal concatenation. Suppose its constituent composite file Fj has descriptor set Sj and concatenated key Kj for horizontal concatenation. Then the following relation must hold,

$$Kj \subset Ki \subset Sj \subset Si$$

As before, a hierarchically structured composite file can also be dynamically restructured.

It can be seen that the sub-partitions of a composite file (or conceptually, the sub-regions of a two-dimensional relational table) can be assigned different protection conditions. Therefore, if part of the patient record is confidential and should never be made public, that portion could be separated out as a constituent file and given the most severe protection condition. This confidential file can also be stored in a separate

TABLE II—Defining a Hierarchical Patient Record

```
DEFINE CFILE F(P#,NAME,DATE,CLINIC#,TEST#,
   RESULT,PRSPTN#,MEDICINE) STRUCTURE (*P#)
DEFINE EFILE R1(P#,NAME)
DEFINE  CFILE  G(P#,DATE,CLINIC#,TEST#,RESULT,
   PRSPTN#,MEDICINE) STRUCTURE (*P#,DATE)
INCLUDE (R1,G) IN CFILE F
DEFINE EFILE R2(P#,DATE,CLINIC#)
DEFINE EFILE R3(P#,DATE,TEST#,RESULT)
DEFINE EFILE R4(P#,DATE,PRSPTN#,MEDICINE)
INCLUDE (R2,R3,R4) IN CFILE G
```

storage volume with tight security control. Thus, the above described structured database protection scheme can be very useful to the database manager in a clinical network environment.

USER INTERFACE

The user interface is frame-oriented, with emphasis on tabular presentation of structured information to the end user. This approach is based upon the frame-oriented approach of the PLATO system.[5] The CVG-II touch panel plasma display terminal is an ideal vehicle for designing such frame-oriented user interface.

There are three modes provided by the user interface. As the user starts the interactive session, he is presented with the first frame, which displays the three modes: the *data entry mode*, the *database manipulation mode*, and the *table manipulation mode*. In addition to the three basic modes, in every frame there is a *help* button. If the user touches the help button, self-explanatory information concerning the user interface itself, the database manipulation language, or the database system will be provided. There is also a *dbs* button. If the user touches the *dbs* button, he can browse through the database skeleton, which can be regarded as an enhanced database directory. Other buttons enable the user to *back up* to the previous frame, *exit* to the starting frame, or *move on* to the next frame.

In the *data entry mode*, the user first selects a file name. The user interface will prompt the user to enter a record, and then send this record to the database system to append to that file. For each record, fields will be checked against the correct format, and default values will be inserted in the unspecified fields. If a descriptor has only a limited number of possible values, such as M or F for the SEX descriptor, these values will be displayed on the screen to allow the user to make a selection.

In the *database manipulation mode*, the user can enter a retrieval/update command by selecting the appropriate files, descriptors, conditions, and operations, which are provided by the user interface. The user interface will translate user's specification into low-level commands of the database manipulation language.

For example, suppose the patient record is hierarchically structured, as shown in Figure 7. The patient file F is a composite file, composed from four elementary files, as illustrated in Table II. The user may wish to find the names of patients who visited Clinic #12. Using the user interface, he makes the following selections:

```
FILENAME: F
DESCRIPTORS TO BE RETRIEVED: NAME
CONDITIONS: *CLINIC# == '12'*
```

The user interface will translate the above specifications into the following commands, with the aid of the database skeleton:

```
T1=R2( *CLINIC# == '12'* )
T2=T1(P#,DATE,CLINIC#) (*P#)
    R1(P#,NAME)
T3=T2(NAME)
PRINT T3
DELETE T1,T2,T3
```

It is obvious that the user interface could attempt to optimize the translated commands by using such information as the size of the constituent files, approximate processing times for various operations, and the structure of the files. These problems are considered in Reference 9.

In the *table manipulation mode*, the user first selects a relational table, such as the patient file F. He can then browse through this big table. He can declare certain descriptors to be *stationary*, such as P#, whose column will always remain on the screen. He can declare certain descriptors to be *movable*, whose columns will be moved in and out the screen. He can also *drop* unwanted descriptors. There are touch buttons allowing him to *scroll left, scroll right, scroll up,* and *scroll down,* positioning the viewing window anywhere in the big table. There is also a *single record* option, allowing the user to view the file in a record-by-record fashion.

In the table manipulation mode, the user can only make projections and restrictions. Other more time consuming database manipulations will not be made available to him. We believe that projections and restrictions are by far the most useful relational algebraic operations. Other relational algebraic operations are too expensive to be provided in the table manipulation mode.

After having selected a desired sub-table, the user can store it as a temporary raw file using the *store* button. Special application programs can then be invoked to *plot* diagrams, compile *histograms,* and perform *data reduction* operations. (The italicized words are touch buttons defined as fixed areas on the touch panel.)

IMPLEMENTATION STATUS

In the preceding sections, the design of a database system in the context of a clinical network has been described in some detail. Currently, a prototype database system has been implemented. The software was developed in the UNIX environment, using the C language. The prototype database system consists of the following:

1. *User interface*—It supports the three modes described above, with the table manipulation programs still under development.
2. *RAIN*—A Relational Algebraic INterpreter was

implemented which accepts and executes commands in the database manipulation language, also called RAIN.

3. *Data compression programs*—Several data compression programs are available to reduce input data into compressed internal format, and to perform corresponding inverse transformation. As far as the end user is concerned, he only sees data in the user-specified external format.
4. *VVL data reduction program*—A data reduction program based upon VVL reduction techniques has been written, which can be invoked to reduce a given relational table into a disjunction of VVL logical expressions. These logical expressions can be evaluated by the user, and used as the characteristic expression describing the contents of a relational table.

The current implementation, when completed, will be used as an experimental tool for trial usage. The above described database system is a first step toward the design of a database system which can support mundane applications as well as certain more esoteric research applications. The system will undoubtedly undergo major modifications and evolution. However, areas for the application of optimization techniques have been identified and are under investigation. Such database systems which are implemented on small computers and still support advanced research applications could find wide range applications involving sophisticated decision making. The clinical network environment provides an interesting test bed for the design of such systems.

APPENDIX—DATABASE MANIPULATION LANGUAGE

A. *File definition and file input output*

A1. DEFINE EFILE R (P1)
(D1(9(2),n1),D2(9(3),n2),D3(X(5),n3))

An elementary file R is defined, and its definition is stored in the database skeleton. The file R is still empty. P1 is name of data compression/conversion program to convert data from external format into a condensed internal format, and vice versa. D1, D2, D3 are descriptors. Their external formats are specified by 9(2), 9(3), and X(5). The integers n1, n2 and n3 refer to conversion rules in P1. If there is no data compression (the external format is the same as the internal format), then P1, n1, n2, and n3 may be omitted.

A2. DEFINE CFILE F(P2)
(D1(9(2),n1),D2(9(3),n2),D3(X(5),n3))
STRUCTURE (//)
CHARACTERISTICS (D1≤200)
RETRIEVAL (D4='X')
DELETION (USERID='SMITH')
MODIFICATION (USERID='SMITH')

A composite file F is defined. Its definition, structure, characteristics and other protection conditions are stored in the database skeleton. The file F is still empty.

A3. INCLUDE (R1, R2, R3) IN CFILE F

The files R1, R2, and R3, which can be either elementary files or composite fiiles, are included as constituent files of the composite file F. The structural links are stored in the database skeleton.

A4. DEFINE RFILE U(P3) EQUAL TO EFILE R

A raw file is defined, and its definition is stored in the directory. The raw file U can be associated with an application program P3, which is a UNIX file. If the clause "EQUAL to R" is added, then the raw file U is equated to a relational table R. All database operations on R will be relegated to P3.

A5. EFILE R

(D1='1',D2='3',D3='4',D4='A')
(D1='3',D2='0',D3='0',D4='B')
&

When the elementary file R is empty, it is initialized by directly specifying its contents. If a certain descriptor is omitted in the specification, its value is undefined. The database skeleton is modified by entering the record number of R and setting a pointer to the first location of the file. When the elementary file R is not empty, the new records are appended to the end of the existing file.

A6. READ $\begin{bmatrix} \text{E} \\ \text{C} \\ \text{N} \end{bmatrix}$ R FROM U1

The elementary file R is initialized by reading in the records from a raw file U1. The database skeleton is modified by entering the record number of R and setting a pointer to the first location of the file R. The conversion code E indicates that the raw file U1 contains data in external format (as specified in the DEFINE statement), C indicates that U1 contains data already in condensed internal format, and N indicates conversion of binary integers. If the clause "FROM U1" is omitted, standard input is assumed.

A7. WRITE $\begin{bmatrix} \text{E} \\ \text{C} \\ \text{N} \end{bmatrix}$ R TO U1

The file R is written to a raw file U1, according to conversion specifications. If the clause "TO U1" is omitted, the standard output is assumed.

B. *Maintenance operations*

B1. ERASE R
The file is deleted from the database skeleton. If a composite file is deleted, all its constituent files are also deleted.

B2. RENAME R1 R2
The name of R1 is changed to R2, and the database skeleton is updated.

B3. DISPLAY F
The format, structure, characteristics, protection conditions and constituent files of F are printed via standard output. If the command is "DISPLAY ALL", the contents of the database skeleton are printed.

B4. PRINT F
File F is printed via standard output, using external format.

C. *Basic data operations*

C1. INSERT (D1='2',D3='0') INTO R1
A record with D1 equal to 2 and D3 equal to 0 is inserted into file R1, which must be either a composite file or an elementary file.

C2. DELETE (<condition>) FROM R1
All records in R1 satisfying given <condition>‡ are deleted.

C3. MODIFY (<condition>) OF R1 TO (D1='2',D3='0')
All records in R1 satisfying given <condition> are modified by changing the value of D1 to '2', and the value of D3 to '0'. Other descriptor values are unchanged.

C4. RETRIEVE (<condition>) of R1 (D1,D2) INTO R2
Records in R1 satisfying the given ⟨condition⟩ are retrieved into a file R2. R2 will have the descriptor set {D1,D2}, and other descriptors of R1 are discarded. If R2 is an existing file, it is redefined.

D. *Relational algebraic operations*

D1. (PROJECTION) R1=R2(D1,D2)
A file R1 with descriptors D1, D2 is created, which is the projection of R2 on D1, D2. If R1 is an existing file, it is redefined.

D2. (RESTRICTION) R1=R2 (<condition>)
A file R1 having the same descriptor set as R2 is created, which is the restriction of R2, so that only records satisfying the given <condition> are in R1. If R1 is an existing file, it is redefined.

D3. (JOIN) R1=R2(D1,D2) (*D2) R3(D2, D3)
R1 is the equijoin of R2(D1,D2) and R3(D2, D3) on key D2. R1 has descriptor set {D1, D2, D3}. If R1 is an existing file, it is redefined.

D4. (DIVISION) R1=R2(D1,D2) (/D2) R3 (D2)
R1 is the division of R2(D1,D2) by R3(D2) on D2. R1 has descriptor set {D1}. If R1 is an existing file, it is redefined.

D5. (VERTICAL CONCATENATION) R1=R2 (D1,D2)//R3(D1,D2)
R1 is the vertical concatenation of R2 and R3. R1 has same descriptor set as R2 or R3. If R1 is an existing file, it is redefined.

D6. (DIFFERENCE) R1=R2(D1,D2)−R3,(D1,D2)

R1 is the set-theoretic difference of R2 and R3. R1 has same descriptor set as R2 or R3. If R1 is an existing file, it is redefined.

D7. (PRODUCT) R1=R2(D1,D2) ** R3(D3,D4)

R1 is the Cartesian product of R2 and R3. R1 has descriptor set {D1,D2,D3,D4}. If R2 and R3 contain same descriptor Di, R1 will contain Di and $Di. If R1 is an existing file, it is redefined.

D8. (INTERSECTION) R1=R2(D1,D2) * R3 (D1,D2)

R1 is the set-theoretic intersection of R2 and R3. R1 has same descriptor set as R2 or R3. If R1 is an existing file, it is redefined.

D9. (UNION) R1=R2(D1,D2)+R3(D1,D3)

R1 is the set-theoretic union of R2 and R3. The descriptor set of R1 is union of that of R2 and R3, provided that R2 and R3 have common concatenated key. If R1 is an existing file, it is redefined.

E. *Miscellaneous*

E1. END $\begin{bmatrix}\text{SAVE}\\ \text{NOSAVE}\end{bmatrix}$

Notes

* We will use "relational table" or "table" to refer to the physical realization of a mathematical relation.

** Any command in the database manipulation language can be split into several lines, provided that a back-slash (\) is entered immediately preceding the new-line or return key.

‡ A condition is a Boolean expression of terms, where each term is either of the form <descriptor> <rel-op><literal>, or of the form <descriptor> <rel-op><descriptor>. <rel-op> is any one of the relational operators: ==(equal), != (not equal), > (greater than), >= (greater or equal), < (less than), <= (less or equal). A logical "and" is written as &&, and a logical "or" is written as ||. The logical expression is surrounded by two asterisks.

Correct problem statements in biomedical data processing

by N. I. MOISEEVA, M. YU. SIMONOV and V. M. SYSUEV
Academy of the Medical Sciences of the USSR
Leningrad, USSR

ABSTRACT

The correct formulation of any task appears to be not only the first step in its solution but sometimes the solution itself. Biomedical data processing is unlike other problems encountered by biologists and they often use mathematical methods without taking into consideration both the possibilities and limitations of the given methodology and the properties of the data to be processed. As a result the approach to the solution of the problem is often inadequate.[1]

Moreover, biologists encounter difficulties with the choice of a method for data conversion into the form suitable for mathematical processing. Often this leads to the incomplete utilization of the power of a given mathematical method. Sometimes only the correct data representation is sufficient to draw final conclusions. For example, data given in the form of an interval distribution histogram or mean frequency function allow the investigator to obtain information on time-dependent features of the process.

Science "creates and supports conditions whereby functional foundations become the field of controversy, resulting in competitive but different ways of doing the same thing. In other words the number of alternatives constantly increases due to science."[2]

In fact the problem of choice always faces the investigator not only in relation to the optimal method of data processing, but also in relation to optimally configuring electronic devices to be used in the implementation of these methods.

The correctly formulated requirements for biomedical data processing could be and should be used as a basis for this choice. Thus there arises the special problem of stating correctly the processing task itself. From our point of view the correct approach to its solution must take into account all a priori information. We must systematically look at the final aims of our research (in the sense that it is a biological data processing task) and at existing methods of analysis, their scope and limitations.

PECULIARITIES IN THE STATEMENT OF BIOMEDICAL TASKS

The complications arising in the study of biological objects derive above all from the fact that life itself, from the point of view of physics, "is too intricate and does not lend itself to mathematical interpretation."[3] Living organisms possess a large number of possible stable states; every concrete subject during its whole life uses only some of them, and different subjects prefer different approaches (if it is possible to use this word in reference to processes in the vegetatic nervous system). Moreover, in the same organism even stable states are different as they depend, for example, on age and functional states. Thus the problem of selecting appropriate statistical tools in biology becomes quite intricate. In fact, even the idea of "normality" is not clearly defined in biology so far.[4]

Transmission of signals in living organisms is carried on both with the aid of discrete impulses (e.g., in the nervous system) and analog-type information, like the constant potential of membranes and tissue, humoral regulation of functions and so on. Under these conditions signals propagate in two ways—along a specific channel to a specific organ or group of cells and "in a general way," without any defined "address." The latter signals could act upon any part of the organism and could, in fact, be perceived either by any part of the organism (i.e., general nonspecific reactions like arousal) or by the tissues and organs specially prepared for the reception of this particular signal or group of signals. For example, the hormones of endocrinous glands excreted in blood are intended for specific "target-tissue."

The next complication arises from the fact that there are no really stable functions in a living organism, every one of them representing oscillation processes.

The relative stability of an organism is the result of the rhythmic activity of the regulating systems. Some of these rhythms are endogenous: That is, they originate in the organism itself. Others reflect external events like the change of day and night, seasons of the year, and other influences from the environment.

As a specific property of this oscillating system the irregularity of growth and decay of different parts should be mentioned. For example, the growth of bones and muscles in human beings practically ceases as we attain adulthood, but some internal organs and the cardio-vascular system continue their development during the whole life. Organisms develop and degrade in an irregular manner.

All this leads to the idea that biological analysis must take into account structural (synchronous) as well as temporal (diachronic, functional) aspects of living objects.

SUGGESTED CLASSIFICATION OF BIOMEDICAL DATA PROCESSING TASKS.

In the literature on this problem we were able to find only one attempt to systematize biomedical tasks. We are here not concerned with the classification based on the coefficient of utilization of computer memory.[5] Rather we refer to the paper by Dixon[6] in which the author discusses both the so-called "source of information" (in fact, dealing with the modelling of functions, selecting interconnections, estimating the state of health etc.) and the desired processes. The taxonomy is rather incidental and classification indicators are not selected.

We made an attempt to distinguish two groups of biomedical processing tasks after having selected as a basic indicator the relation to time: those tasks where some variables and their interconnections are analyzed without regard to time (synchronous analysis) and those tasks where the processes develop in time (diachronic analysis).

Within each of these groups the tasks are classified according to final aims (description and identification or classification) on one side and to the object of the investigation (elementary events, processes or interrelations) on the other side.

In Tables I and II the systematization of biomedical processing tasks is shown both for the synchronous and diachronic analysis.

It is well-known that all the curiosity as to events in our universe can be expressed with the help of only six questions: who (what); what kind of; where; when; how; why (what for). All entries in Table I are in response to questions about the kind of objects and the nature of their interactions; or to questions whether certain objects belong to certain classes. Entries in Table II address the questions "what kind of" and "when" (analysis of elementary events and their interactions within the time continuum), the questions "what kind of", "when" and "where" (analysis of processes and their interconnections), or the questions "what" and "when" (classification of phenomena and processes). The questions "how" and "why" are not within the scope of our analysis.

Definition of causes, aims and mechanisms is derived from the combination of analytical and synthetical processes in the human brain. Without the latter human component the results of analysis bring to life only the question "so what?".

SUGGESTED CLASSIFICATION OF BIOMEDICAL DATA ANALYSIS METHODS

Many books on mathematics for biologists exist, of course, but there are no specific methodologies (and, of course, branches of mathematics) specially tailored to deal with biomedical problems. Biologists in their investigations simply use more or less successfully "standard" mathematics. We were unable to find in the literature any guidelines for biologists to aid their understanding of the relations between different methods or giving advice on the use of various kinds of processing techniques.

Biologists and non-biologists are becoming aware of the need to systematize methods of analysis. Isolated attempts to create particular schemes of analysis have been made, as shown in Tables III and IV (from the

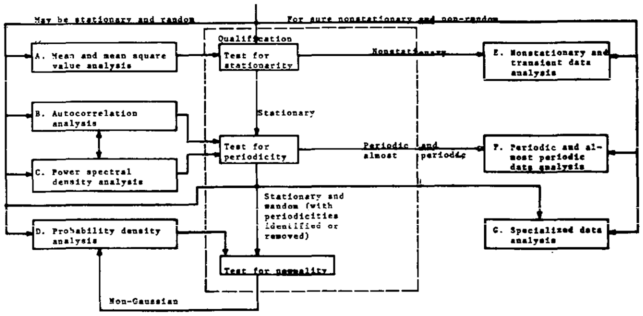
TABLE I—Levels of Structural (Synchronous) Analysis of Biological Objects

	Analysis of structural units within the system		Analysis of the interconnections between the structural units	
	Analysis of separate elements	Analysis of a complex of elements	Analysis of interconnections between the separate elements	Analysis of interconnections between the complexes of elements
Description and identification of objects	Description of indicators of separate elements and the analysis of their informativity	Description of characteristics of a complex of elements as a whole	Description of parameters, general features of the interconnections between the elements	Description of the parameters and general features of interconnections between the systems, classes, taxones, clusters, etc.
Classification of objects	Classification of elements, construction of classes, taxones, clusters, etc	Classification of the complexes of elements (systems, classes, etc.)	Classification of interconnections between the elements, separation of the systemic ones, extraction of groups of elements which form the system	Classification of interconnections between the systems, classes, and separation of the systemic interconnections of the second order

TABLE II—Levels of the Diachronic Analysis of Biological Objects

	Analysis of processes which are set of separate events and have initial and final points		Analysis of processes reflecting the continuous change of element state where the initial and final points can be selected only arbitrarily	
	Analysis of elementary events	Analysis of interconnections between the events	Analysis of processes by themselves	Analysis of interconnections between the processes
Description and Identification	Description of the events by means of time series and evaluation of their parameters	Discovery and description of type and the degree of interconnections between separate events	Description of processes by means of: a) representation in a form of a sequence of momentary states b) representation in the form of a sequence of events c) search of the repeated states and regular changes	Definition of the type and parameters of the interconnections between the processes
Classification	Separation of classes of elementary events	Selection of the causal-consequence interconnections, groups of events forming the phenomenon	Selection of the classes of processes -- relaxational, implulse, hormonic, etc.	Selection of the deterministic and stochastic causal-consequence interconnections

TABLE III—General Procedure for Analyzing Individual Sample Records



May be stationary and random
For sure nonstationary and non-random
Qualification
A. Mean and mean square value analysis
Test for stationarity
Nonstationary
E. Nonstationary and transient data analysis
B. Autocorrelation analysis
Stationary
Test for periodicity
Periodic and almost periodic
F. Periodic and almost periodic data analysis
C. Power spectral density analysis
Stationary and random (with periodicities identified or removed)
D. Probability density analysis
G. Specialized data analysis
Test for normality
Non-Gaussian

book by Bendat and Piersol) for the complex of realization and Table V for time series used for the rhythmometric investigations.

Since neither general schemes nor a classification of methods exist, we made an attempt to classify the methods of analysis on the basis of the above taxonomy of the data processing tasks.

As time and spatial coordinates are processed identically in calculating procedures we combined the methods of spatial structural analysis and methods of time series analysis.

The basis for our classification is the ability of a given method to answer one or more questions from the above mentioned set. Thus we systematized ways of processing and separated the methods which could be used as:

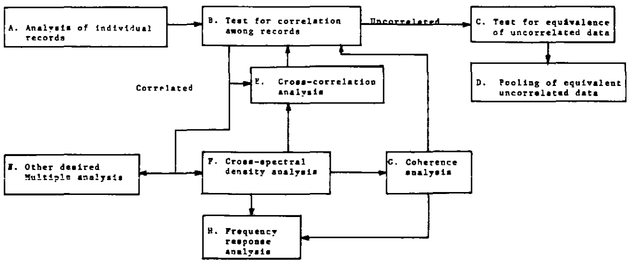
—methods of qualitative analysis (indicative methods) answering questions on the general features of the object, event or a process (from a mathematical point of view).

—quantitative methods of investigation for estimation of the numerical characteristics of processes or objects.

—methods for qualitative and/or numerical description of interconnections.

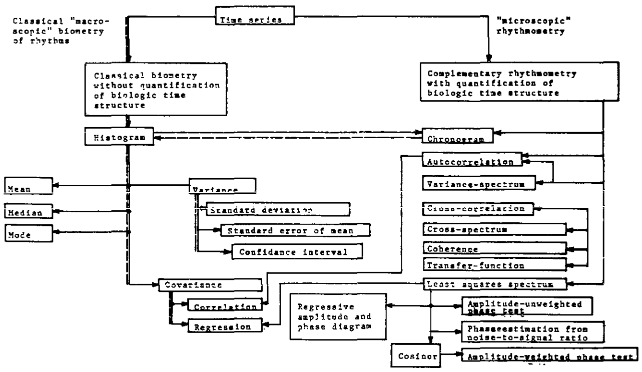
—methods for analysis of external (related to the environment) features of objects and processes.

TABLE IV—General Procedure for Analyzing a Collection of Sample Records



A. Analysis of individual records
B. Test for correlation among records
Uncorrelated
C. Test for equivalence of uncorrelated data
Correlated
E. Cross-correlation analysis
D. Pooling of equivalent uncorrelated data
I. Other desired Multiple analysis
F. Cross-spectral density analysis
G. Coherence analysis
H. Frequency response analysis

Table V—Analysis of Time Series in Rhythmometric Investigations



Time series
Classical "macroscopic" biometry of rhythms
"microscopic" rhythmometry
Classical biometry without quantification of biologic time structure
Complementary rhythmometry with quantification of biologic time structure
Histogram
Chronogram
Autocorrelation
Variance-spectrum
Mean
Median
Mode
Variance
Standard deviation
Standard error of mean
Confidence interval
Cross-correlation
Cross-spectrum
Coherence
Transfer-function
Covariance
Least squares spectrum
Correlation
Regression
Regressive amplitude and phase diagram
Amplitude-unweighted phase test
Phaseestimation from noise-to-signal ratio
Cosinor
Amplitude-weighted phase test

It turned out that this classification satisfactorily covered all biological methods. Still, it was necessary to make an additional subdivision within every class of methods depending on the level of analysis and to select accordingly: (1) the methods for detection of signals on a noisy background (D); (2) methods of phenomenological description (P); (3) analytical methods (A); and (4) methods of systemic analysis (S).

As an indicative method of qualitative analysis answering the question "what kind of", that is, to provide information on the general properties of an object or process, the following methods can be considered:

The methods of detection of signal in the presence of noise or separation of an object

As a result of applying these methods the following can be discovered.

—pure noise

—a signal or a complex of signals

The signal can be separated by the following means:

(1) Filtering—the detection of a signal with known parameters or elimination of noise with known frequency spectrum.

(2) Different ways of smoothing, like least squares method and special type filtering.

(3) Accumulation of signal (synchronous detection, correlation methods).

(4) Identification of signal presence by applying test stimuli.

Methods for testing of stationarity of the processes or, in general, testing for homogeneity within a group of objects

This method implies the reproducibility of characteristics of the process or object under given conditions and in some cases the ergodicity—the stationarity both in time and over the ensemble of realizations.

The following processes can be identified by comparing sequential fragments of the process or by sequentially measuring parameters of an object and also by comparing sequential fragments and separate realizations within the ensemble of realizations:

—nonstationary
—quasistationary
—stationary
—ergodic

Stationarity can be tested as follows:

(1) Calculation of the variance of the parameters as a measure of stationarity.
(2) Comparison of sequential fragments of the processes or sequentially measured parameters of an object, with the aid of statistical criteria and an analysis of the matrix of criterion values.
(3) Calculation of sequential or general correlation coefficients and their comparison in order to detect any dependence on the point of sampling.
(4) Plotting of the sequential spectra (Walsh, Fourier or other basis) to detect any dependence on the point of sampling.
(5) Calculation of the transition probability matrix and estimation of its numerical parameters.
(6) Calculation of reproducibility matrices—the matrices of a criterion value for the sequential fragments of the process.
(7) Selection of the optimal value of intervals of stationarity tested by different methods (primarily, variance analysis).

By applying these methods we learn whether we can use numerical parameters to describe the whole realization (as for stationary or ergodic processes) or only intervals of stationarity (in case of a quasistationary process).

In the absence of stationary fragments we must find other informative parameters, for instance the degree of stationarity.

Methods for analyzing the periodicity of the processes

As a result of their application we can determine whether the signal is:

—periodic with constant period
—quasiperiodic (with changing period)
—aperiodic

The detection of periodicity is possible with the help of the following methods:

(1) Methods of approximation.
(2) Correlation methods.
(3) Spectral methods.
(4) Method of periodograms.
(5) Analysis of extremal values.
(6) Cosinor method.
(7) The calculation of a matrix of reproducibility—the matrix of criterion values for sequential fragments of the process.

Methods for investigating the internal coherence of the process

As a result of this investigation the following can be obtained:

—Markov processes of the 1st, 2nd and higher orders.
—Coherent processes.

The test of coherence requires:

(1) Calculation of the transitional probability matrix and the estimation of the order of the Markov process.
(2) Estimation of the interval of coherence using the correlation function.
(3) Calculation of matrices of reproducibility.

In case a high degree of coherence is discovered filtering of data can be used to reduce their volume without the loss of information.

A high degree of coherence of a process also indicates high inertia of the studied object; that is of practical importance for the study of transient processes.

METHODS FOR EVALUATING NUMERICAL PARAMETERS OF OBJECTS, EVENTS AND PROCESSES

To answer the question "what kind of" in the narrow sense of the word are the following:

Different ways of estimating signal-to-noise ratio:

(1) Smoothing of numerical Data Sequences.
(2) Optimal linear and nonlinear filtering.
(3) Elimination of noise with known frequency parameters.

Methods for evaluating integral parameters of a process

They are different for periodic and aperiodic processes. For periodic processes the following methods are applicable:

(1) Analysis of the probability density distribution:
    (a) calculation of statistical moments (mean, variance, coefficients of asymmetry and

excess, and higher moments) and their comparison by means of parametric criteria.

(b) Calculation of distribution functions and their comparison by means of nonparametric criteria (rank correlation, Spearman, Mann-Witney, Kendall, Kolmogorov-Smirnov criteria and others).

(2) Calculation of reproducibility matrices.

(3) Evaluation of time series of values of the periods (spectrum of periods) by means of calculation of intervals between successive extremal values; crossing the zero line; and analysis of statistical properties of these time series.

(4) Calculation of the spectral density function using different bases.

(5) Investigation of the phase structure of processes analyzing the dependence between the accumulated phase shift and time.

(6) The "Cosinor" method.

(7) Calculation of the transfer function by means of operators method.

(8) Method of test stimuli.

(9) Plotting of the amplitude-frequency characteristics. For aperiodic processes we may apply:

(10) Analysis of amplitude distribution and calculation of moments.

(11) Analysis of power spectrum.

(12) Investigation of overshoots and their statistical properties.

(13) Calculation of the sequence of intervals between events.

(14) Investigation of patterns and their reproducibility.

Methods for detection of coherence of the process

Calculation of the transitional probability matrix and its numerical parameters (trace, determinant etc.).

ANALYSIS OF THE INTERCONNECTIONS BETWEEN ELEMENTS, PHENOMENA AND PROCESSES

As a separate parameter to be investigated (in response to the question "what kind of connection is this?"), we primarily selected the following features of interconnections:

a. Type of interconnection—linear or nonlinear. Within the nonlinear group we study those which can be represented by polynomials of higher order, harmonic functions, exponential, hyperbolic interconnections and so on.

b. Degree of linearity.

c. Direction of interconnection (vector of interconnection).

Tensor of interconnections can be used accordingly to describe completely the interconnections within the group of elements.

The first routine stage in the analysis of interconnection is the calculation of the correlation ratio indicating the presence or absence of any connection. If this parameter exceeds certain thresholds special tests concerning linearity of interconnection can be carried out. For that purpose the correlation coefficient reflecting the strength of linear (or approximately linear) interconnections is calculated.

The direction of interconnection can be obtained either by using the time shift of the principal maximum of the crosscorrelation function or by calculating the regression lines of each process relating to the other ones.

Nonlinear interconnections can be successfully approximated with linear functions within short intervals, principally for monotonic increasing or decreasing functions. In case such an approximation is not accurate enough and for periodical interconnections, we choose empirically approximating functions from routine methods (least squares, maximum likelihood, minimization of objective functions, nonlinear programming). The direction of interconnection can be specified by means of regression or factor analysis.

To investigate the interconnections on different structural levels and between the objects of different complexity we must take the following steps:

(1) In case the parameters of a single object are to be analyzed:

(a) Calculation of value and sign of correlation ratio.

(b) Calculation of correlation coefficient to estimate the degree of linearity of the interconnection.

(2) To analyze the interconnections between elements and elementary events, calculate vector of interconnections.

(3) When analyzing the interconnections within the system calculate tensor of interconnections.

METHODS OF INVESTIGATING THE EXTERNAL PROPERTIES OF PROCESSES AND OBJECTS

These are relating to the environment and answering the questions "what kind of," "when," "where" and "what".

Methods of calculating the unobservable

Observation relates here to the field of metrology space-time coordinates. Such calculations are carried out with the aid of:

(1) Crosscorrelation analysis.

(2) Description of objects' motion in space-time coordinates by means of differential equations.
(3) Calculation of dynamic transfer functions (related to relaxation processes) by routine methods.
(4) Evaluation of accumulated phase shift as a function of time.

Methods of sorting and distributing objects according to certain indicators

(1) Calculation of statistical moments.
(2) Calculation of distribution function.
(3) Calculation of the multidimensional joint probability density functions and estimation of their parameters.

Methods of analysis of motion and functioning of an object in a space-time coordinate system

(1) Calculation of matrices of reproducibility.
(2) Construction and solution of pertinent differential equations.

Methods of identifying and classifying objects, events and processes

As a possible way to answer the question "what" we determine whether one observed phenomenon is similar to another. The problem is to identify an object as belonging to a certain class—it is pattern recognition. In such cases the following methods could be applied:

(1) Search for the complete or partial precedent.
(2) Diagnostic procedures in multidimensional space on the basis of Bayesian or other criteria.
(3) Calculation of discriminant functions of the first and higher orders.

Cases where there is no a priori information on classes

Their images can be constructed using:

(1) Factor analysis—principal components in particular.
(2) Cluster-analysis.
(3) Adaptive classification (with learning).

The enumeration of these methods shows that any one method can belong to more than one group (like correlation analysis which can be applied to signal detection, to testing the periodicity and for estimating the numerical parameters of the process). From our point of view, this does not make the suggested classification less convenient because of the different interpretations of the results in each case.

The complete classification is given in Table VI where the arrows denote what questions can be answered by means of a particular method. Of course, not all the possible mathematical methods are exhibited but only those widely used in the solution of biomedical processing tasks according to the literature.

Not being mathematical specialists we have undoubtedly missed a few "tools" which may appear more or less important to others, but the open-ended structure of the classification scheme allows us to add anything necessary. There is also no doubt that from the pure mathematician's point of view this classification is rather eclectic. However, our aim was not mathematical harmony but the distribution of analytical tools over the "shelves" to make it convenient for the user to take the needed one from there according to his/her requirements.

FEASIBLE FORMULATION OF BIOMEDICAL PROCESSING TASKS

The difficulty of choosing an adequate method of analysis derives not only from the above mentioned large number of possible methods and the complexity of the problems themselves. This was only the tip of the iceberg. Complications arise when optimal time periods must be selected (also the correct digitizing interval) for a given method in order to find the desired parameters. However, it is impossible to discuss these problems here in detail.

The way to overcome these difficulties seems to be formalization of the approach to the statement of biomedical data processing tasks, thus guaranteeing the correct approach.

As a first step along this line we suggest the use of a standard form with the following items:

(1) Parameter (or parameters) to be investigated.
(2) Intervals of parameter values and the given precision of the measurement of each one.
(3) Duration of observations (adding criteria of choice if there are any).
(4) Digitizing interval (number of samples per observation).
(5) Object of analysis (elements, elementary events, processes, interconnections).
(6) The real aim of the analysis (to answer the questions "What kind of," "Where," "When," "What").
(7) The final aim of the analysis (biomedical problem).

These seven pieces of information are supplied by the research worker; the people who deal with the data processing tasks should add one more:

(8) Results of preliminary analysis of data by means of indicative methods (general information about the properties of the object or process).

Here the following are useful:

(a) signal-to-noise ratio.
(b) whether the process is stationary and the in-

terval of stationarity.

(c) statistical parameters, primarily the type of distribution.

(d) whether the process is periodical.

(e) results of Markov property test.

Analysis of data thus obtained in combination with the suggested classification schema will facilitate the choice or the optimal method of data processing. In case there are several possible methods one should remember the Okkam razor and choose the simplest one so as not to increase unnecessarily the number of essential descriptors.

In conclusion we would like to stress that the choice of data processing methods must be based upon their applicability to the data at hand. A bad choice will lead to the data having to be "reprepared" in a perhaps less useful format.

An adaptable, modular data-collection system suitable for scientific experimentation — Analog to digital transformation, short-term digital storage, formatted digital tape-recording, and computer entry of experimental data

by HAROLD H. SHLEVIN
University of Rochester School of Medicine
Rochester, New York

ABSTRACT *

This paper describes an adaptable, modular data acquisition system suitable for the collection of experimental data in a form readily adapted to subsequent digital computer entry and analysis. The system utilizes voltage-to-frequency conversion of an input analog signal over precisely regulated timing intervals. The digitized data is initially stored in shift-registers and later digitally formatted and digitally tape-recorded. The recorded data is read by a complimentary tape reading system and entered into a mini-computer for subsequent analysis and long-term storage. The digital formatting technique permits unambiguous definition and recovery of each data word as the tape is read.

Adaptations of this system necessary to accommodate variations in the length of each data-word and the number of words per message block are discussed.

Commercially available TTL integrated circuits and modular components are used in the design of this system.

INTRODUCTION

Scientific experiments often require a means of rapidly collecting and storing analog experimental data in a form readily adapted to later digital computer entry and analysis Although commercial systems are available, individual systems better suited for the particular experimental configuration can be constructed with relative ease and at significantly reduced cost by using readily available TTL and CMOS integrated-circuits.

The data collection system described in this paper evolved from a desire to carry out electrophysiological experiments aimed at further characterizing the membrane charge movement phenomenons in single, skeletal muscle cells (Schneider, M. F. and Chandler, W. K., 1973). A Digital Equipment Corporation PDP-8/E minicomputer was available for off-line analysis. Therefore, an interim means of storing the data for later computer entry was needed.

This paper describes an adaptable, modular data-collection system suitable for the collection of experimental data. The description is divided into four logical segments (Figure 1): (1) Data transformation using voltage-to-frequency conversion, and static shift-register storage of the digitized data, (2) Formatting of the stored, digital data using a Universal Asynchronous Receiver-Transmitter (U.A.R.T.), in preparation for tape-recording, (3) Digital tape-recording, and, (4) Reading and computer entry of the digitally tape-recorded data.

DATA TRANSFORMATION

The process of analog-to-digital conversion of the experimental data was simplified by using a voltage-to-

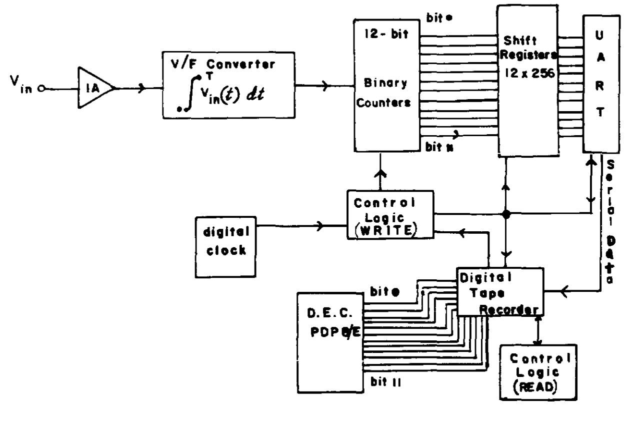

Figure 1—Block diagram of the data-collection system

frequency (V/F) converter module (Anadex Instruments, Inc. Model 1700-5044-00). The converter produces TTL/DTL compatible output frequencies of 0-1.0 MHz that are directly proportional to input D.C. voltage signals of 0-10 V.D.C. The linearity of the converter is better than 0.01 percent of full-scale, and its output responds virtually instantaneously to changes in input voltage. Experimental input D.C. voltages of ±100 mV. in amplitude are amplified to a level commensurate with that of the V/F converter by an instrumentation amplifier (Analog Devices, Inc. Model AD520J) with externally adjustable gains of 1, 20, 50, or 100, and adjustable reference levels.

Voltage-to-frequency converters require less complex wiring for data transmission than do conventional analog-to-digital converters; only a single line is needed for a serial pulse-train. A clock signal and a counter at the receiving end are used to encode the pulse train. The process results in an analog-to-digital conversion and time-integration of the input signal. This was particularly desirable for later data analysis (Figure 1).

The output pulses of the V/F converter were counted by three cascaded four-bit binary counters (SN 74193) for externally adjusted intervals of 0.1, 0.5, 1.0, 2.0, 5.0, or 10.0 milli-seconds. Timing pulses, which had been buffered to TTL levels, were generated by a gated, pulse train output channel of a digital stimulator (Digitimer Ltd., Hertfordshire, England, Model 4030). When the binary counters for the V/F converter output receive a timing signal, the following sequence of events occur (Figure 2): (1) The input to the counters from the V/F converter is disabled, (2) The twelve-bit binary number presently in the counters is transferred to a digital (12 X 256)—bit storage register (NS 5055), (3) The binary counters are cleared, (4) A Master-Event-Counter is advanced by one count, and (5) The input to the V/F counters is again enabled. These five steps occur within 3.8 micro-seconds. By repetition of this sequence, a total of 256 sequential data, points are sampled during any collection interval, (e.g. one oscilloscope sweep).

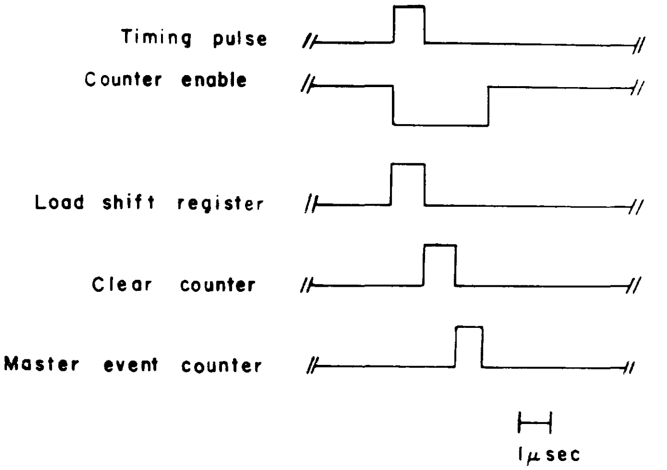

Figure 2—Voltage-to-frequency converter; Timing sequence

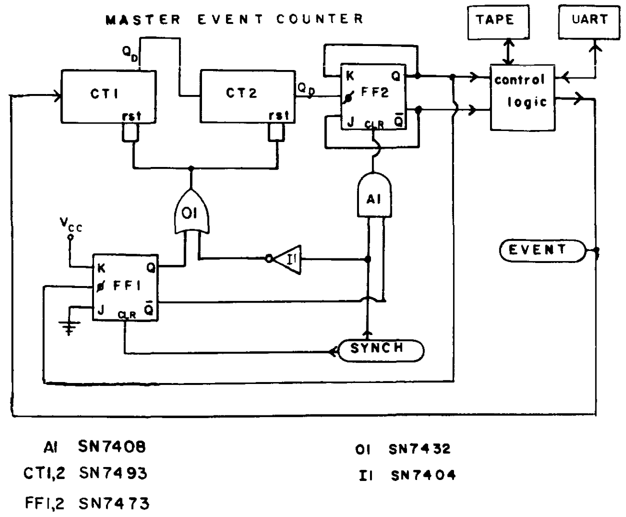

Figure 3—Master-event-counter; Circuit diagram arrows indicate direction of information flow
(A1=SN 7408; CT1, CT2=SN 7493; FF1, FF2=SN 7473; 01=SN 7432; and I1=SN 7404)

A Master-Event-Counter circuit serves to control two distinct sequences (Figures 1, 3, and 4): (1) The actual digital transformation of the analog data and the static storage of 256 digital data points, and (2) The digital formatting and then digital tape-recording of the previously collected 256, twelve-bit binary data words.

In conjunction with an initializing SYNCH pulse, CT1 and CT2 (cascaded four-bit binary counters SN 7493), and FF1 and FF2 (dual J-K flip flops with clear SN7473) are cleared. This sets $\overline{QFF2}$ to logic high and enables the Master-Event-Counter and the sequence of events necessary to digitally transform and store the experimental data signal, as previously described. After 256 data points have been sampled, QFF2 toggles to logic high enabling the sequence of events required to format the 256 twelve-bit binary data words, and to initialize and consummate the

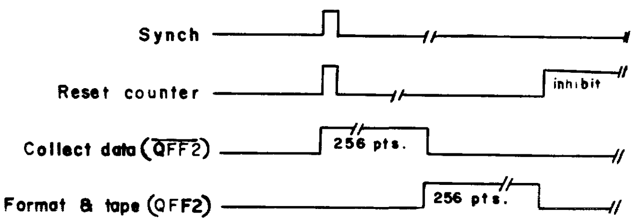

Figure 4—Master-event-counter; Timing sequence

taping process. After taping of all 256 data words has been completed, FF2 again toggles setting QFF1 to logic high. This blocks any further timing pulses and blocks all counters until another SYNCH pulse is received.

Although independent and variable clocks are used to collect the data and to format and tape the data, the control logic segment assures that only a single Master-Event-Counter pulse is generated for each twelve-bit binary data word collected and for each original twelve-bit data word transmitted by the U.A.R.T. to the tape-recorder.

Although the data-collection system is designed specifically for the digital transformation and taping of 256 twelve-bit binary data words, it is easily adapted to any multiple of 2^n points by simply changing the Master-Event-Counter, the length and/or width of the shift-register buffer, and the number of bits per data word as may be appropriate for the resolution desired.

FORMATTING OF THE STORED DATA WORDS

A Universal - Asynchronous - Receiver/Transmitter (U.A.R.T.) in half-duplex mode was used to ensure the competency of the data interface between the 256 word shift-register buffer and transmission to the digital tape-recorder The transmitter section of the U.A.R.T. (Texas Instrument Co. Model TMS 6011NC) accepts the parallel data from the shift-registers, converts it to serial form and generates a start, parity, and stop (1 to 2) bit(s) for each original twelve-bit binary data word. The data word length (5 to 8 bits long), the baud rate (0 to 200 KHz.), and the sign of a parity bit are externally selected. The formatting function and parity generation of the U.A.R.T. allow for unambiguous definition of each data word when reading the data tape and for the detection of dropped bits.

To transmit one twelve-bit word from the shift-registers to the tape-recorder, two ten-bit data words are sent by the U.A.R.T. Each word is formatted as shown in Figure 5. Each half (six bits) of the original twelve-bit data word is concatenated to an indicator bit. The indicator bit is used to indicate whether we have the front-half or the back-half of the original twelve-bit data word; this is rechecked when reading the tape.

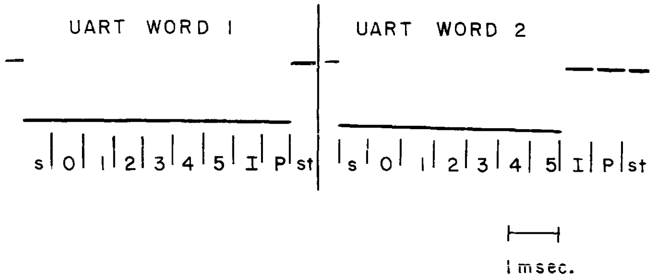

Figure 5(b)—Actual oscillographic record of formatted output from the U.A.R.T. sent to WRITE unit

The U.A.R.T. clock, derived from an internal oscillator, runs at a frequency of sixteen times the baud rate. Successive divisions of the U.A.R.T. clock rate by sixteen (for the baud rate), by ten (signalling each half-word), and then by two (denoting complete transmission of the two halves of the original twelve-bit data word), together with appropriate internal and external control logic allow for constant checking and control over the formatting and transmission processes. For each original twelve-bit data word, transmitted as two ten-bit, formatted U.A.R.T. words, the Master-Event-Counter is advanced by one count.

This configuration is easily adapted to any length data word by appropriate fragmentation of the data word into separate U.A.R.T. words, indicators bit(s), and appropriate division of the U.A.R.T. clock to form the clock pulse which serves as input to the Master-Event-Counter.

DIGITAL TAPE RECORDING

The core of the system is a MicroVox tape recording/reading unit (Micro Communications Corporation, Waltham, Massachusetts). There are two separate, hand-size units in this system: a WRITE unit and a READ unit. Each unit consists of a tape drive system, plus all the necessary data transfer and tape handling

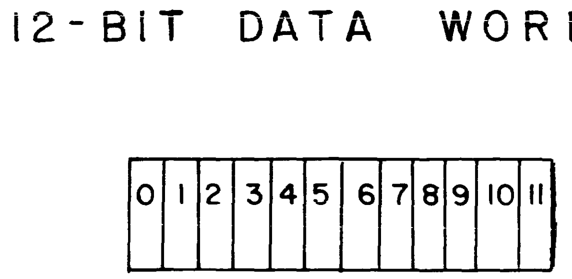

Figure 5—Formatting. (a)—Original twelve bit binary word from counters for V/F converter

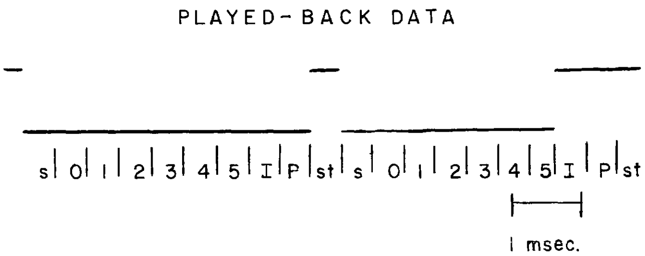

Figure 5(c)—Actual oscillographic record of DATA recovered from the READ unit, on expanded time base for comparison with Figure 5b logic. The available lines are: CLOCK_IN, CLOCK_OUT, DATA, READY, END_OF_TAPE/BEGINNING_OF_TAPE, ON, and FAST_FORWARD. The internal CMOS circuitry of the MicroVox units provides true TTL-compatible logic interfaces (after appropriate buffering) to and from the data-collection system.

The WRITE unit is functionally a phase-lock loop (P.L.L.) (Figure 6). The P.L.L. functions as an electronic servo consisting of a phase detector, a low pass filter, and a voltage-controlled oscillator (V.C.O.). The V.C.O. enables the P.L.L. to synchronize or "lock" on the incoming clock signal. The clock signal (CLKIN) serves to clock in each bit of the word. As the phase of the clock signal changes, indicating a change in incoming frequency, the output of the phase detector will change just enough to keep the V.C.O. frequency the same as the incoming frequency. This allows the baud rate to be varied both dynamically and statically over a wide range.

In external-clock mode, the MicroVox WRITE system's P.L.L. synchronizes with the leading edge of a user supplied clock-in (CLKIN) signal. This signal is derived from the successive division of the U.A.R.T. clock signal (÷ 16), described earlier. The WRITE system furnishes an externally available clock-out (CLKOUT) signal which is checked by the data-collection system to verify phase-locking quality. A modulator, internal to the WRITE system, then manufactures the waveforms of logic 1 and logic 0 which are written onto the tape in proper relation and synchrony with the formatted, serial data stream from the U.A.R.T. The MicroVox WRITE system can function over a range of 300 to 3200 bits/second.

This technique of pulse-coded modulation affords significant advantages over more conventional AM or FM recording methods: (1) A greater accuracy, (2) A significantly better signal-to-noise ratio (up to 90 db), (3) The capability for relatively long-distance transmission of the data without degradation since the digital signal can be regenerated with a very low probability of loss, and (4) The ability to computer process the information with virtually no modifications.

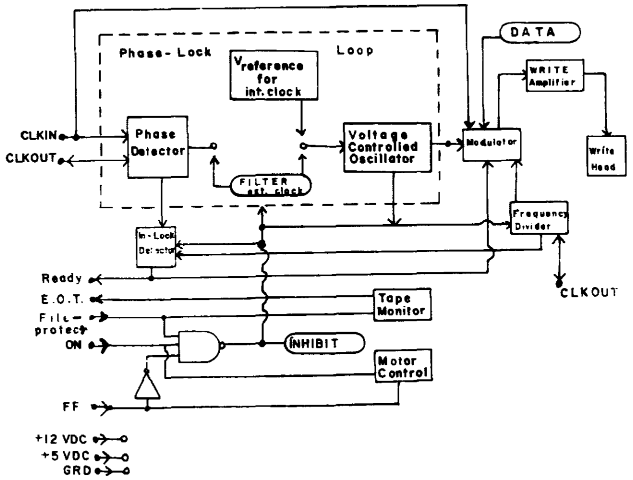

Figure 6—MicroVox WRITE unit: Functional block diagram reproduced with permission of Micro Communications Corporation

The tapes are continuous loop, one-track cartridges available in a variety of lengths. Since the tape is a loop, the physical end-of-tape (EOT) and beginning-of-tape (BOT) are the same. Provisions exist for detection of EOT/BOT as well as for file protecting each cartridge.

Transition of QFF2 of the Master-Event-Counter from logic low to logic high initializes the following sequence of events by the data-collection system leading to consummation of the WRITE function (Figures 6, 7): (1) Fast_Forward (FF) is set to logic 0 and ON to logic 1, thereby entering WRITE mode and accelerating the tape to speed. If initially stopped, the tape unit reaches speed within 60 milli-seconds. (2) The CLKIN signal derived from successive division of the U.A.R.T. clock is supplied. The MicroVox WRITE unit then furnishes an external READY (RDY) signal indicating that phase-lock and speed have been attained. This permits the external data-collection interface to transmit DATA to the recorder and allows the recorder to write the formatted DATA onto the tape. Had CLKIN not been supplied, the RDY signal would not be furnished and the data-collection interface would not permit the sending of DATA to the recorder. During such a state, the MicroVox WRITE unit would write bias onto the tape; this prevents mangling of message blocks and later allows the MicroVox READ system to start and stop between two consecutive message blocks. (3) Each data bit is clocked to the recorder by the CLKIN signal. There is a delay of approximately 1½ CLKIN cycles between the occurrence of a CLKIN pulse and the actual writing of that particular data bit onto the tape.

In this fashion all 256 original twelve-bit data words (or 5120 U.A.R.T. bits) are transmitted. Upon com-

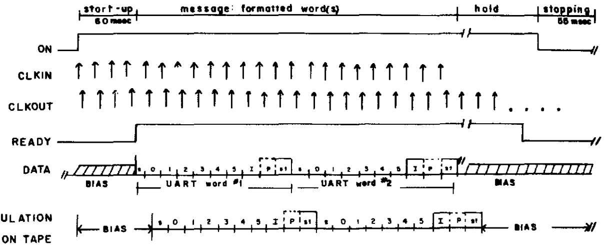

Figure 7—MicroVox WRITE system: Operating sequence A formatted U.A.R.T. word is shown: s=start bit, 0-5 denote data bits, I=indicator bit (0 or 1), P=parity (odd or even), and st=stop bit (1 shown)

pletion of transmission, QFF2 of the Master-Event-Counter flips to logic low and in conjunction with a U.A.R.T. done flag, the CLKIN signal is discontinued. After 1½ bit periods, the time needed to write the last bit, RDY drops to logic 0. (4) The data-collection interface then sets ON to logic 0 and the tape dynamically brakes to a standstill.

The external data-collection interface provides the option of slewing to the EOT/BOT in Fast_Forward or slow mode (with CLKIN discontinued, FF=1, ON=1). EOT/BOT is optically sensed by the MicroVox WRITE and READ systems from two foil-reflectors spaced 3″ apart and affixed to the tape.

During the writing of data, the occurrence of the first EOT applique causes the data-collection interface to finish writing only the current twelve-bit word (20 U.A.R.T. bits), and then the recorder is stopped. A new cartridge is inserted, and writing resumes under control of the Master-Event-Counter. However, in slew to EOT/BOT mode, the external interface stops the tape immediately after the second EOT applique in preparation for later reading or writing.

No modifications to either the data-collection interface controlling the MicroVox WRITE system (other than those already described) or to the tape unit itself are necessary to write any word-length, or number of words per data block.

DIGITAL TAPE READING AND COMPUTER ENTRY

The MicroVox READ system is specifically designed to read tapes produced by the MicroVox WRITE system. A high degree of cooperativity between the two units minimizes errors that could result from tape speed irregularities (e.g., wow and flutter), allows for writing and reading the same tape-wafer at widely different speeds, and results in simple adaptation of the tape units to a large number of external interfaces.

The instrumentation of the motor control functions (ON, FF, EOT/BOT) of the READ system are identical to those of the WRITE system; their functions are similarly controlled by the external data-collection interface. The bit density (b.p.i.) written on the tape, and the speed (i.p.s.) at which the tape is read determine the waveform presented to the READ head. Above a density of 800 b.p.i., the READ waveform is no longer usable. A dual-peak-detecting system, with a decent frequency response and insensitive to both amplitude and waveform, is used to allow for large variations in the amplitude, frequency, and shape of the waveform presented to the READ head.

To read a tape-wafer, the external data-collection interface is used to control the following sequence of events (Figure 8): (1) Fast Forward is set to logic 0 and ON to logic 1, thereby entering READ mode and accelerating the tape to speed. (2) The READY signal rises to logic 1 a full bit-interval before the first data bit is shifted to the external interface, allowing the maximum possible time in which to ready the external data interface. (3) A CLKOUT pulse is furnished by the READ unit approximately 5 μsecs. after each DATA bit is shifted. The process continues until modulation ceases, then (4) READY drops to logic low, and depending upon the states of the external interface and the computer program either the tape is stopped (ON to logic 0) or reading is continued (ON remains at logic 1).

Data collection system—computer interface

The use of the U.A.R.T. to format the data sent to the MicroVox WRITE system allows the data collection interface to unambiguously define the beginning, end, and origin (front-half or back-half of the original twelve-bit data word) of the words being read.

The start of each U.A.R.T.—word is defined as a transition of the READ system bit—output from logic high to logic low. This transition is detected by the external data-collection interface which is preset for the word-length, the parity (even or odd) and the number of stop bits (1 or 2) written.

Detection of a start-bit by the external interface enables the following sequence of events (Figure 8): (1) A word-length counter (SN 7490), parity generator (SN 74180), and a ten-bit series-to-parallel shift-register (SN 7496) are cleared. (2) Each bit of the ten-bit U.A.R.T.-word is clocked into the ten-bit series-to-parallel shift-register by the CLKOUT signal derived from the MicroVox READ unit. When a complete ten-bit U.A.R.T.-word has been shifted, (3) The word-length counter overflows, (4) Parity is checked and error flag(s) set as necessary, (5) Either the first-six or last-six bits of a twelve-bit parallel-in, parallel-out

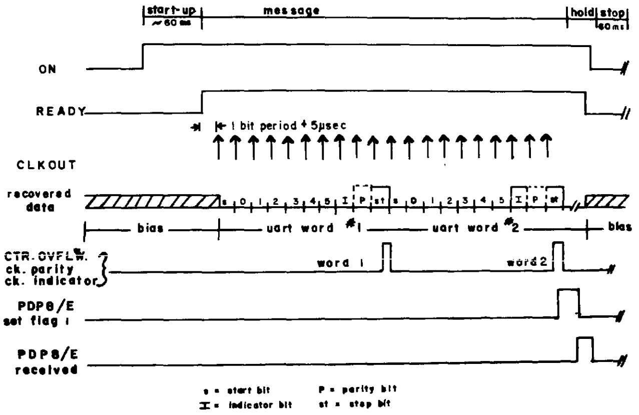

Figure 8—MicroVox READ system and DATA interface operation

A recovered DATA word is shown: s=start bit, 0-5 denote data bits, I=indicator bit (0 or 1), P=parity (odd or even), and st=stop bit (1 shown) buffer register (SN 74174) are loaded (with the data bits of the U.A.R.T. word) depending on whether the indicator-bit is a logic 1 or a logic 0, respectively. These five steps are repeated until the second U.A.R.T.-word has been received; then, (6) The data-collection interface flags the computer (D.E.C.—PDP-8/E) and a complete twelve-bit binary data word is read into core memory. (7) In response, the computer acknowledges receipt of the data word.

This process is continued until a total of 256 twelve-bit, binary data words (1 sweep) have been received and acknowledged by the computer. The controlling program then either stops the READ unit or continues the reading process as may be appropriate.

A Digital Equipment Corporation PDP-8/E mini-computer was used to control the read portion of the data collection system, and perform subsequent data analysis. During the READ cycle the data collection system communicates with the PDP-8/E through a D.E.C. M1709 omnibus interface module.

The computer was programmed in OS/8 Fortran IV. The actual control of the data-collection system is implemented by a RALF assembly language subroutine. The starting and stopping of the READ unit, the number of 256-word data blocks read, the handling of all error flags, and the transfer of the core resident data to Dectape for long term storage are all under program control. To maximize efficient use of storage, three twelve-bit binary data words are stored in both core and on Dectape in the space allocated for one Fortran floating point variable.

In subsequent analysis of such condensed data it is necessary to "float" each twelve-bit, binary data word into one Fortran floating-point variable. Each Fortran floating-point variable occupies 3 contiguous storage locations. This is accomplished by executing a call from the main FTN IV program to a specific RALF subroutine which floats a binary word. All program generated output destined for Dectape is recondensed before transfer.

The programs and interfaces are easily adapted to accommodate a variety of word-lengths, words per message block and other necessary control functions.

ACKNOWLEDGMENTS

It is a pleasure to thank Dr. Martin F. Schneider for his helpful advice and discussion concerning this system, as well as his continual encouragement.

I am grateful to my wife, Barbara for her continual encouragement and love, and for her help with the illustrations; and to Mrs. Lillian Peracchia for help with photography.

I thank Mr. John Young of the Department of Biomathematics for his helpful discussion and debugging aide; and also thank Irma Johnson, and John Hemmert of Micro Communications Corporation for much helpful advice.

This work has been supported by NIH/USPHS Training Grant #5-T01-GM00394 and in part by a research grant from the Muscular Dystrophy Associations of America to Dr. Martin F. Schneider.

The author gratefully acknowledges the support of Micro Communications Corporation for travel-expenses necessary to attend this conference.

Classification of personal information for privacy protection purposes*

by REIN TURN
The Rand Corporation
Santa Monica, California

ABSTRACT

Laws now in effect require protection of individual privacy in personal information record-keeping systems maintained by the federal government and by several states. These requirements will be extended to the private sphere in the future. It is necessary for their implementation in record-keeping systems to establish a standard sensitivity scale and classification system for personal information. This paper surveys several classification systems that have been discussed in the literature, examines the criteria for setting up such systems, proposes a new sensitivity scale and corresponding classification system, discusses the information integrity and security provisions that should be adequate for each classification level, and examines the problems that arise in assigning sensitivity and classification levels to personal information items, records, and record-keeping systems.

INTRODUCTION

The federal Privacy Act of 1974[1] and similar laws in several states (Minnesota, Arkansas and Utah) have established certain rights of individuals regarding personal information maintained on them by government agencies, restricted the use and dissemination of personal information, and prescribed requirements for information quality, integrity and security. In particular, the Privacy Act of 1974 states that any agency of the federal government must "maintain all records which are used by the agency in making determinations about an individual with such accuracy, relevance, timeliness and completeness as is reasonably necessary to assure fairness to the individual in the determination," and must "establish appropriate administrative, technical, and physical safeguards to insure the security and confidentiality of records and to protect against any anticipated threats or hazards to their security or integrity which could result in substantial harm, embarrassment, inconveniences or unfairness to any individual on whom information is maintained." The Act and state privacy laws also note that certain personal information items are available to anyone under the provisions of the Freedom of Information Act,[2] certain other items must be restricted to the agency personnel on a need-to-know basis, and still other items may be withheld even from the individual data subject himself.

The privacy protection laws recognize implicitly that not all items of personal information are equally critical in making a fair determination about an individual, that they are not equally sensitive from the point of view of their dissemination causing harm or embarrassment to an individual, and that the information quality, integrity and security requirements may vary among information items, types of records, and types of record-keeping systems. Even the same information item may be innocuous in one system of records, but very sensitive in another. For example, while a person's name is usually public information, it becomes sensitive when associated with a system of psychiatric treatment records.

Since most of the personal information record-keeping systems do not contain highly sensitive information, it is not necessary nor would it be economically practical to require absolute quality, integrity and security for all personal information in all record-keeping systems. Rather, following the approach taken in handling sensitive national defense information, a set of information sensitivity categories could be established such that, for each category, the access and dissemination restrictions would be specified and the minimal levels of required information quality, integrity and security would be defined. Thus, the technical questions of assuring quality and integrity, and providing security would be separated from the social policy questions of determining what level of integrity and protection must be provided for a particular type of information in a particular record-keeping system—several sensitivity categories are available and the

* Any views expressed in this paper are those of the author. They should not be interpreted as reflecting the views of The Rand Corporation or the official opinion or policy of any of its governmental or private research sponsors.

corresponding access control, integrity and security levels are provided by the system, such that any information item can be assigned to the sensitivity category most suitable under the circumstances.

This paper surveys several sensitivity classification systems that have been discussed in the literature, examines the criteria for setting up such systems, and proposes a generalized set of sensitivity categories for personal information in governmental as well as private record-keeping systems.

PROPOSED CLASSIFICATION SYSTEMS

Several suggestions for classification of personal information have been made in the literature. One of the earliest proposals by Comber[3] defines three categories based on dissemination controls that are applied:

1. *Unclassified*—All data maintained by a public agency not otherwise classified as restricted or confidential.
2. *Restricted*—Data that are not prohibited from full and free disclosure by statute (confidential), but whose unauthorized use could constitute an unwarranted invasion of personal privacy.
3. *Confidential*—Data that are prohibited from free and full disclosure by statutory regulation (law).

Comber suggests that among the criteria for classifying personal information as "restricted" should be whether or not the disclosure of data in question would: (1) Facilitate unwarranted identification of individuals, (2) Cause unjust economic loss or public stigma or harassment, and (3) Result in unnecessary loss of property right. The classification decisions would be made on the basis of public policy, laws, legal interpretations, agency specifications and personal needs of individuals. However, the decisions would be expected to vary among record-keeping systems depending on the context in which the data are embedded, the amount of information and its intrinsic nature, the sophistication of the social values of the individuals involved, and the significance of personal attributes in the sub-culture involved. Among the examples of personal information that may be classified as "restricted," Comber cites political and religious preference, marital history, family attributes, ancestry and names of relatives.

A more detailed information classification system and sensitivity scales have been proposed by the British Computer Society:[4]

1. *Public*—Any personal information that is generally available in a listed form, such as various directories, biographic publications, etc.
2. *Published*—Information that is available but has not been collected, such as court records or hospital admission records. This category differs from "public" information in that if the individual involved does not draw attention to its existence, this information is not generally known.
3. *Confidential*—Information that is not generally available, although it is available and known to the individuals concerned.
4. *Secret*—Information that is not generally available, including the individuals concerned. Information in this category would be collected only under statutory authority or when authorized by the individual involved.

Within these four sensitivity categories there could be a more detailed sensitivity scale, such as illustrated in Table I. The authors of this classification system also point out that sensitivity of personal information varies with the circumstances and ideally each case should be determined according to precedents within the framework of legislation or professional codes of conduct, and that it appears not practicable to define degrees of sensitivity in any rigorous manner.

A very detailed catalog of classification of personal information items on the basis of sensitivity has been developed by Bing[5] from the point of view of Norwegian societal, legal and cultural concepts. The index contains some 400 data elements that are graded on the basis of three sensitivity levels:

1. *Normal aspects* (*GS1*)—General factual information about an individual's person, family, housing, property, employment, and other information in public record-keeping systems.
2. *Personal aspects* (*GS2*)—Intimate, detailed or specific information on an individual that could be used to make a social judgment about him as well as to obtain a detailed picture of his person, health, family, life style and views.

TABLE I—A Scale for Data Sensitivity (British)

Value Scale	Examples
0	Information collected and available, such as telephone books, professional listings
1	Selected general information (e.g., titles such as Miss, Mrs. or which indicate the marital status)
2	Public utilities account inquiry systems
3	Public information in schools
4	Vehicle licensing systems
5	Financial information (e.g., bank records; medical records)
6	More sensitive financial information (e.g., company finances)
7	Commercial secure information (e.g., trade secrets)
8	Confidential police records (e.g., records used by inquiry agents)
9	Police records relating to convictions
10	Secret information (diplomatic secrets; defense secrets)

3. *Disparaging and defamatory aspects* (*GS3*)—Information that could be used to form a moral or ethical picture of an individual, as well as information on especially sensitive health conditions or handicaps, ideological views and beliefs, law enforcement information, personal idiosyncracies and habits and evaluations of abilities.

The criteria for categorizing a data element depend, as in other classification systems that have been proposed, on considerations such as the individual and societal values, quantity of information involved, purpose of its collection and use, context and age of the information.

Sensitivity categories have also been proposed for various specialized record-keeping systems. For example, in the guidelines for record-keeping in public schools[6] the following sensitivity categories are proposed:

1. *Category A*—Official administrative records that constitute the minimum personal data on students necessary for the operation of the school (identification, attendance, academic work completed, level of achievement, emergency information).
2. *Category B*—Verified information of clear importance but not absolutely necessary (intelligence, aptitude and achievement test scores; health and family background; teacher and counselor ratings; verified reports of recurrent behavior patterns).
3. *Category C*—Potentially useful information, but not verified or clearly necessary beyond immediate use (legal or clinical findings, personality test results, unevaluated reports by teachers or counselors).

Specific administrative procedures are proposed for each category regarding access and dissemination, retention and use. For example, it is recommended that unless category C items are verified and, thus, moved into category B, they should not be retained longer than one year without discussing the reasons for this with the student's parents.

Finally, the following set of sensitivity categories has been proposed for criminal justice information systems:[7]

1. *Restricted*—Data that require minimum special security consistent with good security and privacy practices.
2. *Confidential*—Criminal justice information on individuals disseminated to criminal justice agencies, research reports derived from such information, and documentation of the information system itself.
3. *Highly sensitive*—Data that require maximum special security provisions and particularized privacy protection, such as criminal history information accessed by using other than personal identifying characteristics, arrest information without conviction, intelligence information, and computer programs and systems used for processing criminal justice information.

The lowest sensitivity category proposed in this system is "restricted" even though much of criminal justice information is public by statute. This is explained by pointing out that there is still a need to assure the integrity of such information.

A GENERALIZED CLASSIFICATION SYSTEM

The establishment of a standard classification system for controlling the use, dissemination and protection of personal information in record-keeping systems has the obvious benefit of clarifying for everyone concerned the level of privacy protection that can be expected and must be provided, and the consequences of not doing so. For each category would be specified the requirements for maintaining information quality, integrity and security; information handling and accountability procedures; personnel clearance criteria and procedures; information retention periods and classification criteria and procedures; and penalties for willful violations of these requirements. A framework for such a classification system is outlined below. It is discussed in more detail elsewhere.[8]

A very important consideration in setting up a classification system is the number of categories that are defined. Too many categories may make the use and implementation of the system too cumbersome and costly; too few categories may result in overclassification and excessive privacy protection requirements. Important considerations here are the number of sensitivity levels of personal information and the number of different dissemination restrictions.

Sensitivity levels

Personal information becomes sensitive when its uncontrolled dissemination may have adverse effects on the individual concerned and on his activities within his social group, or when it can reveal that the individual does not possess values expected by his family, acquaintances, those making determinations affecting him or the society. Two situations arise: the individual wants to limit circulation of the information, or the information is kept from the individual for "his own good" or the society's good. For example, the information may include an individual's past transgressions, views or associations or, in the second case, it may include results of medical or psychiatric examinations, or information on an ongoing criminal investigation of the individual.

The adverse effects of revealing personal information on an individual to others or, as the case may be, to himself, may range from a mild annoyance to physical harm or even loss of life. Between these extremes it is possible to define many other levels of adverse effects on the individual's physical and mental health and well-being, employment, family life, reputation, social life, and values. However, in order to keep the number of sensitivity levels small a scale of six categories is proposed in Table II. Shown are only the primary potential adverse effects of uncontrolled dissemination of information in each category; it is possible for adverse effects to escalate into the higher categories. For example, the release of information that results in a loss of self-respect may further lead to antisocial behavior, loss of employment and serious mental conditions.

Dissemination categories

Another consideration in setting up a classification system involves the restrictions that are placed on dissemination of the information by statutes such as the Privacy Act and the Freedom of Information Act, and by procedures adopted by the record-keeping organizations. The following possible recipients of information must be considered:

- The individual to whom the information pertains or those formally representing his interests (guardian, physician, lawyer, accountant). There are two aspects here—knowledge by the individual that a record of information is kept on him, and access to that information.
- Personnel of the record-keeping organization. There are two groups—those who have a specific need to use the information, and other personnel of the organization.
- Organizations with subpoena power, such as courts, grand juries, investigative committees at various levels of government.
- Any member of the general public who requests to see the information.

For each of the above, gaining access to the information is the principal consideration. However, for certain types of information the individual himself may need to be denied knowledge of the existence of a record on him, denied access to the content of the record, or both. For example, the Privacy Act of 1974

TABLE II—Sensitivity Scales for Personal Information

Category	Individual		Access granted to users		Subject to subpoena	Access to Public	Examples of information; information sensitivity levels
	Knows	Has access	Authorized	Others			
AS: Public (by statute)	Yes	Yes	Yes	Yes	Yes	Yes	Property tax rosters; Level 0 information
A: Public	Yes	Yes	Yes	Yes	Yes	Yes	Employee directory; Level 0 information
B: Limited, Official	Yes	Yes	Yes	Yes	Yes	No	Personnel records; Level 1 information
C: Restricted	Yes	Yes	Yes	No	Yes	No	Payroll records; Level 2 information
D: Confidential (by statute)	Yes	Yes	Yes	No	No	No	Social research data; Level 3 and 4 information
E: Sensitive (by statute	Yes	No	Yes	No	No	No	Psychiatric examination records; Level 4 and 5 information
F: Secret (by statute)	No	No	Yes	No	No	No	Organized crime investigation records; Level 5

exempts certain testing information from access by the individual, and the existence of certain criminal investigation records may be kept secret from the individual while the investigation is in progress.

Organizations with subpoena power can demand access to any record-keeping system which they consider important for their investigation and which is not provided a privileged status by law.[9] Information that is protected from subpoena includes the U.S. Census data and certain medical and psychiatric records. Other information granted statutory immunity from subpoenae in various states includes[10] drug abuse, alcoholism, and venereal disease records; information on victims of sex crimes, adoption proceedings, and illegitimacy records. However, personal information gathered for research purposes in social, behavioral and political sciences areas, and in education and psychology, is not provided with statutory protection against subpoenae and, as illustrated by recent cases,[11,12] the researchers' promises to keep the information confidential often have no substance. Hence, every classification category should also indicate whether or not protection against subpoena is provided.

Based on these considerations, dissemination control categories can range from "public" information which is accessible to anyone to "secret" information which is accessible only to authorized users of the record-keeping organization (the individual concerned neither has access to such information on him nor can he determine whether or not such a record on him exists). Table III depicts a classification system of six categories that should be suitable for personal information record-keeping systems both in government and in private sphere.

Clearly, the classification categories in Table III do not represent all possible combinations of access control restrictions. For example, it is conceivable that access to a particular type of information may be denied to the individual, but it may still be subject to subpoena power. In such cases the present classification system may have to be expanded.

INTEGRITY AND SECURITY PROVISIONS

Given a set of access control categories such as those defined in Table III, a set of requirements for assuring integrity and security of the information in each category can be specified. However, not every category may need a separate set of specifications. In Table III the categories AS and A are essentially the same, and so are the categories C and D (they differ only in whether or not information in these categories is subject to subpoena power). Thus, three or four levels of integrity and security provisions may be sufficient. In

TABLE III—Classification of Personal Information

Sensitivity level	Potential Adverse Effects on the Individual	Examples of Information Revealed
0	No appreciable adverse effects	Widely available, common information
1	Loss of respect in social sphere, loss of friends, loss of privacy and solitude	Remarks made in private; publicly available information not widely disseminated; information on views, preferences, leisure activities
2	Loss of reputation, recognition, social acceptance, self-respect, loyalty, competence	Information on political views, anti-social behavior, evaluative statements by the individual or others
3	Loss of economic security and opportunities, employment; disruption of family life	Information on medical and psychiatric treatments; sexual deviations; extra-marital affairs; evaluative statements by or about family members; criminal history
4	Loss of civil rights, imprisonment, serious effects on mental and physical health	Self-reported information on illegal or anti-social behavior; information on medical and mental condition; psychiatric evaluations
5	Loss of life or physical safety	Information that the individual is an under-cover agent for an investigative agency

any computer system there must be implemented a set of "basic" integrity, security and auditing procedures to prevent inadvertent interference of users with each other, accidental modification or destruction of information, and physical damage to the equipment.[8,13-16] Such a basic set of requirements should be sufficient for information in categories AS, A, and B (and to the sensitivity categories 0-2 in Table II).

A "medium" level of integrity, security and auditing is needed for information in categories C and D (and in sensitivity levels 3 and 4) since access to this information is limited to authorized users only and this information has a greater potential for adversely affecting the individual. The security and integrity provisions should include marking of the information items and records, and hard copy, either as "Restricted" or "Confidential"; establishing users' accountability for such information; implementing more sophisticated identification, authentication, and authorization procedures;[17] implementing audit logs; and strengthening the basic integrity assurance provisions.

A "high" level of integrity and security assurance would be provided to information in categories E and F (and for sensitivity levels 4 and 5). All files in the computer and all hard copy should be marked as "Sensitive" or "Secret" and stored securely; encryption techniques* should be used to protect information in these categories on removable storage media and in communication systems; sharing of the computer system with other computer activity should be limited, the system should be entirely dedicated to the record-keeping system in question, or (especially for sensitivity level 5) the information may have to be kept off-line or even in manual files; there should be full accountability of the users for handling information in these categories; sophisticated audit trails to trace file accesses to users and enhanced integrity control procedures such as change and error detecting codes should be implemented.

The above are only a set of general suggestions of what types of protection and integrity procedures might be used for the various information categories. In practice, the provisions adopted should reflect the specific circumstances of the record-keeping system and a thorough analysis of the security risk exposure of the information as well as a cost-benefit tradeoff. However, the methodology for risk assessment is still in the development phase at the National Bureau of Standards and elsewhere, and the cost of providing integrity and security is also known only in a very rough term.[20,21]

Classification policies and problems

Given a sensitivity scale and a corresponding classification system it is necessary to establish a set of standard criteria and a standard policy for classifying personal information items, records that contain several information items, and entire systems of records. Certain types of personal information used by the government can be classified directly on the basis of statutes that apply to the record-keeping system or to the information categories involved. For example, all personal information collected as part of the census are automatically "confidential," while property tax records are "public by statute" and psychiatric records are "confidential" or "sensitive." For other information not covered by statutes it may be necessary to first determine its sensitivity level and then to use this for making the classification decision.

One approach to standardize the assignment of sensitivity levels is to generate a handbook where, as suggested by Bing,[5] sensitivity levels are assigned to all personal information items that are known to occur in record-keeping systems (e.g., name, date of birth, amount of income, name of the employer, names of acquaintances, leisure time activities, etc.). A less detailed approach that is being considered for implementation of the Privacy Act of 1974 would assign sensitivity levels only to categories of information (e.g., identifiers, physical characteristics, employment history, evaluations, etc.) rather than individual information items and provide a list of these. In both cases there is the problem of deciding what sensitivity level should be assigned. Sensitivity is a highly subjective and context-dependent property of personal information—what one individual may consider very sensitive may be regarded with indifference by many others, and it is likely that there is a large range of sensitivity assessments for every information item. However, it would not be practical to assign the top sensitivity level of this range to each information item. Instead, a reasonable sensitivity level must be determined through the use of surveys and expert opinion.

A traditional approach to classifying a record that contains several information items that have already been classified, or for declassifying an entire record-keeping system, is to assign it to the highest classification found among its elements. Here, too complications may be found. For example, under some circumstances a collection of information items may be more sensitive than any one of the elements. In other record-keeping systems only very few information items may have a higher sensitivity level than the rest of the records and, thus, escalate the classification of the entire record-keeping system. The first case requires the development of an algorithm for increasing the sensitivity level of a record or record-keeping system as a function of the amount, type, sensitivity and uses of its elements. Research on this is yet to be done. The second case could be handled by using special security techniques (e.g., encryption) to reduce the sensitivity level of the information items in question, or by establishing a separate record system for these

* See papers on encryption in this Volume and References 17 and 19

information items. Other problems that must be tackled in assigning sensitivity levels to personal information and making classification decisions include automated classification of records and information derived from existing records, and downgrading of sensitivity levels and classifications as circumstances change.

Concluding remarks

Laws now in force require that privacy protection be provided to personal information in record-keeping systems maintained by the federal government, and by state and local governments in three states. Other states are expected to enact similar legislation, and pending in Congress is a bill, H.R. 1984, the Comprehensive Right of Privacy Act, which would extend privacy protection also to record-keeping systems in the private sphere.

It is necessary for effective implementation of these requirements to establish a standard sensitivity classification system for personal information such that for each classification level it is known what integrity and security assurance must be provided, what information handling practices must be followed, and what penalties apply for non-compliance. Information items can then be assigned into appropriate categories on the basis of their potential to adversely affect individual data subjects, and on the basis of access and dissemination limitations that may be required by law. One such classification system and a sensitivity scale is proposed in this paper. Important questions still being researched deal with criteria and policies for determining the sensitivity and classification levels of information items, records and record-keeping systems.

Philadelphia justice information system

by IRVING J. CHASEN
PJIS Project
Philadelphia, Pa.

ABSTRACT

The Philadelphia Justice Information System (PJIS) concept was designed via a joint study with a major computer manufacturer. Functions—generally threefold: (1) Monitor and Control—to act in an active and directive nature to insure completion of all tasks, to automatically issue reminders for tasks not completed on schedule, and to make administrative contacts for corrective action until all tasks are completed, (2) Data Collection—merger of and improvement upon existing data processing systems and (3) Communication—to make information available upon request to all cooperating agencies. All agencies related to the criminal court system (e.g., Public Defender, Clerk of Court, District Attorney, Probation Department, Prison) will share PJIS Data Base with Courts and Police. PJIS Data Base will be result of merger of two extensive existing Criminal Justice Data Processing Systems—Police and Courts. Goals of single system—(1) eliminate redundancy, (2) reduce overall costs, (3) attempt to accomplish conflict-free scheduling, (4) assure back-up capability, and (5) more effective coordination of man and machine resources within the courts and agencies of the Philadelphia Justice Information System to increase fair and speedy case disposition. Guidelines are being drawn to build in protection of the individual's right to privacy.

The Philadelphia Justice Information System (PJIS) is a computer-based system designed to serve the information needs of all the agencies of the Justice System. These agencies include the Police, Courts, District Attorney, Public Defender, Prisons, and Probation Department. The PJIS concept was designed via a joint study conducted with a major computer manufacturer between 1971-1974. The system is being implemented by the PJIS Project which is currently funded through a LEAA Discretionary Grant. The focal point of this system will be a central computer with associated programs, centralized data base and communications network.

Currently, most of the planned functions of the system are operational. There are automated systems now serving the Courts, the Prisons (PRINS), the Police (On-Line Booking) and the District Attorney's Management Information System (DAMIS). The next step will be the incorporation of the existing applications into one single data base serving the various agencies with a minimum of data redundancy.

PJIS is oriented around a single Data Base, a central repository of Justice System information. The justice agencies share this common fund of information in performing their separate but related tasks. Each agency has responsibility for entering information into the Data Base, and personnel in each agency are permitted access to information for which they have a legitimate need. Data Base information is organized so that each user can refer to it and analyze it according to his own needs. Thus, each agency may—quite realistically—view the computer as being its own. The single Data Base allows ready access to accurate, current, comprehensive information. Persons in each functional area can feel confident that the information they are using is consistent with that being used in other functional areas.

Beside the specific information services it provides, the Data Base also has a more subtle, though important, value. The mere existence of this shared resource should have an integrative impact on the justice community, since it enhances the single-process idea and helps to create an atmosphere in which agency interdependencies become more apparent and increased cooperation is seen to be both possible and mutually profitable.

Each of the Justice agencies is directly linked to the shared Data Base by a network of computer terminals. These devices, equipped with a video display, a keyboard, and a printer are dispersed throughout each agency's facilities. Each terminal is a window to the Data Base: each makes the Data Base continuously present to authorized persons.

It is through these terminals that each agency enters its information into the Data Base. It is also through these terminals that information is retrieved, in one of several ways:

(a) INQUIRIES: The computer system will provide immediate response to requests for information; responses are in the form of printed copy or video display or both.

(b) NOTIFICATIONS: The computer system will issue unsolicited printed messages whenever it needs to inform someone of a new responsibility (Task) assigned to them or when it is necessary to quickly distribute newly received information about a particular incident, person, or case.

(c) DOCUMENTS: Whenever practicable, the computer system *will* create file folder documents on printers located within each agency. This method of document distribution, when used, replaces the exchanging of carbon copies.

(d) REPORTS: Statistical analyses, trial listings, and other reports of that type *will* be created on printers located within each agency rather than being printed at a central location and distributed manually.

The system provides a common statistical base which is used to prepare analyses for management use. While individuals with different viewpoints may question the significance of certain statistics or may interpret them differently, everyone in the justice community will be using figures derived from a single source—the PJIS Data Base.

Because each agency is an active participant in PJIS, the computer system has the necessary information to assist in scheduling judicial proceedings. It knows scheduling rules and case data, and it maintains availability schedules of courtrooms and of Justice System professionals. The system uses this information to recommend conflict-free dates and locations each time someone indicates a need to schedule a courtroom event.

Thus, the system "closes the loop" in its ability to assist in controlling Justice System activities. It actively participates in scheduling the majority of events, and then, as outlined earlier, the system actively monitors the accomplishment of tasks necessary to make those events occur as scheduled.

File folders will continue to be used in PJIS, but the method of creating and distributing many of the documents for those folders will change. For example, a single document showing the known facts about each new case *will* be printed onto a single document at the time a case enters the Justice System. In addition, a follow-up document, showing data accumulated since the case entered the system, will be printed each time a case is due for a court hearing. Interested agencies receive these documents on printers located on their own premises. These consolidated information sheets serve a dual purpose: they keep case folder information current while using a minimum number of pieces of paper.

In summary, PJIS interacts with operational and administrative personnel in the performance of their daily activities. Through terminals, it prompts them, and responds to their requests for immediate information. As a result of the system's active participation in events as they occur, the Data Base always reflects a current and comprehensive picture of the Justice System and the status of every incident, person and case. Thus, the system is able to respond to requests from management and professional staff for information on demand.

The Data Base integrates Justice System information into a cohesive collection of related data. It is the central repository for two general categories of information:

> Operational Data—supplied by and used by Justice System personnel directly in the course of day-today operations. This "live" information represents the facts of the Justice System, such as statistics, historical records, and details concerning current cases, incidents, persons, and scheduled hearings.
>
> Control Data—supplied by Justice System management and used by the computer in its decision-making processes. This relatively static (but easily changeable) information specifies available resources, system policy and operating guidelines. It includes such things as a description of courtroom facilities, availability schedules for police, judges, attorneys (for use in scheduling); rules for granting continuances; allowable intervals between successive stages of defendant processing; and who is permitted access to what data. This kind of information will be stored in Data Base tables rather than being embedded within numerous application programs, a scheme which permits easy modification by authorized persons and enables management to readily exercise control over system operation.

The communication network links remote locations with the computer and the data base. Online terminals equipped with video display and printing capabilities will be placed at strategic locations to allow information retrieval on demand, and in some cases, to also permit keyboard entry of data into the data base. In addition to the local communications network, the system also includes provisions for exchanging information directly with State and National Law Enforcement data bases (the CLEAN and NCIC Systems).

The independent justice agencies jointly use the system facilities. These users effectively share a common fund of information, the PJIS Data Base, in performing their separate but related tasks involved in processing defendants through the Justice System. In this cooperative effort, each has responsibility for entering data according to fixed rules, and personnel in each agency are permitted access to data on the basis of their need to know.

Data Base information is organized so that all users can refer to it and analyze it according to their own needs. The Data Base allows maximum accessibility to accurate and current information by authorized Justice System personnel, so that each functional area can perform its tasks with the knowledge that the information being used is consistent with that used by other functional areas. While PJIS is intended to aid operating personnel, it also is the means by which management personnel can maintain a comprehensive awareness of overall system status—who is presently responsible for doing what, when, and where; what are the sources of recurring problems which disrupt the system; and in what departments information-handling operations need revision.

The ultimate goal of any information system is to make reliable data readily available when, where, and in the form it is needed. Accordingly, the design of modern automated systems, including PJIS, is directed away from paper movement and toward the use of data bases and online terminals for recording, retrieving, and exchanging information between system users.

PJIS collects, stores, and distributes data concerning three type of entities:

(a) Incidents: The matter for which a subject (person) has entered the Justice System. In most cases, it is a police incident, but incidents may also be originated by other means, principally by the District Attorney's Office which handles private criminal complaints and investigative grand juries.

(b) Persons: defendants processed through the Justice System. At various points in the processing cycle, an individual may be referred to as the subject, suspect, arrestee, defendant, offender, prisoner, parolee, juvenile, detainee, client.

(c) Cases: court units of scheduling.

PJIS could be referred to as an incident-tracking system, or a defendant-tracking system, or a case-tracking system—and all such descriptions would be partly correct, because the system does track all of these entity types rather comprehensively.

PJIS plays an active role in the justice process; it is far more than a passive record-keeping and reporting system.

The control capabilities incorporated in the computer system design give it the ability to:

Assist in scheduling judicial proceedings
Coordinate tasks and events
Monitor the accomplishment of tasks
Manage the distribution of information
Assist data entry operations
Provide for data security
Assist with enforcement of Justice System rules

Each of these capabilities operates together in a systematic manner. Numbered steps in the following narrative refer to correspondingly numbered items in Figure 1.

(1) Major events are scheduled by persons, not by the computer system. However, where the event is a judicial proceeding, the computer system assists in establishing a conflict-free date and location for the hearing. It is able to assist in this way since it maintains availability schedules for courtrooms and for key participants in the system (Judges, Attorneys, Police witnesses).

(2) Each time a major event is scheduled, the Coordinate function is informed. The Coordinate function knows what standard tasks must be performed before, during, and immediately after each type of major event. Since it has been told when a particular event is to occur, and since it also knows how many days before or after an event that each task must be performed, the Coordinate function can easily calculate the date by which each routinely-performed task must be completed.

(3) The Coordinate function passes to the Monitor function information about each task which must be performed. This information specifies (a) the identification of the entity (incident, person, case) for which the task is to be performed; (b) a description of the task; (c) who is responsible for performing it; (d) the time by which it must be accomplished; (e) the time when the Monitor function should first check to see whether the task has been completed. The task is placed into a Pending Tasks List which is continuously reviewed by the Monitor function.

(4) Persons may inform the system at any time that special tasks, not routinely performed for every entity, must be performed for a particular one.

(5) Each time someone informs the system that a special task is needed, the Coordinate function handles it essentially as if it were a normally required task and places it into the Pending Tasks List. In addition, the Coordinate function usually issues an immediate notification to inform the responsible Justice Unit of the non-routine task to be performed.

(6) Persons spread throughout the Justice System are continually entering information into the Data Base through remote terminals equipped with keyboards and video displays. In doing so, they operate in a conversational mode with the computer system which: (a) performs a security check to uniquely identify each operator and to ensure that persons entering particular kinds of data are authorized to do so; and (b) guides the operator through successive steps of data entry to ensure, to the maximum extent possible, that information being entered is both complete and logically con-

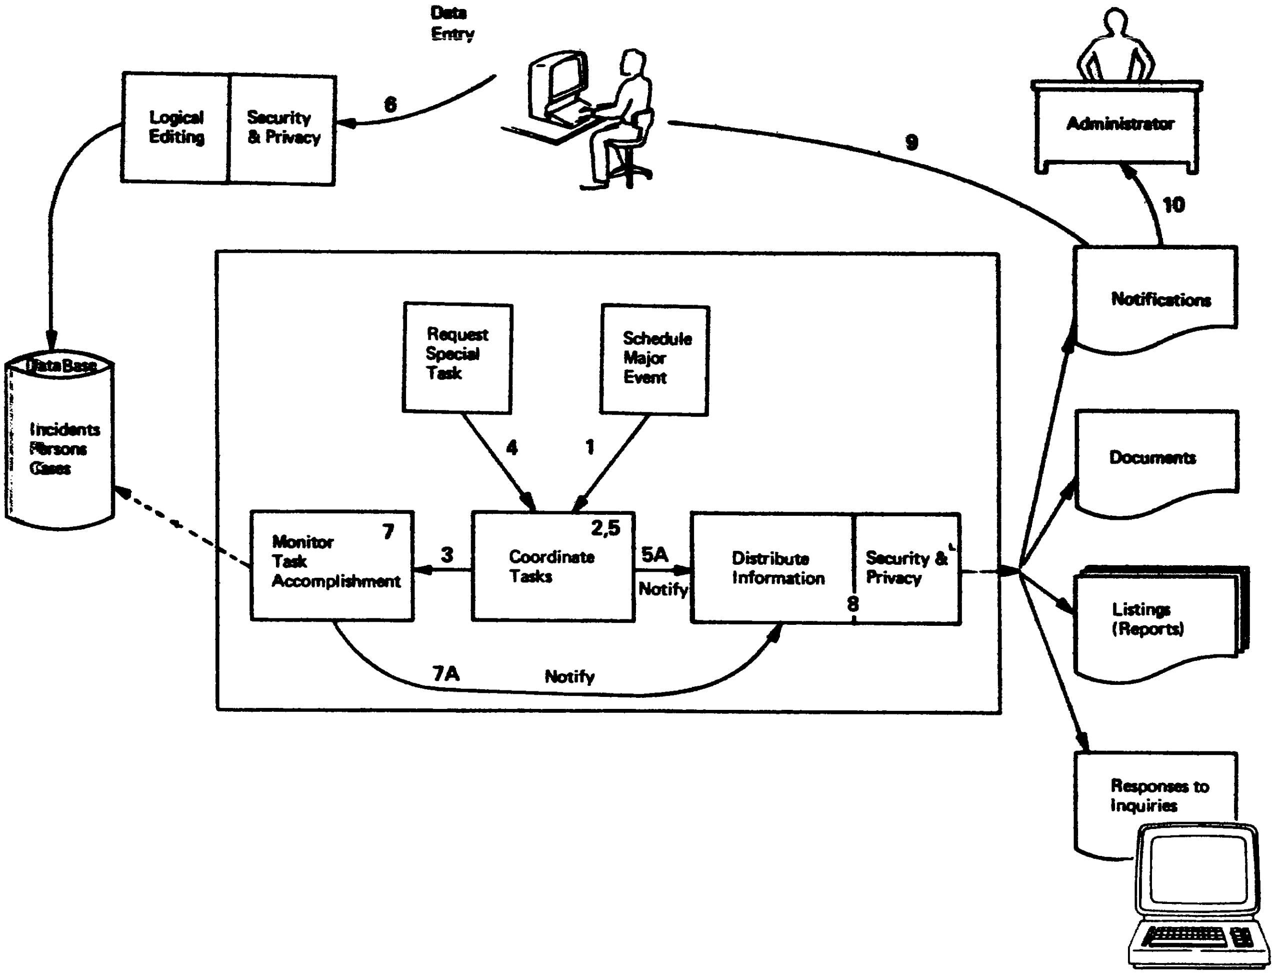

Figure 1—Overview of "principal capabilities"

sistent. Most input transactions fulfill a requirement specified in the Pending Tasks List. That is so because, ideally, the system (via the Pending Tasks List) anticipates all input transactions so that it may remind responsible persons when input has not been received when due. It should be noted all input transactions are automatically logged and time-stamped within the computer system. This information is a useful aid in constructing audit trails.

(7) The Monitor function continuously selects items from the Pending Tasks List which have become due (each item carries with it the date and time at which it should be reviewed by the Monitor function). The Monitor function then looks at the Data Base to see whether a task due for completion actually has been accomplished. Where it has been, no further action is required. But where it has not, the Monitor function issues a notification to the appropriate Justice Unit reminding them that a task for which they are responsible has become due. The item is placed back into the Pending Tasks List for another review a short time later. If the task is not performed after some period of time, a notification will be issued to a responsible administrator to inform him of the exceptional situation.

Of course, the Monitor function also keeps statistics on the types of tasks it is monitoring and the number of times those tasks are or are not completed satisfactorily. These statistics will be used by administrative personnel to evaluate procedures and to determine the root causes of Justice System problems.

(8) The Distribute function manages the distribution of all information produced by the com-

puter system. This material falls into four general categories:

(a) Notifications: messages about a single entity. They are always created by the computer system (not by persons outside) either to request that someone perform some specific task or simply to provide new information as soon as it becomes available. Whenever possible, notifications are transmitted from the computer directly to the Justice Unit for which the information is intended.

(b) Documents: computer-printed forms containing facts about a single entity. They are generally intended for insertion into file folders for reference purpose.

(c) Listings (reports): computer-printed forms containing information about groups of entities. They include such things as trial listings and statistical analyses.

(d) Responses to Inquiries: the computer system responds immediately to requests for information on demand (subject to privacy restrictions). These requests are made through terminal keyboards at locations remote from the computer site. Computer responses are in the form of video displays or printed material or both. PJIS is heavily oriented toward distributing specific information in this way rather than through the regular production of voluminous printed reports. Most information that is regularly published in printed form is also available through terminal inquiry as well. It should be noted that all outputs are logged and time-stamped within the computer system.

(9) For the present discussion, attention is focused on notifications, specifically those created by the Coordinate and Monitor functions. The Coordinate function creates notifications to inform Justice Units that special tasks, which are not routinely performed for every entity, must be performed for a particular one. Every task requires entry of information into the Data Base, even if it is only an affirmative report that some task, known to the computer system, has been performed.

The Monitor function creates notifications to remind Justice Units that tasks for which they are responsible are due but have not yet been reported as accomplished. Before requesting corrective action by administrative personnel, the Monitor function usually checks again a short while later to see whether, as a result of the prompting, overdue tasks have been accomplished.

(10) The Monitor function also creates notifications to inform administrative personnel that the deadline for accomplishing a certain task has passed, and some action on their part is required. For example, if a psychiatric report will not be available as ordered, a request for continuance of a sentencing hearing may be necessary; or, if no outcome has been reported for a particular hearing, even after the responsible unit has been reminded of its absence, an administrative manager is informed so that he may research the problem.

An illustration of the operational services is provided in Figure 2. This example illustrates the flow of information that is contained in Agency file folders and that is also entered into or retrieved from the computer system data base. The operations shown occur in stages or over many stages but are consolidated for the purposes of this example.

The first entry into the system occurs at the Justice System Entry stage with a good deal of the information recorded at booking. The Static Information Sheets are printed on the agencies' administrative terminals from which they create their file folders. The agencies' File Folder Control Unit records the location and party responsible for file folders checked in or out.

Updates to the file folders are accomplished with the Volatile Information Sheets which are produced some time prior to each hearing. The information that changes or adds to the Volatile Information Sheets is stored on the Data Base. The Data Base is constantly being updated by all agencies over remote terminals which are also used to retrieve required system information.

The Data Base is updated at the hearings by the Court Clerk with case proceedings such as judicial orders, case disposition, next hearing schedule, and attorney appearances. Each agency's audit unit then compares the system information recorded in the file folder at the hearings.

The flow is then repeated for each additional hearing until the case is completely disposed. The data base information and the file folder for that case are then purged from active storage but retained in high density storage for historical purposes.

The above description applies to each agency concerned with file folders in the process of the hearing stages. Although only one agency illustrates the complete flow, it actually occurs in parallel with multiple agencies.

OVERALL SYSTEM BENEFITS

Effective data recording

By requiring information to be recorded only once and at its source, the system provides the following benefits:

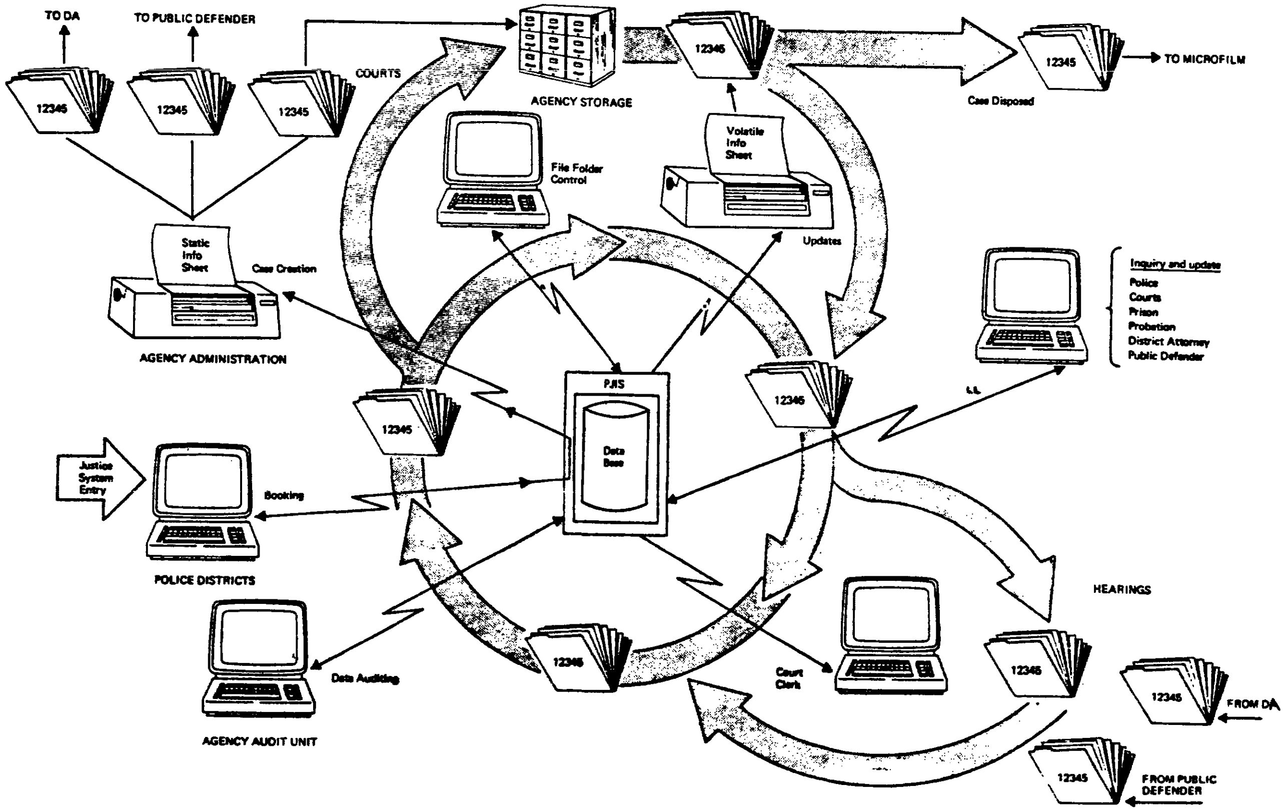

Figure 2—Conceptual Information Flow

1. Complete entry of all data related to each transaction
2. Accuracy of data entered
3. Reduction of redundant effort
4. Improved auditing and accountability
5. Reduced paper volume
6. Improved consistency of data

Improved security

PJIS exercises positive control over attempts to access information thus providing greater security than is possible with the existing information systems in Philadelphia.

Improved resource management

1. Flexible resource allocation
2. Increased personnel productivity
3. Better performance evaluation
4. Improved program planning and control
5. Management by exception
6. Concise management reports

Improved communications

1. Intra-agency communications
2. Inter-agency communications
3. Distribution of pertinent notices

REDUCED FILE MAINTENANCE

Reduction of continuances

1. Assistance with conflict-free scheduling
2. Optimum courtroom loading
3. Monitoring preparatory tasks

IMPROVED FEEDBACK AND FOLLOW-THROUGH ON ALL ACTIONS

Improved public image

Responsiveness to change

1. New applications
2. Changes in law
3. Policy and procedure revisions
4. Data Base content changes

Computers in architecture

by GENEVIEVE GREENWALD-KATZ
Max O. Urbahn Associates
New York, New York

ABSTRACT

The union of computers and architecture has not come about in spite of glowing predictions over the last ten years. This paper describes several of the reasons why this may be so: the complexity of the profession, the inattention as to how the architects actually design and the lack of top management dedicaton. The current state of the architectural profession is explored and why the architect's entry into new areas should spark a demand for computer technology is discussed.

INTRODUCTION

Over ten years ago, articles extolling the wonders of computers and predicting, in glowing terms, their impact on architecture began to appear. What has happened to this prediction—why has it failed? To understand this turn of events, we must look both at computing, and at architecture itself. Perhaps there, we might find clues regarding the introduction of new techniques into old professions that might even have more universal implications. What is the state of architecture today and of computer utilization in architectural practice? The architectural profession, as we know it, is going through a major upheaval. The recent deterioration in the economy has had a strong negative impact. Statistics from the New York Chapter of the American Institute of Architects state that architectural commissions have declined 55 percent from the year 1972 to 1973 and dropped an additional 50 percent in 1974. Reflecting this, the employment level shows a drop of 75 percent from 1969.

Some architects are now beginning to ask the question . . . how did we get to be so non-essential? In a time of rapid technological change and increasing costs, long established practices must be reevaluated in order for the profession to continue its existence . Architects are still designing buildings by hand—row upon row of people bending over drafting tables draw the details of each building.

In situations where resources are limited, the architect must be able to explore alternatives to building, to financing and to forms of energy utilization. With costs escalating, he must solve problems that are more complex and solve them faster than he ever has before. The architect must recognize these new needs and adapt his skills to solving these new problems.

Shrinking staffs and lack of work, however, is not being experienced by all firms. There are some firms that are expanding their offices. Some who are expanding currently are those who are using computers. It is not the "magic" of the machine that is doing this, rather, the computer can be seen as being symbolic of the architect's ability to learn new skills, handle large amounts of data and apply his expertise to the broad areas surrounding that of building. Let us look more closely at this phenomenon.

HISTORY

The coupling of computers with architecture began about ten years ago. While computers had been in use long before that, the period between 1963-1966 was marked by a significant development in computer graphics.

In 1963, direct-view bistable storage tubes were first used in terminals. That year, at the Spring Joint Computer Conference, Timothy Johnson and Ivan Sutherland announced their development of Sketchpad. That program made it possible for the architectural designer to input pictorial data into a computer by drawing on an electronic tablet. The drawing was displayed on a C.R.T. and could be modified with a light pen. The Rand tablet (the device used by Sketchpad) made its appearance at the Fall Joint Computer Conference in 1964.

Responding to the new advances being made, the First Boston Architectural Center Conference, held in December of 1964, had as its theme, "Architecture and the Computer." It was well attended and included many of the persons who were to make advances in computers for architects. Articles linking computers with architecture began appearing in architectural journals and trade magazines. Predictions ranged from computer takeover and subsequent dehumanization of architecture to an office where the computer would be the powerful servant of the architect, relieving him of all tedious tasks and leaving him free to spend all his time designing and dealing with high level abstractions. The dire predictions of computer takeover have not occurred and fears along that line have been quieted. Articles anticipating the widespread use of computers by the architectural profession however, continue unabated.

The time frame for this transformation was always within the next ten-year range. The ten years are now up. The tone of the articles has changed from enthusiasm about the use of the computers to bewilderment as to why the architectural profession has snubbed the computer, and finally to philosophizing that perhaps architecture and computers are totally incompatible. But what actually is happening?

I do not believe that architecture and computers are incompatible. However, I do feel that many of the people who would like to see computers being used more by architects:

(a) Do not understand what motivates the architect.
(b) Do not have a grasp of the complexity and variety of disciplines which the architectural profession encompasses.
(c) Have no idea as to how architectural offices function and in turn, how they effect how the architect works.

Furthermore, advancement in computer technology takes place primarily in the university, and many of the students are only remotely aware of how architecture offices work. Many of the programs developed in the academic environment are directed more towards the purpose of understanding the discipline of architecture than towards advancing the practice of architecture. I am not here questioning if it could or should be otherwise, but trying to explain why some of the "advances" do not make it to the office.

HOW WIDESPREAD IS THE USE OF COMPUTERS

First of all, the architecture profession is a small one. Figures from the 1970 U.S. Census show the comparative size of various professions:

Architects	57,081
Engineers	653,925
Lawyers	264,752
Physicians	280,557

A tally done by the American Institute of Architects from the state rosters of registered architects lowers the figure to 45,000. (The difference between the two figures can be explained in that "registered" means holding a license to practice, while in the U.S. Census "architect" referred to those people who stated that as their professional status).

While it has been the larger architectural firms that have gone into computers, the profession is characterized by an organization into small offices. Approximately 40 percent of the architectural firms are sole proprietorships. It is estimated that 90 percent of the firms employ six people or less. So the small number of actual users is explained in part by the logistics of the profession.

It is difficult to estimate the actual number of architectural firms using computers. The New York Times (August 29, 1971) estimates that of the 15,000 design firms in this country only 200 use computers. The 15,000 probably represent purely architectural offices and most likely includes the sole proprietorship type of office. To get some idea of the number of large firms, we can refer to The Engineering News Record which publishes a list each year of the top 500 design firms. "Top" refers to dollar billings and the 'types' of firm include architect-engineers, engineers-architects, consulting engineers, architects and design-contractors. Of the total number of firms listed about half are involved with architecture.

The issue for May 21, 1970 also included information as to the use of computers by these firms. Excluding design-contractors, "357 of the 460 top design firms reported the use of computers in their operations. Of the 357 firms, 32 percent rent their equipment, 29 percent use a time-sharing system and 13 percent own their own hardware. The balance used varieties of rental and time-share plans."

While the established pattern has been for the larger architecture firms to be exploring the use of the computer, there is growing evidence that smaller firms are also beginning to utilize computers. One of the reasons for this transition could be the lower cost of hardware. It is now possible to buy a small, but essentially complete computer with one high level language (Basic) for under $10,000. Ten years ago comparable equipment would cost between $30-50,000. Leasing a terminal in 1968 cost $100 per month while now terminals can be had for $50. Time sharing costs ($10-15 per hour) are essentially the same as they were in 1968.

Smaller firms have an easier time than larger ones in adapting to the changes brought about by the introduction of computers. Organizational changes and even new directions are not only simpler to effect, but often the younger members of the firms have less invested in the established way of doing things. There is also evidence that the use of computers by small firms differ from that of large firms. With large firms, computer usage is more likely to be only a small part of the office routine and only used by a small fraction of the staff. When small firms use the computer, the whole office may well be organized around its use. The entire staff is encouraged to put "hands on" the terminal. It is this "hands on" approach that allows an office to explore the tool. This exploration can lead to the application of computer technology to various areas of architecture. The important thing here is that the people working in the field are the ones who should begin to develop the programs.

In order to better understand how firms make use of computers, the New York Chapter of the American Institute of Architects has recently become interested in what motivates a firm to go into the use of computers. Some of the reasons given were:

(1) The approval of the systems approach and the methodology behind computer use.
(2) The need to process vast amounts of data in short time.
(3) The entry into a new discipline which has not yet developed a methodology.
(4) The fascination with the process and a feeling that this must be the future direction for architecture.

This last reason is essentially a commitment to architectural research.

Some of the reasons are frankly window dressing—ways of impressing a client with the firm's grasp of the new technology. But one thing they all have in common is that using computers involves a top management decision. It is the eye of the vice president that this tool catches. It involves top management decisions as to new directions for the firm. Most certainly it will involve a considerable investment and (for the success of the venture) it must have management's continuing active interest, often in the form of a single enthusiastic partner. This last factor explains, in part, why the various branch offices of firms differ widely in computer usage. In one firm, one office uses sophisticated graphics and computer-aided design programs, while in another branch, changes to specifications are done by the architect dictating to a secretary who is seated at a terminal. At one time it was thought that computers would make inroads into the architectural offices by way of the accounting departments. Unfortunately, once into the accounting office, it rarely gets out into the design section.

HOW MIGHT NEW AREAS OF INTEREST INCREASE COMPUTER USAGE?

A new factor which may cause an increase in the use of computers by architects is the entry by the architect into fields which are very compatible with computer usage: information manipulation, numerical calculations, linear programming and graph theory. Because of the decline of building, architects are exploring some of the other areas which are related to the building process. The architect is now looking into the processes which are active before the building is designed, such as economic analysis, building programming, establishment of standards; processes active after a building is built, such as evaluation; and processes involving not-building, such as renovation. "Programming" for an architect is the assembly of the detailed requirements for a project into a coherent form, not the writing of computer procedures. Some of the more specific areas where computers are beginning to be of assistance are the following. It will be interesting to see if in moving into new areas, the architect accepts the new technology.

LIMITED RESOURCES PLANNING

A decade ago 'limited resources' was a concept that architects did not have to concern themselves with. The recognition that earth's resources are finite demands that the profession deal responsibly with energy, time, money, land and space. Today it is irresponsible for an architect to plan hospitals without taking into consideration the logistics of health care delivery, population trends and availability of technical staffing. There are programs utilizing the techniques of linear programming which are useful in this area. They allow the architect to consider the effects of a number of variables operating at the same time to arrive at an optimum solution for that situation. Graphic output aids in understanding how the various factors operate.

ECONOMETRIC MODELS

Just as architects use physical models to explore design solutions, they will also use econometric models to help them with the many other factors influencing design decisions. Life-cycle costing, value analysis and cost benefit analysis are three current methods in favor with both the architect and his more sophisticated client. Computer techniques are extremely useful here because of the iterative process of the analysis. The analysis may cover a wide range of items, such as building components, systems, services and social benefits. Solutions are arrived at by combinations and recombinations of the variables. If many items are to be considered, the analysis by hand is extremely tedious and slow.

THEORY OF DESIGN

Not a new area but clearly one of the more favored. The push to demystify the design process and to understand how the architect evolves his solution is more in the purview of the architect-computer-researcher than of the architect-teacher. In order for computer programs to be able to assist the architect they must be designed with an understanding of the process which they are assisting. A comprehensive study of the design activity in architecture has been carried out in the Department of Design Research at the Royal College of Art in London by a team of researchers headed by Patrick A. Purcell. The study, "Analysis of Architectural Design Activity in the Working Environment" attempts both to develop a model of design activity and to evaluate computer-aided design techniques. The study begins to define clearly the points in the design process when the architect needs information and how he incorporates various types of information into his "internal representation." Insights derived from work done on design corroborate the architect's feeling as to the importance of this area. Design and planning may comprise about one half of the total time of the entire job. In complex building types, such as hospitals, economies in design and planning time can save a building from being obsolete upon completion.

Attempts to deal more objectively with the design process are being made by design offices. Governmental agencies and corporate clients, with increasing frequency, are asking for an "objective" analysis of the design. Cluster analysis and hierarchical composition, and resolution are some of the techniques being used to arrive at decisions. However, sometimes what is passed off as an objective scientific analysis of the problem is simply putting numbers on subjective decisions.

BUILDING PROGRAMMING

Architectural firms which have experience in a particular building type are eminently qualified to write programs for that type of building. Most firms have not developed techniques for saving and reusing their data and so, much of their valuable experience is only partly carried over to the next job of type.

Non-architectural firms which have become involved with preparing "Building Programs" have developed sophisticated data gathering and data processing techniques. Architectural firms, in general, have been slow in utilizing these techniques. And yet, the application of these techniques could amplify the architect's experience into a powerful programming tool. There is also an increasing demand for pre-programming analysis of data relevant to the proposed project and this analysis is becoming so complex that perhaps computerization is the only rational way to do it. Feasibility studies are also used to make some assessment before proceeding to the long and expensive process of writing a "building program."

FACILITIES MANAGEMENT

Different from construction management and more suited to the architectural firm with some expertise in general management, this area covers the comprehensive management of the existing and future building activity of a large facility. Real estate, financial and building cost data are manipulated in various ways in order to arrive at a most beneficial mix for the client. Again, it is necessary to explore a large range of alternatives.

Architecture contains a vast assortment of skills and disciplines which are necessary to produce a building. As the profession adapts to new needs, new skills will have to be acquired. The pattern of growth is outward, in the direction of higher order generalities such as the understanding of the socio-economic processes which affect the building, rather than towards areas which are more specific and circumscribed. Perhaps this fundamental outlook underlies the fact that there has been no great movement by architects, even in a time of unemployment, to go into the field of engineering.

ARCHITECT-COMPUTER INTERFACE

In designing an architect-computer interface one should be aware that the architect feels differently about different areas.

(1) There are things an architect cannot do or cannot do well, but which he is interested in doing.
(2) There are things which he doesn't want to do.
(3) There are things which he doesn't want to do—but he has to.
(4) There are things he does well in which he feels he doesn't need any help.

1. Things an architect cannot do or cannot do well, but which he is interested in doing. Computer assistance in this area is welcomed by the architect because with it he can attempt areas previously inaccessible. An example of this type is Christos Tountas' 3-dimensional tent construction program. In it the designer specifies the anchor points in plan and elevation and the computer generates the shape of the tent in which the stresses will be equally developed. The program will then provide load analysis and coordinates of all the nodes. The designer can, in addition, specify various elastic properties to the edge cables and because the system is interactive, the computer will redraw the resultant shape of the tent. This technique for designing tents far surpasses the method presently used—the construction of actual models.

Any program which allows an architect to design curved forms as easily as he does in straight lines would free him from the constraints of his straight line geometry. It would assist him in conceptualizing shapes and spaces which are currently too difficult to draw.

Simulation programs showing movement of material and people through a building would also be useful. The architect, while he can visualize space easily, finds it difficult to visualize continuing processes through the space. Since he must make design allowances for them, visual representation can be very helpful in understanding the problem.

2. Things which he doesn't want to do. If a program is provided that would simplify these tasks he probably would still rather someone else did them. An example of this are programs for structural analysis. Regardless of how easy it becomes, on any large project the architect will still want the engineer to do it.

3. Things which he doesn't want to do—but has to. These are areas of his responsibility like code compliance and specification writing. The simpler the process, the better. Moreover, it is not what the masterbuilder will get involved with as much as the guy in the back room. Furthermore, for a firm to buy a computer program, it will have to be cost competitive with their consultant.

4. Things which he does well, such as design, and feels he doesn't need any help—in fact, he is competitive with the computer. However, since these are areas which he enjoys he is willing to experiment with computer assistance providing he is clearly the boss and sets the pace. He is highly critical of the system design and is intolerant of frustration. Because he builds up his design on consecutive inputs—turnaround time, machine response must be fast in order to be useful. This usually works best in interactive systems. Examples of this area are the various computer-aided design programs. They can range from a printout of the dimensions to a design solution to interactive design in three-dimensions with color and perspective, time sequenced.

Drawing is a relevant step in the architect's strategy for evolving a design solution because he thinks graphically. He literally "sees" his solution. It is his form of data compression, data manipulation and data transmission. That is why computer use for the architect must involve graphics. It can be simple tables, charts, and even simple line drawings will do. Because the architect can visualize easily, it is not necessary for an object to be colored and shaded before he finds it meaningful. Because the embellishments are not essential the architect is not likely to pay for it for himself. The trimmings are more appropriately saved for the client. But there is a great difference between designing a computer program for an architect and for his client.

SCHOOLS

The America Institute of Architects held a seminar for architectural students on The Changing Role of Architecture and invited the deans of two eastern schools. Their answers to the question "What are you trying to teach the students?"—one answered, "To dream," the other "To think." Needless to say, in these schools there is little emphasis placed on the use of computers in architecture. There are schools where students are taught to think and dream and to use computers. To visit such a place is an electrifying experience. The Architecture Machine at M.I.T., under the aegis of Nicholas Negroponti is one such place. Students are expected to investigate, explore and contribute to the new technology. These graduates unfortunately find little place for their skills in the architecture profession and often go back into the university or to other industries and so the dissemination of new techniques slowly reaches the profession.

CONCLUSION

And so . . . how is the use of computers coming along in the field of architecture? Slowly, and for good reasons.

First, it is a complex field which covers many disciplines and it is difficult to know which parts will take to computerization.

Second, the computer people have not understood the architect. They have not amplified his strengths nor have they mitigated his weaknesses. They do not know how to bring the computer to him nor how to bring him to the computer. They don't even know of what stuff his dreams are made.

Third, progress in computer technology, for the architect, has been mostly in the universities and in the larger firms. The universities are often not aware of the real-life problems of the architect. The larger firms are too few in number and have too often been content with the computer's power to impress, rather than its power to compute.

But, the smaller firms, of which there are many, are beginning to get into the picture. After all, one can now buy a computer for the cost of a sports car. Hopefully, these small firms will contribute to the use of computers because more people, who are architects, will be using them. In addition, the new areas into which the architect is heading, are eminently suited for computer assistance and indeed many of these areas have been substantially touched by computers. Under the impetus of becoming extinct, there will be architects who, with the help of computers will finally make it into the 20th century.

APPENDIX

A selected list of articles dealing with computers and architecture. Most of them have appeared in architectural journals. They are listed chronologically because it provides an historical overview of architectural interest in computers and computer related areas.

1965 Cowan, H. J., "Industrialized Architecture," *A.I.A. Journal*, pp. 51-57, April.

1966 Ludwig, M. E., "Prejudice and the Computer," *A.I.A. Journal*, p. 70, July.

1966 Stewart, C. D. and F. de Serio, "Design with Computers? It's what's Happening, Baby!," *Progressive Architecture*, pp. 156-158, July.

1967 Swinburne, H. H., "Change is the Challenge," *A.I.A. Journal*, pp. 83-90, May.

1968 Berkeley, E. P., "Computers for Design and Design for the Computer," *Forum*, pp. 60-65, March.

1969 Catalano, E., "A Case for Systems," *Progressive Architecture*, pp. 162-166, May.

Prospective capabilities in hardware*

by MARGARET K. BUTLER
Argonne National Laboratory
Argonne, Illinois

ABSTRACT

Today we can look back over the past thirty years and view the entire history of the electronic digital computer! In addressing the topic of prospective capabilities in hardware, this paper first attempts to extrapolate, from today's state-of-the-art and vantage point, general industry-wide trends and likely achievements. Then, an effort is made to cover in more detail specific areas of interest to the ERDA community. Subjects discussed include available large-scale computers—their architecture and viability. The microprocessor's impact on computer systems is considered, and potential applications of the microcomputer are identified. Then mass storage offerings and their role in predicted memory hierarchies is assessed; progress in the development of alternate storage technologies is reviewed. New products and anticipated innovations in peripheral and input-output equipment, probably the most lethargic segment of the dynamic hardware market, are described, and a survey of network and communications activity examines future directions this rapidly-expanding field might be expected to follow.

Whenever possible in each of these areas, examples with descriptive characteristics, accompanied by cost and performance statistics, are presented in support of the initially-forecast broad technological trends. These examples, chosen for illustration, represent new hardware products, advanced technologies in the developmental stages, or planned enhancements of existing product lines.

INTRODUCTION

Beginning in 1946 with the dedication of the ENIAC at the Moore School in Philadelphia, this history is generally perceived as a sequence of eras. These eras, traditionally referred to as generations, are characterized by the technology employed by the computer industry during that period. The history of the computer industry, as customarily represented, is shown below with the fourth generation introduced to reflect the technological advances of this decade.

The transition from the first to second generation is clear-cut, defined by the industry's shift from vacuum tube to transistor technology. Emergence of later generations becomes blurred as the increased investment in the existing technology, coupled with the need for acceptance on a cost-performance basis, serves to retard the new alternative technologies. For example, the incorporation of large semiconductor memories was postponed by economic considerations until production quantities reached proportions permitting the technology to compete with the entrenched magnetic core storage.

In addressing the topic of prospective capabilities in hardware, this paper first attempts to extrapolate, from today's state-of-the-art and vantage point, general industry-wide trends and likely achievements. Then, an effort is made to cover in more detail specific areas of interest to the ERDA community and the agency's environmental science and analysis programs. Subjects discussed include available large-scale computers—their architecture and viability. The microprocessor's impact on computer systems is considered,

	1946 . . .	1959 . . .	1965 . . .	1971 . . .
TECHNOLOGY:	vacuum tube	transistor	integrated circuit	large-scale integration
MEMORY:	mercury delay line or electrostatic	magnetic core	magnetic core or plated wire	semiconductor

and potential applications of the microcomputer are identified. Then, the recently-announced mass storage offerings and their role in predicted memory hierarchies is assessed; progress in the development of alternate storage technologies is reviewed. New products and anticipated innovations in peripheral and input-output equipment, probably the most lethargic segment of the dynamic hardware market, are described, and a survey of network and communications activity examines future directions this rapidly-expanding field might be expected to follow.

Whenever possible in each of these areas, examples with descriptive characteristics, accompanied by cost and performance statistics, are presented in support of the initially-forecast broad technological trends. These examples, chosen for illustration, represent new hardware products, advanced technologies in the developmental stages, or planned enhancements of existing product lines.

TECHNOLOGICAL TRENDS

In 1970 the largest second-order suppliers to the computer industry, the semiconductor manufacturers, were doing a 348 million-dollar business annually, producing logic components and peripheral system elements while developing the technology to permit integration of larger logical functions on a single semiconductor chip.[1] Large-scale integration, the hallmark of the fourth generation, is the name given the technology used to produce high-density electronic circuits. Although not defined precisely, it is generally interpreted to imply over a hundred "gates", or individual circuit functions, at a density exceeding 50,000 components per square inch.[2]

Major benefits and industry-wide trends resulting directly from the steady improvement in production of LSI modules and fabrication techniques are:

- *reduced cost per logic function, or memory bit, with an accompanying decrease in physical size,*
- *increased complexity with implied enhanced capability and performance, and*
- *improved reliability.*

These trends can be expected to continue. Today, chips less than a quarter of an inch on an edge incorporate well over 20,000 components at a cost under a small fraction of a cent per component.[3] This low cost is achieved primarily by economies of volume production, although advances in semiconductor fabrication techniques, and adoption of computer-aided design (CAD), manufacturing (CAM), and automated component testing procedures have played a part. The reduction in the number of interconnections and components brought about by LSI has contributed to the realization of both increased complexity and higher reliability in the hardware product. It is, and will remain, expensive to produce custom-tailored LSI; standardized circuitry is required for low prices. A plot showing the density and cost of integrated-circuit components over the 1960-1980 time period reconstructed from an August 1973 Scientific American article is shown as Figure 2.[4]

Semiconductor manufacturers concentrated much of their early LSI effort on the production of computer memory arrays because of their inherent regular structure and potential volume market as a replacement for magnetic-core storage. Fabrication technology known as MOS, for metal-oxide-semiconductor, was introduced to achieve higher-component density than realizable with the older, higher-speed "bipolar" technique. Early utilization of semiconductor memories was limited, because of cost considerations, to read-only memory (ROM) control storage or to small arrays of read/write memory (RAM) employed, in hierarchical memory organizations, as buffers or caches. In 1971 IBM delivered the first System 370/145 with its semiconductor main memory, and finally, during the 1972-73 time-period, semiconductor storage overcame the cost advantage maintained for so long by magnetic-core technology.

The MOS process was also utilized in the manufacture of chips for the popular, electronic desk and pocket calculators, which created a new large-volume semiconductor market. As an outgrowth of this effort, and in an attempt to stimulate sales of its semiconductor memory modules, Intel Corporation in 1971 announced the first, programmable, single-chip LSI processor. Soon other microprocessors appeared; these "micro" versions of the traditional CPU—the computer's control and arithmetic-and-logic units—were quickly incorporated in a variety of applications ranging from electronic games to point-of-sale and bank terminals, and laboratory instrumentation. Combined

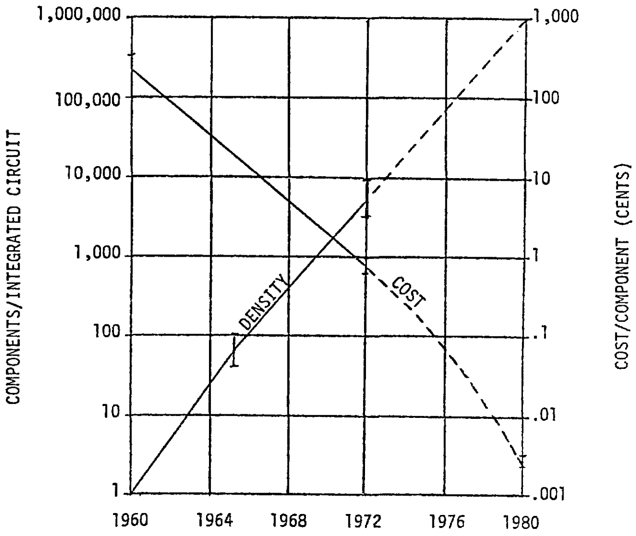

Figure 2—Density and cost of integrated circuits for the period 1960-1980

with timing, memory, and input-output facilities the long-heralded "computer-on-a-chip", or perhaps a few chips, had arrived. The microcomputer is here, and in time we can expect a nanoprocessor, capable of instruction times in the range of 100 nanoseconds. Nanoprocessors can be implemented in bipolar technology if kept simple; bipolar has yielded speeds well under 100 nanoseconds for 1024-bit RAM and ROM chips, and cost is decreasing rapidly to levels comparable to the MOS devices.[5] A silicon-on-sapphire (SOS) approach offering increased speed and component density shows promise for the future.

Entire new areas of applications have become accessible to the computer industry with the advent of the inexpensive yet powerful microprocessor. Trends in progress, or anticipated, as a result include:[1,6,7]

- *"intelligence" added to practically every type of control and data entry equipment (i.e. remote sensor and monitoring devices, automobiles, appliances, process control, data entry, graphics, and word-processing terminals),*
- *dedicated small digital systems incorporated in computer subsystems (e.g. computer peripherals controllers, communications controllers), and*
- *evolutionary changes in system design occasioned by the availability of near "zero" cost hardware and the attendant distributed intelligence possibilities.*

In addition to the trends forecast as directly attributable to LSI technology and the availability of microprocessors, a review of characteristics, components, and the organization postulated for next decade's computer indicates:[8,9]

- *processor speeds greater than 100 MIPS (million instructions per second),*
- *increased size (up to 100 megabytes) of semiconductor main memory,*
- *available on-line archival mass storage facilities using different technologies,*
- *architecture directed toward multiprocessor network configurations utilizing multilevel memory, and computer, hierarchical organizations,*
- *extensive use of microcode to accommodate dedicated or special processes and distributed-function concepts,*
- *decentralization of communications, input-output, and peripheral file management subsystems,*
- *firmware implementation of many of today's operating system features and other system software,*
- *incorporated performance-measurement monitoring, maintenance, and error-logging, and fail-soft and fault-tolerant design for increased hardware reliability and availability.*

Historically, computers have been classified as small, medium, or large-scale primarily on the basis of price and performance. Size defined the minicomputer of the sixties and the microcomputer in this decade. Such distinctions are no longer relevant; a full spectrum of computer power from microprocessor to mainframe is available for the choosing. The user pays his money and takes his choice, and he has progressively, year by year, been offered more performance for his dollar. This trend can be expected to continue, particularly at the low end of the spectrum. Tomorrow's moderately-priced computer system will afford the user much the same computing power as today's high-priced spread; the low-priced system can be expected to provide moderate capability at a reduced price, etc. Price in the computer industry is negatively correlated with quantity, or market volume. This coupling could cause the most significant impact on the scientific community, and ERDA, of all these trends. The larger, more powerful, state-of-the-art processors required for ERDA's programs will tend to represent an increasingly smaller fraction of the market; consequently, fewer such computers will be developed, and those will tend to be expensive when compared, on a cost-performance basis, to the models produced in response to market demand. Two possible reactions, should such a situation come to pass, are the approach taken by the Controlled Thermonuclear Research (CTR) Division in providing computer capability for its program, and the action taken earlier by the AEC in ensuring adequate computational resources to meet laboratory requirements. The CTR approach is to provide the top-of-the-line, number-crunching capability at a single-site, the Lawrence Livermore Laboratory, together with the network and station facilities necessary to make this power accessible to off-site program participants. The LARC and STRETCH projects were cooperative ventures undertaken by the AEC with Remington Rand and IBM to develop the computer capability needed for the Commission's research and development activities.

LARGE-SCALE COMPUTERS

About four years ago at the Idaho Falls topical meeting of the American Nuclear Society's Mathematics and Computation Division, Jack Worlton of the Los Alamos laboratory, presented an entertaining talk on a theme similar to the one covered by this paper. At that time, he noted that the IBM 360/195 and the CDC 7600, both capable of executing ten million instructions per second, were the fastest computers installed, and speculated that even faster computers would be delivered in the next few years.[10]

The number of faster computers delivered in the intervening years has been dismally small, and their power has not been uniformly impressive. ILLIAC IV, the Texas Instruments ASC (Advanced Scientific Computer), and the Control Data Corporation's STAR-100, all unconventional machines from a system architect's point of view, have arrived on the scene, each culminating about ten years of research and development effort. Standing in the wings is CRAY-1, the initial product of Seymour Cray's Cray Research, Inc., which is expected to provide five times the performance of the CDC 7600 when delivered in January of next year.

Meanwhile, work on the CDC 8600 expected as a follow-on to the CDC 7600 has been discontinued; neither the postulated IBM 370/178 nor FS, the giant's Future System has emerged. Instead, CDC is upgrading their 7600 system, IBM has announced enhancements to their 370/158 and 168, UNIVAC has souped-up its 1100 series, and Amdahl recently delivered its first machine, the 470 V/6 aimed at the IBM 370/168 marketplace. The future of large-scale, fast and powerful scientific computers is unclear.

ILLIAC IV is generally described as a parallel computer, or array processor. The concept was first explored in the early sixties at the Westinghouse Electric Corporation on the premise that large-scale computing could be characterized as repetitive execution of the same algorithm on different data streams.[11] The assumption that much of the cost of that day's conventional computer was associated with the control logic also had an influence on the design. Inherent in the Westinghouse SOLOMON design is the concept of many simple, identical processors, each programmed by a common central control unit to directly simulate the physical process being studied.[12,13] The basic system considered, consisted of multiple processing elements, (PEs), configured in an array, with each PE a complete arithmetic-and-logic unit capable of executing a full instruction set. Each element contained its own memory unit, could optionally execute or ignore a given instruction, and could transfer data to any of its four nearest-neighbors.

During the latter part of 1966 a project was initiated at the University of Illinois, funded by the Advanced Research Projects Agency (ARPA), providing for construction by the Burroughs Corporation of the ILLIAC IV parallel computer based on the prototype SOLOMON studies.[14] Sixty-four PEs were implemented in ILLIAC IV, each with a memory unit capable of storing 2048 64-bit data entities in a variety of 8-, 32-, or 64-bit fixed and floating-point formats.[15] In addition to this 8.4 million bits of main memory, the machine has a one-billion-bit diskfile secondary memory, and a one-trillion-bit archival storage subsystem. A front-end Burroughs 6500 computer was incorporated in the design to control the laser-beam read and record third-level memory, the usual array of peripheral card, printer, tape, disk and display equipment, and telephone-line communications. The machine was designed to be accessible to ARPA research contractors via the ARPANET resource-sharing network. Since the ILLIAC IV project was moved to the NASA Ames installation in California little has been heard of it, except for occasional mention of the fact that the system is not operational.[16] At the IEEE Lake Arrowhead Workshop in 1973 D. L. Slotnick, who was responsible for the project at the University of Illinois, was quoted as commenting that in an up-to-date miniaturized ILLIAC IV the processing elements would be in the reading heads of a disk.[17]

Starting with the overlapping of input-output and peripheral device operation with CPU execution 15 years ago, designers have successively introduced forms of parallelism in the initially serial stored-program computer in an attempt to achieve higher-performance with existing components and state-of-the-art technology. Pipelining techniques are implemented which segment the various stages of instruction execution and pass operands from one to the next to allow many operations to be in progress simultaneously. Multiple functional units are incorporated to permit several operations to be executed simultaneously, and microprogram control is utilized to meet the associated timing constraints. To provide the supply of operands required at a rate consonant with the CPU operation memory modules are interleaved, data paths widened, instruction stacks with "look ahead" logic and cache memories are added. In three of the available large-scale systems—the CDC STAR-100, TI's ASC, and the CRAY-1—vector capabilities have been included in the machines' instruction sets to achieve increased processor speed, leading these computers to be referred to as vector processors.

Development programs for the STAR-100 and ASC were initiated in the mid-sixties and, to date, two STARs and six ASCs have been delivered. Both STAR-100s are at the Lawrence Livermore Laboratory where personnel have been involved in the STAR development from its inception. Three ASCs are in use at Texas Instruments, one for system development and two on contract seismic applications; a fourth is employed on seismic work in the TI Amstelveen, Holland facility, and the fifth and sixth are at the Army Ballistic Missile Defense Agency Huntsville research center and the NOAA Geophysical Fluid Dynamics Laboratory at Princeton University. When Cray Research, Inc. was established in April of 1972 work began on the initial CRAY-1 machine. It is expected to be available for delivery in January 1976, and a second unit is under construction in Chippewa Falls.

A table summarizing characteristics of these three machines is shown as Table I.

Several features of these machines deserve mention as illustrative of the trends projected earlier. In the STAR-100 the CPU's stream unit, which directs the instruction and operand streams into the arithmetic unit, uses microcode resident in two 80-nanosecond ROM components to initiate and terminate vector and string operations and to monitor interrupt conditions.[18] When an interrupt occurs, information necessary to restart is saved, an interrupt flag is set, and the microcode program triggers the exchange from job to monitor mode. In the stream unit, too, is the 256 64-bit

TABLE I—Characteristics of the Available Vector Processors

CPU:	STAR	ASC	CRAY-1
Instruction size (bits)	32 or 64	32	16 or 32
Clock period (nsec)	40	60	12.5
Instruction stack/buffers	32 words (2048 bits)	16 or 32 words (512 or 1024 bits)	256 parcels (4096 bits)
Functional units	3 1 string unit 2 floating-point units	1, 2 or 4 pipes, with memory buffer unit & arithmetic unit	12 3 integer add 1 integer multiply 2 shift 1 pop. count 2 logical 1 floating add 1 floating multiply 1 reciprocal approx.
Program-addressable registers	256 64-bit	48 or 96 32-bit	8 64-element 64-bit 73 64-bit 72 24-bit 1 7-bit
MEMORY:			
Technology	magnetic core	bipolar semiconductor	bipolar semiconductor
Word length (bits)	64	32	64
Address space (words)	4×10^{12}	16M	4M
Data path width (bits)	512 (=1 s(uper)word)	256 (=1 octet)	64
Cycle time	1.28 μs	160 nsec	50 nsec
Size (words)	512K or 1M	128K to 16M*	1M
Organization/interleave	32 banks	8 module	16 banks
Maximum band width (words/sec)	200×10^6	400×10^6	80×10^6
Maximum band width (bits/sec)	12.8×10^9	12.8×10^9	5.1×10^9
Error checking	2 parity bits/word	single-bit error correction double-bit error detection	1 parity bit/word
LOGIC:**	TCS	ECL	ECL

* optional MOS semiconductor memory extension of up to 1M words with 1 μs cycle time and 64×10^6 band width

** TCS (transistor current switch), ECL (emitter-coupled logic)

register file which is implemented in read-or-write semiconductor hardware with a 20-nanosecond cycle time. The register file provides instruction and operand addressing, indexing, stores constants and field-length counts, and is the source and destination for the register-to-register three-address type instructions.[19] Distributed-function architecture is realized in the I/O Station concept of the STAR system. An I/O Station consists of a station control unit (SCU) and a station buffer unit (SBU) together with the hardware for the particular function being controlled. The SCU is a 16-bit minicomputer with 8-64K words of 1.2 ms core, CRT display, and refresh microdrum; the SBU is a 32K 16-bit word core memory. System autoload, diagnostic testing, and performance monitoring take place in the Maintenance Control Unit on one of the system's I/O channels; others accommodate the STAR paging, unit record, tape, and disk stations.

In the ASC system the peripheral processor assumes the system control and data management functions. It is designed as a multiprocessor with eight independent virtual processors, (VPs), sharing a common 4K 32-bit ROM, arithmetic unit, instruction processing unit, central memory, and access to the communication register (CR) file where control and status information necessary for system coordination is stored. Use of these shared facilities is distributed either dynamically, to suit individual processing demands, or equally with two 65-nanosecond cycles assigned each VP every 1.4 μs. The ASC operating system executes in the peripheral processor taking advantage of its hardware features. Most important of these, complete access to central memory, permits a single re-entrant copy of code to be accessed by all VPs.[20] ASC data communications are controlled by a TI980A minicomputer specially-equipped for the task; transfer rates up to 240,000 bits per second are supported.

The CRAY-1 design, which retains much of the flavor of the 7600, is based on a 1024-bit, bipolar RAM chip with a cycle time of 50 nanoseconds. The system consists of the central processor with 1M words of central memory, 12 I/O channels, a maintenance control unit, and a CDC 819 disk subsystem. All units are tightly synchronous with a clock period of 12.5 nanoseconds. The memory is organized as 16 banks of 65,536 64-bit words. Each memory module consisting of 64 chips, 32 per side, represents a bit position; 64 modules constitute a bank of 65,536 words. Two banks are packaged vertically per chassis with the eight memory chassis positioned four on each side of the CPU in the CRAY-1 main frame.

Contained in the central processor are four instruction parcel buffers (IPBs), over 150 program-addressable registers, and 12 independent algorithm or functional units. Each CRAY-1 instruction is either a one-parcel (16-bit) or two-parcel (32-bit) instruction. The 64-parcel instruction buffers are organized in 4 to 1 correspondence with the 16-memory banks so that the first four parcel positions in a buffer are always filled from bank 0, parcels 5 through 8 come from bank 1, etc. This feature, combined with the use of four 64-bit paths, in parallel, between memory and the IPBs, makes possible a transfer rate of four words per clock period. Buffers are filled in turn; whenever an instruction fetch from memory is required, the "least recently filled" IPB is used. The fetched instruction is always read in with the first parcels regardless of its memory bank source and associated buffer-position destination.

The machine complement of program-addressable registers resembles a greatly-expanded CDC 7600 collection. Registers have been added to hold vector instruction parameters and to serve as source and destination addresses for operands in, up to 64-element, vector arithmetic and logical instructions. In addition, the eight principal address-length registers used as address registers for memory reference and index registers, and the eight principal word-length registers which act as source and destination registers for scalar operands, are each backed-up by 64 secondary registers designed to provide quick-access, temporary storage. Operands can be recalled from secondary to principal register storage in one clock period, and the secondary registers can be loaded from memory, or stored away in stream-fashion with a single block copy command at the rate of one clock period per operand after a startup period. Contents of a vector register are stored in, or loaded from, memory by specifying the initial address, an increment for succeeding addresses, and the vector length, at a one-clock-period rate once eight elements have been transferred.

Functional units are designed with one-clock period segmentation; the source and destination addresses are limited, and the algorithm chosen so that the time required for each unit to complete its task is fixed.[21] In vector mode results are produced at a one-clock-period rate, and these results may interact with other vector instructions in "chained" operations since all functional units have the same result rate. Three integer add units, an integer multiply, two shift units, a population counter, two logical operations units, and floating-point add, multiply, and reciprocal approximation units are included in the central processor. The machine performs floating-point division by reciprocal approximation; four instructions are necessary to obtain 48-bit precision. When vectors longer than 64 elements are used, programming is required to divide them into 64-element sequences for processing.

Twelve full-duplex, 64-bit wide, input-output channels are included in the CRAY-1 system; however, the only peripheral equipment supplied will be the CDC 819 disk which is used as the resident device for the operating system. The system described is priced at 7 to 8 million dollars and purchasers are expected to acquire their unit record, disk, tape, display, and terminal equipment from other vendors.

Today, although both STAR and ASC systems are in operation it is difficult to find performance comparisons with conventional machines or published benchmark problem results. The "promised" computing power of vector processors a decade ago has yet to be realized. The architecture is designed to optimize vector-mode operations in which the vector elements are at contiguous storage locations, and the number of elements in the vector is large; the latter is especially true in the STAR-100 implementation. Consequently, it is essential that programs written for these vector processors exhibit a high ratio of vector to non-vector (scalar, branch, test, execute) instructions and that both code and data be ordered to minimize memory references and maximize parallel operations. Over the past six years LLL computer personnel have been working on the construction of the STAR operating system and related software to achieve their announced goal of incorporating the machines as worker computers in the Laboratory's OCTOPUS time-sharing network.[22] During this same period they have developed techniques and methods for transforming existing large production codes into "vectorized" STAR code.[23] This has proved to be an arduous task.[24]

Texas Instruments has, since 1968, been developing a sophisticated FORTRAN compiler, ASC NX, with array-oriented language extensions to generate "vectorized" code for their machine.[25] The NX compiler translates FORTRAN DO-loops into vector instructions, and, if instructed that the code is for a multi-pipe machine, can introduce parallel instruction streams. An extensive optimization analysis is performed and as output, the programmer receives information intended to assist hand-tailoring of the source code to allow further iterative compiler optimization, if desired. Factors to be considered, and techniques, for improving the efficiency of execution of ASC scalar instructions were presented in a recent paper.[26] Table II summarizes performance statistics which have been reported for the two machines.

The CRAY-1 second generation vector processor is obviously intended to take care of many of the problems that have been encountered in attempting to use the first-generation processors, and both CDC and TI are planning for the future. CDC expects to replace their core memory with a bipolar semiconductor memory and to add a front-end computer to the system. Before the year is out, they intend to announce STAR as a product, send staff to Livermore to assist with the STAR-OCTOPUS merger, deliver model 103 to

NASA Langley, and add 104 to their own CYBERNET computer service network. TI is readying a 61,500 word per second mass-storage videotape subsystem for use with the serial 4 ASC at the Princeton Geophysical Fluid Dynamics Laboratory, and that machine's main memory will probably be expanded to 4M words utilizing a 1024-bit memory chip with a 100 nsec store time instead of the present 256-bit chip. Serial 7 will be delivered to the Naval Research Laboratory in January of next year and late in 1976 announcement of a 6-megaword compatible channel can be expected. Presently being looked at as a cost reduction measure is a 16M-word-memory design incorporating a 4K MOS chip with 200 nsec access and increased interleaving. The company is interested, also, in locating a customer seeking faster scalar capability; they believe a two- to fourfold increase in speed can be realized within two years, following such an order.

While the array and vector processors were being designed and constructed, the mainstream large-scale computer systems were evolving toward a flexible, modular architecture in which the major system components such as memory, processor, and input-output control are treated as logically separate entities. Keenly aware of the user's evergrowing investment in applications programs and computer-based data, manufacturers have attempted to structure their product lines to accommodate the user. The number and performance capabilities of the component units can be tailored to meet budget constraints and growth requirements, and technological advances offering improved component performance can be incorporated quickly and effectively, all with minimal impact on the user's operation. Increasing emphasis is being placed on system reliability and availability.

Control Data Corporation's 7600 has found wide acceptance in ERDA laboratories and the nuclear industry where 18 of the 38 delivered systems are employed. Later this year the company plans to enhance this system with expanded and improved memory components. Characteristics of the current and proposed 7600 SCM and LCM units appear in Table III. The CTR Computer Center at Livermore is scheduled to receive the first of the small semiconductor memory models during the latter half of this year, and the revamped 7600 can be expected to appear in CDC's product line about a year later.

TABLE II—Performance Statistics and Comparisons of Vector Processors Relative to the CDC 7600 and IBM Model 195

COMPUTATIONAL MODEL OR PROBLEM	CDC 7600 OR IBM 360/195	STAR	ASC	CRAY-1
Scalar	1	0.25		5
Vector				
(10 elements)	1	0.4		6
(25 elements)	1	1		
(200 elements)	1	5		
(1000 elements)	1	5		10
Scatter-Gather	1	0.67		5
1-D HYDRO	1	1.6		
Matrix Inversion				
(25×25)	1		1.58	
(50×50)	1		1.75	
Matrix Multiplication				
(25×25)	1		1.27	
(50×50)	1		1.32	
GFDL models	1		3 to 14	
GFDL jobstream	1		2.5 to 3	

IBM announced the 168-3, an enhancement of their 370 Model 168, in March of this year; first customer shipment is scheduled for June.[27] Using a new 1K bipolar chip IBM has increased the machine's 80 ns cache buffer memory capacity from 16K to 32K bytes. New microcode in the processor's reloadable control increases the speed of a number of frequently-used instructions and internal interrupts. A service processor added to the 168-3 monitors and stores machine status information to aid engineers in servicing and diagnosis of machine failure; the service processor also provides a teleprocessing interface with the company's Field Engineering Large Systems Support Center.[28] A 5 to 13 percent increase in performance has been predicted for the improved 168, which is priced at 5 million dollars when equipped with the top-of-the-line 8-megabyte memory.

TABLE III—Characteristics of CDC 7600 Memories

	CURRENT		PROPOSED	
	SMALL	LARGE	SMALL	LARGE
Technology	core	core	semiconductor	core
Size (words)	32K or 64K	256K or 512K	64K or 128K	512K, 1M, or 2M
Organization (banks)	16 or 32	4 or 8	16 or 32	2, 4, or 8
Cycle time (nsec)	275	1760	110 read, 165 write	1760
Holding register (words)		8		16
Error checking	5 parity bits/word	4 parity bits/word	single-bit error correction double-bit error detection	

In March, too, Sperry Univac announced its 1100/40 system, successor to the 1100 as the largest of the firm's large-scale systems.[29] The 1100/40, like the 1110, has two levels of memory: a primary memory with from 28K to 512K 36-bit words and an extended memory with 128K to 1M-word capacity. Implemented in 1K bipolar the 1100/40 main memory offers double the primary storage available with the earlier plated-wire technology. This memory has 280 ns read and 380 ns write time, while the extended MOS memory for the 1100/40 has an 800 ns cycle time. The processor component in the system is the Command/Arithmetic Unit (CAU) with 300-nanosecond basic instruction time and 1.8 MIPS capability.[30] Input/Output Access Units (IOAUs) control communications among system components and peripheral input-output. Multiprocessor configurations as announced offer up to four each CAUs and IOAUs. Gains of 10 to 25 percent in throughput over the 1110 are expected for the new system. Recently, NASA selected this system for a potential 8-million-dollar space shuttle simulation complex at the Houston Johnson Spacecraft Center. The NASA system will have 6 CAUs and 3 IOAUs extending the 1100/40s multiprocessor capability.

Advanced LSI technology is stressed in the newest entry in the large-scale computer industry, the Amdahl 470 V/6. This machine is designed to compete for the IBM 370/168 market using slightly-modified IBM software systems and, like the CRAY-1—letting the customer select his peripherals from other vendors. Central processor circuits are custom-designed emitter-coupled logic.[31] The Amdahl LSI chips, 10 mils thick and measuring 0.154 inch square, can hold up to 100 circuits; speeds on the chip are on the order of 600 picoseconds. Chips are mounted on a ten-layer multilayer board in specially-designed multichip carriers, (MCCs), which serve as the field-replaceable unit. Fifty-one MCCs, each containing about 3000 circuits, make up the 470 V/6 CPU and channel. From 1 to 8 megabytes of directly-addressable MOS memory is offered with a 16K high-speed bipolar cache and 16 I/O channels in the basic configuration. The channels provide standard 360/370 interfaces for attachment of peripheral devices. At the system console, equipped with keyboard/CRT display, minicomputer, cassette tape reader, modem, and disk storage unit, console operation, hardware control, and system maintenance functions are carried out. The first Amdahl computer, delivered to NASA's Institute for Space Studies at Columbia University the beginning of June, was up and running in a week's time.[32] Table IV shows some reported single-job NOAA benchmark comparisons of the 470 V/6 with the IBM Model 195.

TABLE IV—Benchmark Performance Comparisons of the Amdahl 470 V/6 with the IBM Model 195

		Amdahl 470 V/6	
	IBM Model 195	CPU	Total
1A	1	.71	.69
1B	1	.58	.59
2	1	.52	.56
2 Main step	1	.52	.57
3	1	1.31	1.06
3 Main step	1	1.30	1.03

MICROPROCESSORS AND MICROCOMPUTER APPLICATIONS

In fiscal year 1974 over half of the computers in the Atomic Energy Commission were Digital Equipment Corporation machines.[33] A large majority of these were minicomputers incorporated in dedicated laboratory applications. It is reasonable to expect that, in the future, with the growing availability of microprocessors and microcomputers, the instrumentation and computer requirements for many ERDA laboratory applications will be supplied by cheaper, smaller, more specialized, and more reliable LSI technology. This year DEC introduced an LSI-11 microcomputer at the low end of its PDP-11 product line. An LSI-11 configured with 64K bits of read/write memory, 64K bits of PROM (programmable ROM) memory, a 16-bit parallel input-output interface, and floating-point arithmetic is available at a cost of around 1500 dollars. The PDP 11/40 instruction set is emulated in microcode.

Two laboratory applications of microcomputers at LLL were reported in a paper presented at a February computer conference.[34] One dealt with tritium monitoring in various environments; the second was concerned with calculations on spectral data output from a pulse height analyzer. LSI technology is particularly adaptable to the area of environmental monitoring, and the low cost of microprocessors and microcomputers can be expected to lead to new applications not previously considered.

MASS STORAGE SYSTEMS

In the past year with the announcements of the IBM and CDC mass storage systems there has been a resurgence of interest in archival mass storage to replace manually-mounted magnetic tape, to allow installations to service evergrowing numbers of interactive users, and to place burgeoning data bases on-line particularly in a multi-computer environment. To appeal, such systems must be available at a cost approximating that of magnetic tape and be easily integrated into the customer's operation.

The IBM 3850 Mass Storage System (MSS) is a hierarchical storage system capable of storing and managing up to 472 billion bytes of data on-line.[35,36] The data is stored on 64-foot lengths of magnetic tape, about 3 inches wide, "spooled" in plastic cartridges, 4 inches wide and 2 inches in diameter. Data recorded on the tape as IBM 3336-1 cylinder images, each cylinder appearing at a fixed location on the tape. A single cartridge can contain 202 cylinders; a pair of cartridges, the equivalent of one disk pack, is referred to as a mass storage volume (MSV). All space in the MSS is managed in terms of these MSVs. Cartridges are stored in cells in a honeycomb arrangement in the unit. Data are transferred from the cartridges to staging buffers (dedicated 3330 drives) when requested. Once staged there, data are accessible just as any other data resident on a 3330. When no longer needed, and the space on the staging device is required for other data, any "cylinder" containing new or updated data is destaged back onto the data cartridge. MSS uses a "least recently used" replacement algorithm. Important concepts in the IBM 3850 implementation are the ideas of virtual device and virtual volume. The virtual device concept allows more drives to be addressed than actually exist in the hardware configuration. The virtual volume concept allows many partial MSVs to reside on a single staging drive, or different parts of an MSV to reside on several staging drives. Industry sources believe IBM already has 700 to 1000 firm orders for the 3850.[37]

The CDC system is composed of a mass storage adapter (MSA) unit and a mass storage facility (MSF) with two, three, or four read/write stations mechanically coupled to a cartridge storage unit.[37] The cartridge file provides storage for up to 16 billion characters. The MSF may be configured modularly in sizes greater than 16 billion bytes. A single MSA can handle up to 8 or 16 elements depending on the model; an element is defined as either a read/write station or a cartridge storage unit. Up to 8 MSAs can be attached to a single 3830-2 controller. Data in the MSF are recorded on 100-inch lengths of 2.7-inch-wide magnetic tape in a 9-track format at 6250 bpi density. One hundred and forty-four tracks can be recorded. The tape strip, containing up to 8 megabytes of information, is enclosed in a plastic cartridge, measuring 1.125″ x 1.25″ x 3.3″. Two thousand such cartridges are stored in the rectangular array of cells making up the cartridge file. When a data set is required the applicable data set cartridge is located by its x-y coordinate address in the file, selected from its cell by the unit's cartridge selector, a pneumatic pick mechanism, and transported to a read/write station. At the station the cartridge is opened, the tape unwound, and drawn into two vacuum columns for reading. After being read the tape is rewound into the cartridge, and the cartridge is sealed and returned to its file location. The tape is never detached from its protective housing. Data can be staged to any available disk space in the host system, or staging can be eliminated altogether. Data sets can be read directly to main memory and returned directly to the cartridges, if desired. Two cartridge I/O drawers, with 8 cartridge slots apiece, allow the operator to enter and remove cartridges from the unit manually, and a write-inhibit plug can be used to ensure that master library tapes are not written over accidentally. A CDC MP16 minicomputer incorporated in the MSA performs on-the-fly error correction and detects illegal commands and incorrect sequences. Control Data estimates ten million dollars has been spent over the past five years developing this system.[38] One of the first systems scheduled for shipment in the fourth quarter of 1976 will go to LLL.

Two other currently-available mass storage systems are the CalComp Automated Tape Library (ATL) and the Ampex TBM Mass Storage System. The ATL was originally designed and marketed by Xytex Corporation of Boulder, Colorado.[39] In early 1974 CalComp acquired the company, which was formally merged into XTX, a wholly-owned CalComp subsidiary in January of this year. ATL is a modular system with a basic configuration of a control unit, two storage units, a reel selector mechanism, and one automatic reel-mounting unit servicing one tape drive. This configuration is capable of storing 762 tape reels, and can be expanded by incremental addition of storage units and tape drives to accommodate 6250 magnetic tape reels and 32 tape drives. Under computer control the storage system automatically retrieves requested tapes, mounts them on the self-threading tape drives for system use, and dismounts and refiles them upon job completion. A complete inventory of status, usage, and location information for all tape files is maintained.

Ampex's random access terabit memory utilizes standard 2-inch-wide video tape recorded in a block format to provide up to 350 billion bytes of data on-line at a cost of about .0001 cent per bit.[40,41] Each block is identified by a unique address allowing block-address searches, forward and backward, at 1000 inches per second. The system is in two parts: a data storage section composed of the transport modules, transport drivers, and data channels, and the control section with its storage control processor for system control and data channel processors to control data transfer between the TBM and the host computers. Each transport module includes two transports and has an 11-billion-byte capacity; a TBM system can have up to 32 transport modules, and with up to six transport drivers up to six concurrent accesses are possible. Each data channel unit performs independent read and write operations at a rate of 700 kilobytes per second. With three data channel units, the system maximum, six simultaneous read/write commands yield throughput of 4.2 megabytes per second. Switching matrices allow any transport to be accessed by any driver and data channel and provide flexibility for dynamic reconfiguration and off-line maintenance of part of the system. The TBM is capable of operating independently of host processors; when used with host computers, the system can either stage data to shared disks or route the data directly to host channels.

The availability of two additional mass storage systems is questionable at this time. These two are the Precision Instrument trillion-bit laser-based mass storage System 190, a follow-on to their UNICON system which is installed on ILLIAC IV, and the Grumman Masstape system, presently under reevaluation by its developers.[42,43] System 190s had been ordered by the Social Security Administration, and by Holifield National Laboratory for ERDA Technical Information Center applications, before the company went into receivership. Refinancing plans have recently been announced, and it is now probable System 190 will be marketed. Characteristics of these two systems, as well as those of the IVC-1000 video tape recorder being adapted by TI for the GFDL ASC, have been included in the Table V mass storage system summary.

ALTERNATE STORAGE TECHNOLOGIES

Alternate storage technologies bridging the classical memory access gap between main memory and the peripheral storage devices, and at the same time, offering the per bit cost of the rotating disks and drums, have been the object of continuing research. During the past five years three areas in which there have been significant development efforts are: charge-coupled devices (CCD), bubble domain technology, and electron-beam addressed memories. The first two have been described as belonging to the "moving the bits to the sensor" philosophy, while the third applies the "moving the sensor to the bits" approach.[45]

The CCD is, basically, a shift register for analog signals made in the form of a string of MOS capacitors. CCD memories, being serial in nature, are block- rather than bit-oriented. Primary incentive for CCD memory development is its potential low cost derived from higher packing density and the inherently simpler fabrication. One drawback is the long access time associated with the serial nature of CCD technology. At this year's National Computer Conference, Fairchild described their CCD 450 9216-bit storage which is organized as 1024 9-bit bytes.[46] The unit is viewed as a possible storage unit for portable terminals where its byte format and low power features can be exploited.

Throughout the past five years magnetic bubble memories have been envisioned as a technology which is just two to three years away. Their most attractive characteristic is their non-volatility. Like CCD technology, the bubble domain systems offer low power consumption and high density per chip. By November of last year prototype bubble memory systems had been constructed by three companies, and Rockwell presented three illustrations of the technology at the NCC.[47] One application was as a spacecraft tape recorder replacement, the second as an alternative to a tape cassette or floppy disk in a data logging device, and the third example was a block-organized memory for a data processing system. Access time quoted for the 64K-1024K, 16-bit, block-organized memory was 0.5 to 1 ms at a 0.05 cent-per-bit price.

Electron beam technology which dates back to first-generation computer memories, is once again showing promise. General Electric's Research and Development Center is presently building 32-million-bit BEAMOS (Beam-Addressed MOS) memory modules in pilot quantities.[48] The BEAMOS module consists of a memory plane and electron-beam accessing system enclosed in a glass envelope; it has an access time of 30 μs and a transfer rate of 10 megabits per second. A "matrix electron lens" with 289 lenslets is used to direct the cathode-ray-tube beam to read, write, or erase at precise sites on the four silicon storage chips of the memory plane. Each of the chips holds 8 million bits. In a multimodule system, 16 or more tubes can be linked to provide a 512-million-bit or greater storage capacity. Data transfer rates of 160 megabits per second could be realized by accessing a 16-module system in parallel. Cost of the electron-beam addressed memory system is estimated to be in the .02 to .1 cent/bit range.

PERIPHERAL AND INPUT-OUTPUT EQUIPMENT

Although the industry has been actively seeking an all-electronic auxiliary memory, this has not seemed to discourage efforts in disk technology. New products introduced include the Storage Technology 8800 "super disk" with 800 megabyte capacity and the CDC 819 high-capacity disk subsystem with a 412-million-character capacity. Delivery of the 819, already incorporated in the STAR systems, is scheduled for August. This disk has an average access time of 50 ms, 8.3 ms average latency, and a transfer rate of 6.2 million characters per second. IBM and the IBM-plug-compatible manufacturers continue to turn out the 3330 200-megabyte disks and the Winchester 3340 with its 25 ms average access time. Electronic News reported in May that disk drive shipments by U.S. firms were expected to reach 1.2 billion dollars this year, and tape drive shipments 1.3 billion. The ANSI 6250 magnetic tape standard will soon be out for public review and comment. This tape will become and remain a high-volume product due to its high data rate, low cost, and interchange capability.

Three I/O product areas projected for growth are high-speed printers, intelligent terminals, and floppy disks. Both Honeywell and IBM have introduced non-impact, high-speed printers. Livermore has had two of the Honeywell printer subsystems, which use Honeywell 716 minicomputers as controllers, in use off-line for over a year. Each 12,000-18,000 lpm unit has a read-only memory character generator which prints up to 192 characters using an electrostatic technique. Cost of the Honeywell subsystem is $162,120. In April of this year IBM announced a printer system that combines laser and electrophotographic techniques to

TABLE V—Summary of Characteristics of Mass Storage Systems

	AMPEX TBM	CALCOMP ATL	CDC MSS	IBM MSS	PI 190	GRUMMAN MASSTAPE	IVC-1000
Host interfaces:	IBM 360/370, CDC, DEC	IBM 360/370	IBM 370 CDC	IBM 370 VS only			IBM 370[44] TI ASC
Capacity:	350B bytes	762-6250 reels	16B byte increments	35B-472B bytes	16B byte increments—128B bytes	11.8B byte increments	
Media:	2″ video tape on 10½″ reel	½″ tape on 10½″ reel	2.75″ tape in plastic cartridge	3″ tape in plastic cartridge	rhodium-coated mylar strip	½″ tape in cartridge	1″ video tape on 12½″ reel
Unit capacity:	11B bytes/ module (module=2 reels)	standard 3420 tape	8M bytes	50.4M bytes	200M bytes	36M bytes	9×10^{10} bits
Unit cost:	$150/reel		$15/cartridge	$20/cartridge	$20-$25/strip		
Recording:	transverse VTR, block-addressable	longitudinal	longitudinal	helical VTR	laser beam	file-addressable	helical VTR
Access time:	search 1000 ips	11 to 14 sec	5 sec	3 to 8 sec	7 to 10 sec track access: 220 ms	avg 5 sec max 15 sec	search 400 ips
Data rate:	4.2M bytes/s (6 channels)	1.25M bytes/sec	806K bytes/s from disk 400K bytes/s staging	806K bytes/s from disk 200K bytes/s staging	440K bytes/s	100K bytes/s single file 350K bytes/s per host	1M bytes/s
Price:	$400,000 to $1.5 million	$70,000 to $250,000	~$400,000 (16B system)	$700,000 to $4.5 million	~$400,000 (16B system)		

print up to 13,360 lpm on plain paper. It may be purchased for $310,000, and first customer shipments are scheduled for the third quarter of 1976. The 3800 can be attached to any channel and can print up to 225 characters, in four character sets at a time, on any of 50 page sizes. Characters can be produced in 12 to the inch, and 15 to the inch, as well as in the standard 10 to the inch size. A number of standard character fonts are included. Xerox markets a 4000 lpm page printer, known as the 1200, which is available on a rental basis only; the cost is $1500/month with a monthly page charge of 11 mills each for the first 100,000 pages, 7 mills each for the next 200,000, and 4 mills for each page thereafter. UNIVAC is rumored to be working on a 14,000 lmp laser printer, and at NCC Canon distributed literature on their off-line 1000 to 4000 lpm laser beam unit. Paper costs for the equipment vary as shown in Table VI.

Reports on terminals have predicted a rise from fewer than 200,000 in 1970 to almost 3,500,000 by 1980.[49] LSI technology coupled with the growing trends to communications-based systems and distributed-function architecture make even that estimate appear conservative.

Floppy disk drive sales are expected to show a five-fold increase between 1975 and 1980. Applications of floppies are primarily in data entry systems, intelligent and point-of-sale terminals, and as minicomputer and microcomputer peripherals. The disk holds up to 1898 128-character records and is a very inexpensive memory unit; today's prices vary between $4.50 and $8.00 and reductions can be expected as market volume increases.

NETWORK AND COMMUNICATIONS ACTIVITY

The network and communications area is the area destined to receive the most attention from the computer manufacturers in the next five years. An IEEE Computer Society glossary defines a computer network as an interconnected group of independent computer systems which communicate with one another and share resources such as programs, data, hardware, and software. Under this definition most of today's computer facilities can be classified as networks. With data traffic in the United States growing at an annual rate of 35 percent, computer manufacturers have become increasingly committed to the development of

TABLE VI—A Comparison of Available High-Speed Printer Subsystems

	Honeywell	IBM	Xerox
Technology:	Electrostatic	Laser	Xerographic
Speed (lpm):	12,000-18,000	up to 13,360	4000
Paper-use fees:	$2.61-$2.31/1000	$2.30/1000	1.1 to 0.4¢/ copy
Purchase price:	$162,120	$310,000	NOT SOLD
Rental:	$3667 minimum	$7,344	$2100 or $2600

coordinated hardware and software systems for communications-based information networks.

IBM's effort to provide a single uniform environment for data communications is identified as Systems Network Architecture, or SNA.[50] Digital Equipment Corporation calls its DECNET software a set of tools to allow intersystem communication,[51] and CDC has opted for the title Network Communications System (NCS) to describe a set of hardware and software being produced to accomplish the four processing functions:

(1) interfacing one or more host computers;
(2) interfacing a great number of terminals, often of widely varied use and manufacture;
(3) routing data between its sources and its destinations;
(4) interfacing, within the host computer, between user programs and external communication equipment.[52]

The manufacturers are employing state-of-the-art technology and distributed-processing concepts in implementing communications subsystems to perform some of the functions previously assigned the central processor, such as communications management, data formatting, device control, and even application processing. In addition, they are defining the system software protocols for interfacing. SNA software elements defined include: Virtual Telecommunications Access Method (VTAM) to manage the connection and disconnection of terminals to application programs; NCP, the Network Control Program, to perform tasks associated with physical network requirements; and SDLC, the data transfer protocol defining the format for data exchange between two network nodes. NCP can be resident in a programmable communications controller.

DECNET utilizes three protocols, as well. The first, DAP, for Data Access Protocol, is designed to allow programs on one node of a network to use the I/O services of other nodes; the second, the Network Services Protocol, handles the routing of messages within or between systems; and the third, DDCMP, Digital Data Communications Message Protocol, serves as the data transfer, or link, protocol. Burroughs recently released a Burroughs Data Link Control (BDLC) designated as that company's data transfer protocol. The next step is to get all computer manufacturers to agree on common protocol. It appears adoption of an ANSI standard for data link control is about a year to a year and a half away. Until such a standard is adopted the incompatibility of communications hardware and software products will deter network growth. Once the bit-oriented data transfer level standard has been accepted, standards for the higher-level network protocols should be forthcoming.

SNA hardware to date consists of terminals and communications controllers, some general-purpose and others dedicated to a specific industry, or application. Any new IBM system line, such as FS, is expected to be communications-based. CDC's first step in NCS hardware development was their 2550 Host Communications Processor (HCP) designed to interface terminals to a host computer, such as a CYBER 170. The HCP hardware includes a 16-bit microprocessor and is scheduled for delivery the latter half of this year.

In addition to the prospects of networking capabilities originating with the computer manufacturers, the Argonne, Berkeley, and Brookhaven laboratories are scheduled to complete connections to the ARPANET this year, and the first commercial packet-switched carrier is expected to begin service to customers in a seven-city operation soon.[53]

Four years ago when Jack Worlton concluded his presentation it was with the thought that the long-awaited computer revolution was still a way off. His criterion for determining the advent of such a revolution required that the computer effectively penetrate to a large fraction of the private homes in our society. At such a time he felt it would be valid to speak of a computer revolution, and not until then, and he speculated that maybe this could happen by 1984. It will not be long before the microprocessor, incorporated in washing machines, automatic dryers, etc. will have done just that! By 1984, a personal computer equipped with keyboard/CRT, hard-copy device, and floppy disk could be available for under $500. With corresponding advances in information processing network technology, it will at some point become unprofitable to collect people in office buildings simply to talk to each other and pass papers. Given suitable computing and communications media, work of this nature can be done, possibly more effectively, on a distributed basis by people working at home. This "cottage industry" concept has some interesting social consequences, not the least of these is a reduction in the consumption of energy, which is in short supply, through increased information processing capability, which appears to have no perceivable limit. Indeed, the very existence of the human species is proof that information processing "power" does have survival value!

ACKNOWLEDGMENTS

In preparing this paper information and assistance were requested from a number of sources, who contributed written material and presentations of ongoing research and development efforts. The assistance and cooperation of the following individuals, associated with the computer manufacturers listed, is gratefully recognized:

W. Andreen, D. Baugatz, P. Crum, R. H. Lee, G. Van Guilder, and D. M. Wareham	Control Data Corporation
L. Davis, G. Grenander, and G. Hanson	Cray Research

G. Bell, H. Bynum, P. Christe, R. Corbin, D. Reinke, R. Rutledge, and R. B. Wham	Digital Equipment Corporation
E. E. Hayes	IBM
D. Best, G. Boswell, A. Riccomi, D. Sifferd, and D. Wedel	Texas Instruments
P. Dodge, H. Gyllstrom, F. Lexa, and J. Macina	UNIVAC

At Argonne the secretarial services and editorial help provided by Catherine Hughes, technical discussions with colleagues D. Jacobsohn and W. Lidinsky, and the cooperation of R. Royston are acknowledged with thanks.

An evaluation of the East German RYAD 1040 system

by ROBERT A. KOENIG
Control Data Corporation
Minneapolis, Minnesota

ABSTRACT

In the early 1970's, several East European countries and the USSR developed a compatible computer family called the Unified System, or RYAD. In 1975, Control Data purchased the ES-1040, a member of the RYAD family for testing and evaluation. Performance and compatibility tests were made and the technology was assessed. Tests determined that the ES-1040 is compatible with IBM 360 instruction set. Benchmark programs show the ES-1040 to be twice as powerful as the IBM 370/145 in scientific/engineering applications, and at least as powerful in BDP work. The processor, using TTL IC's lags the U.S. by three years, the core memory shows a lag of about eight years, while peripheral equipment is eight to ten years behind the U.S.

INTRODUCTION

My purpose is to present an evaluation of the East European RYAD 1040 Computer System, and to share with you some of the significant results. Before we go into the details, some background is necessary to set the stage for further remarks.

In 1969, the five year plan for the CMEA (Council for Mutual Economic Assistance) countries specified the development of a computer family called the Unified System of Electronic Computing Techniques. This family is commonly referred to as the RYAD which is the Russian word for series. The CMEA countries consist of Bulgaria, Czechoslovakia, the German Democratic Republic, Hungary, Poland and the USSR. The development and production of the various models were delegated to the different countries, as was the peripheral equipment. In some cases, variants of a single model are produced in more than one country.

The family consists of six processors, numbered from 1010 to 1060, and a complement of peripheral equipment. The family uses an instruction set compatible with that of the IBM 360, and has common peripheral interfaces at the I/O channels. Because of the strong resemblance to the IBM 360/370, much of the evaluation is couched in terms of comparison to the IBM products.

In early 1975, Control Data purchased the largest available member of the RYAD family, an ES-1040 system made by the Robotron organization of the GDR. The system was received and installed at our Plymouth, Minnesota facility in July, and later moved to Washington, D.C. It is now installed in a CDC facility in Vienna.

THE ES-1040 SYSTEM

The system we received consisted of the hardware shown in Figure 1, together with operating software. The computer hardware consists of the central processor, an operator console, a main memory of 256 kilobytes of core storage, a byte multiplexer channel, and one selector channel. The peripheral equipment consisted of a card reader, card punch, line printer, two 7.25 MB disk drives, and two 79 IPS tape drives. I will discuss the hardware characteristics somewhat later.

We augmented the system by attaching some CDC peripheral subsystems normally offered in the plug-compatible market. The augmented system is shown in Figure 2. The specific items we attached, and used

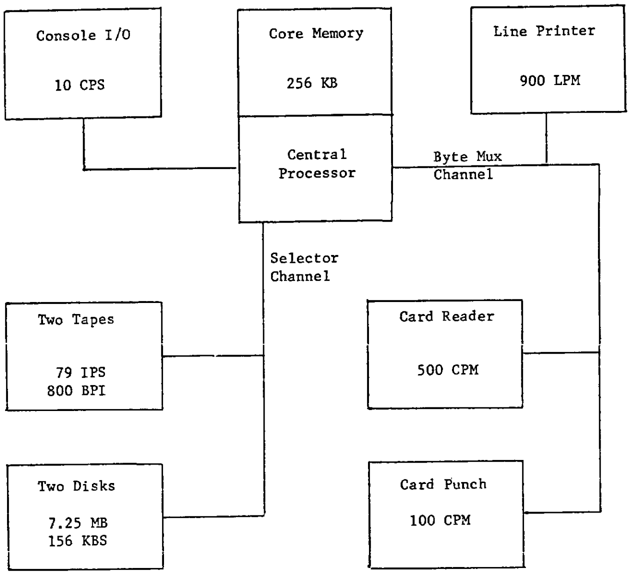

Figure 1

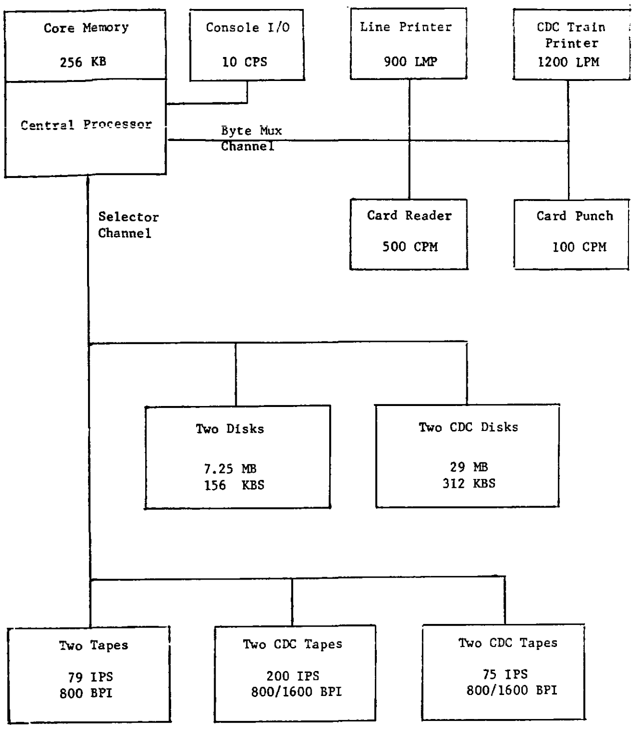

Figure 2

routinely with the ES-1040 consisted of a 1200 LPM train printer, two 29 MB disk drives, and two magnetic tape subsystems. One of these tape subsystems had two 200 IPS dual density tape units, while the other had two 75 IPS dual density drives. All these subsystems operated successfully after appropriate modifications were made.

COMPATIBILITY TESTING

As I noted earlier, the RYAD family uses an IBM 360 instruction set. To test this compatibility we ran a set of jobs from the Service Bureau Company. In this test, SBC personnel brought their operating system, recorded on a 2316 disk pack, customer programs and customer data. The SBC software, normally run on an IBM 360, was loaded into the ES-1040 via an IPL, and the customer programs were successfully executed. In our programming efforts, we routinely used IBM manuals, since the Robotron manuals were written in German, and English language translations were generally not available.

The peripheral equipment used compatible international standards. We interchanged magnetic tapes between the ES-1040 and IBM systems with no difficulty. We also were able to use a 1316 disk pack formatted for an IBM 2311 drive on the system, although we did not test interchangeability since we couldn't locate a 2311. The card equipment uses standard 80 column cards.

DESCRIPTION OF THE ES-1040

In general terms, the ES-1040 processor can be classified as a medium to large machine, falling between the IBM 360/50 and 360/65 in terms of compute power. It is an integrated circuit machine constructed from TTL devices produced in East Germany. These devices are mounted on 72-pack multilayer boards which average four to five layers. The backpanel is wirewrapped, although fully automatic techniques are not used in production. The general workmanship in the processor was very good, and the reliability extremely high. We experienced one hour of CPU downtime during five months of operation, and had no CPU card failures. It is the routine practice to turn off power at the end of each day, turning it on again the following day.

The operation of the processor is based on the use of microprogram control. The microprograms are stored in a ROM core memory containing 3K words of 130 bits each. This memory has an access time of 100 nanoseconds and a full cycle of 450 nanoseconds, the latter constituting a major timing cycle.

Insofar as registers are concerned, the ES-1040 looks very much like an IBM 360. For example, it has 16 general purpose and four floating point registers. Because of its compatibility with the 360, an instruction may consist of two, four, or six bytes. The repertoire contains 143 commands, of which 87 are basic, eight deal with decimal arithmetic, 44 are for floating point operations, two are for storage keys, and the other two are used for direct control.

There are some important differences between the ES-1040 and IBM 360 models as far as the internal design is concerned. As I will bring up later, the 1040 performance is hampered by a relatively slow memory. However, this is masked to a large extent by an instruction lookahead feature. This allows memory accessing, address modification, and instruction execution to be overlapped. When considering the basic TTL circuit speeds and the major timing cycle of 450 nanoseconds, the execution times of complex operations, such as divide, indicate that some rather sophisticated algorithms have been employed.

ES-1040 MEMORY

The ES-1040 uses a main memory constructed from 21 mil cores. It has an access time of 450 nanoseconds, and a cycle time of 1200 nanoseconds, although the effective systems-level time is three CPU cycles, or 1350 nanoseconds. In our machine, the memory is composed of two 128K independent modules. In a maximum system of one megabyte, four modules are used. The access path to memory is eight bytes, with a theoretical bandwidth of 142 megabits per second possible when three or more modules are used. The memory uses a single parity bit for each 8-bit byte.

I/O CHANNELS

As I mentioned earlier, the ES-1040 we received had one byte mux channel for attachment of low-speed devices and one selector channel. The I/O structure can be expanded to include one byte mux and up to six selector channels. The first selector channel has a speed of 1300 kilobytes per second. Channels 2 and 3 comprise Group 2 and have an aggregate rate of 1100 KBS, assignable to a single channel if only one is used, or split evenly between the two when both are installed. Similarly, channels 4, 5, and 6 have a total rate of 900 KBS, which can be used on one channel, or divided into 300 KBS increments, if more than one is used. These rates apply when all channels are active.

In general, the channel rates far exceed the capabilities of the peripheral equipment used with the system.

PERFORMANCE EVALUATION

I would now like to discuss some of the evaluation results. We concentrated most of our efforts in evaluating the performance of the processor, since I/O-bound jobs would be highly affected by the restrictions of a single selector channel and by the peripheral configuration. One of the first things we did was a Gibson mix analysis. As you are probably aware, this analysis evaluates CPU performance primarily in a scientific and engineering environment. The results are displayed in Figure 3 using 64 bits as the floating point mode. As can be seen, the ES-1040 is about twice as fast as the IBM 370/145, two-thirds the speed of the IBM 370/155, and about half the speed of a CDC CYBER 73.

We also wrote some FORTRAN programs designed to test the speed of the 1040 versus the IBM 370/145. The pure floating point arithmetic tests showed that the ES-1040 is three to four times faster than the 370/145. On the other hand, a FORTRAN program stressing memory speed, and using only integer arithmetic showed that the 370/145 ran that program at twice the speed of the 1040. This result confirmed what we expected from comparing specified memory speeds. We also ran a comprehensive FORTRAN test program submitted by a customer to our benchmark center. Neither the 370/145 nor the 1040 could successfully execute this program using single precision REAL variables. When converted to double precision, the 370/145 ran the program in 41 minutes, as compared to 20.3 minutes on the ES-1040, a ratio closely approximating the 2:1 obtained in the Gibson Mix.

MODEL	*VALUE*
IBM 360/50	6.50
IBM 370/145	4.95
ES 1040	2.40
IBM 370/155	1.77
CDC CYBER 73	1.23
CDC CYBER 173	0.78

Figure 3—Gibson Mix Values

We were not nearly as successful in testing the 1040 in BDP applications for several reasons. First, we did not have a COBOL compiler in the Robotron software product set, and secondly, we had only a single channel to service both tape and disk. We did write some assembly language programs using the variable length instructions. The results of these indicate that the ES-1040 will be at least as fast as the IBM 370/145 in BDP applications, provided it were similarly configured.

I should note that our evaluation would have been easier if we could have had a manual fully defining instruction timing. As far as we know, no such manual exists either in English or German.

SOFTWARE AND DOCUMENTATION

At the time we procured the ES-1040, we also purchased a set of operating software known as DOS/ES. This bears striking resemblance to IBM DOS. The product set under DOS/ES included a FORTRAN IV compiler, an assembler, RPG, and PL/1. Notably lacking was a COBOL compiler. It is interesting to note that all compiler diagnostics were printed in English, although certain systems messages and diagnostics were in German.

In addition to DOS/ES, a more advanced system, called OS/ES, is also offered. From the information offered, it appears to be very similar to IBM OS, offering MFT and MVT options. To our knowledge, no ES-1040 systems are using OS/ES, probably because of the lack of adequate mass storage.

The documentation was very mixed in quality. The programmer manuals available in English were inadequate to the point that we used IBM manuals in that area. The German language manuals were better, but still less than what one receives from a domestic manufacturer. The hardware manuals, primarily for CE use, were very thorough and complete, but exclusively in German. This was of little concern to us, since we had Robotron field engineers on-site to supply maintenance.

COMPARISONS WITH WESTERN TECHNOLOGY

There is a great deal of interest in comparing the State-of-the-art of Eastern Europe technology with that of our own. Based on our examination of the ES-1040 equipment, no single statement can be applied across the board. Quite clearly, the CPU is the most advanced element of the system. As I mentioned it is constructed from TTL devices with an U.S.-type numbering scheme. The devices used in the ES-1040 are relatively simple members of the family. By knowing when the equivalent devices were available in the U.S., we estimate that an American company could have completed a 1040 equivalent in 1968 or 1969. Since the first 1040 appeared in late 1972, we conclude that a time lag of three to four years exists in processor area.

The core memory attached to the 1040 is not a good match considering the power of the CPU. The technology is about eight years behind ours. The power consumption is about twice that of comparable memories used on domestic machines. The deficiencies of memory performance were apparently recognized early in the design cycle, and are effectively masked by the use of the instruction lookahead and memory interleaving features.

The peripheral area in general lags the U.S. by eight to ten years. The significance of the lag on general systems performance varies, of course, with the device. The one of most importance is that of disk drives. The two disks and the packs we received were made in Bulgaria, presently the only source of drives and packs in the CMEA countries. Although Bulgaria is also the primary disk controller supplier, the disk controller with the ES-1040 was produced in the GDR. The disks have 2311 characteristics. Its capacity is 7.25 MB, the transfer rate is 156 KBS, the rotational speed is 2400 RPM, and the average access time is about 65 milliseconds, even though a voice coil actuator is used.

Disk drives of the 2311 class went into production in the U.S. over 10 years ago, and since that time we have seen three new generations evolve. As far as the 1040 is concerned, the disks are clearly inadequate, not only for the obvious reason of capacity, but also the other performance parameters.

The ES-1040 tape subsystem, built in the GDR consisted of a controller and two 79 IPS drives, using 800 BPI nine-track format. The tape drives used dual capstans with pinch rollers, an old design approach. The tape loading process was very tedious and required considerable manual dexterity. The U.S. was producing comparable tape units over 10 years ago, and since then we have increased the bit density by a factor of eight and the tape speed by a factor of 2.5.

The line printer and associated controller were built in the GDR. It uses drum printer technology, operates at 900 LPM, and has 156 columns. It contains a unique feature; in effect a split platen, which allows two separate forms to be controlled independently. Thus, the printer can appear as two logical units to a programmer. This feature is supported by the Robotron software. Despite the technological drawbacks of the printer, it is adequate for most uses.

The card I/O equipment was made in the USSR, apparently having been in production for 10 to 15 years. The card reader reads 500 CPM, photoelectrically, while the card punch operates at 100 CPM, punching a row at a time. With the de-emphasis on card I/O, these units are adequate for most cases.

In examining the equipment, one quickly becomes impressed by its ruggedness, and high labor and material content. Workmanship ranges from good to excellent. Despite some old engineering designs, the equipment was very reliable. Preventive maintenance consisted of a daily PM of one to two hours and one weekly PM of four hours. Included in the daily PM was checking the adjustment of the positioners on the disk drive. All PM and EM work was performed by Robotron field engineers assigned to our system in accordance with their normal practices.

SUMMARY

I would like to conclude my remarks by making the following points:

- First, the ES-1040 demonstrated instruction set compatibility with the IBM 360 line.
- Second, the ES-1040 processor is about twice as powerful as the IBM 370/145 in scientific and engineering applications and at least equivalent to the 370/145 in BDP applications.
- Third, general processor technology seems to lag the U.S. by three or four years.
- Fourth, the core memory is about eight years behind.
- Finally, there is a significant lag in peripheral capability, which we estimate at eight to ten years.

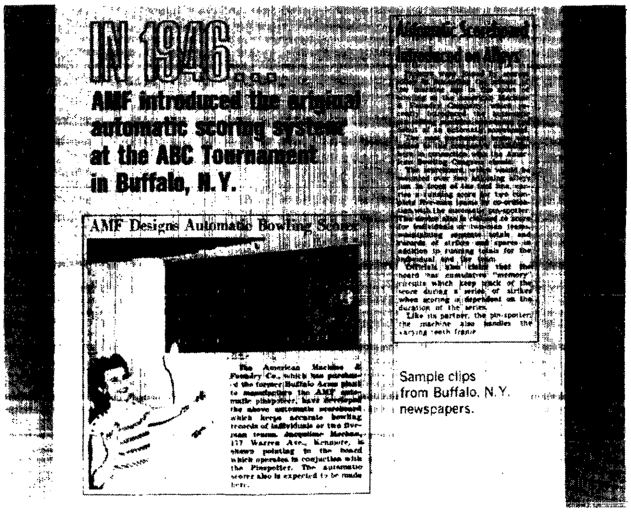
MagicScore bowling scorer—A microprocessor application for fun and profit

by REG A. KAENEL
AMF Incorporated
Stamford, Connecticut

ABSTRACT

Microprocessors have made the implementation of automatic bowling scorers practical. A specific scorer design will be described and illustrated, development considerations associated with this scorer will be discussed, and the future of microprocessor applications will be projected.

Automatic scoring has finally come of age. It has been around for a long time. At stake is a market represented by some 150,000 bowling lanes in the United States alone. AMF Incorporated demonstrated the first working model of a mechanical score board in 1946 when it presented the first automatic pinspotter at the ABC tournament in Buffalo NY (Figure 1). Automatic score keeping was way ahead of its time and far from being economically viable in those days.



IN 1946...
AMF introduced the original automatic scoring system at the ABC Tournament in Buffalo, N.Y.

AMF Designs Automatic Bowling Scorer

The American Machine & Foundry Co., which has purchased the former Buffalo Arms plant to manufacture the AMF automatic pinspotter, have developed the above automatic scoreboard which keeps accurate bowling records of individuals or two five-man teams. Jacqueline Mechan, 117 Warren Ave., Kenmore, is shown pointing to the board which operates in conjunction with the Pinspotter. The automatic scorer also is expected to be made here.

Automatic Scoreboard Introduced on Alleys

[illegible]

The scoreboard, which would be mounted over two adjoining alleys just in front of the foul line, carries a running score for two complete five-man teams in co-ordination with the automatic pin-spotter. The device also is claimed to score for individuals or two-man teams, maintaining separate totals and records of strikes and spares in addition to running totals for the individual and the team.

Officials also claim that the board has cumulative "memory" circuits which keep track of the score during a series of strikes when scoring is dependent on the duration of the series.

Like its partner, the pin-spotter, the machine also handles the varying tenth frame

Sample clips from Buffalo, N.Y. newspapers.

Figure 1—Sample clip from Buffalo, NY newspapers reporting on AMF's automatic score board (1946)

Advances in semiconductor technology made automatic score keeping increasingly more practical ever since then. Accordingly, three different scorers were introduced two decades later with solid-state electronic control. The Automatic Scorer by Brunswick Corporation and the ScoRite scorer by Itek subsidiary, Doban Laboratories, both used a printing projector, by which scores were mechanically impact-printed on transparent pre-printed forms which were projected onto a screen through an optical system. An experimental model of the MagicScore bowling scorer system by AMF used CRT displays. Detection of standing pins was accomplished electromechanically with both the AMF and Brunswick systems using existing pin light switch-mechanisms of the automatic pinspotters. The Itek system used an array of photodetectors and directional light sources to perform this pindetection function. Each Brunswick console served two pairs of lanes, each AMF and Itek console one pair of lanes, but the AMF consoles were controlled from a central unit (Figure 2) for up to 30 consoles shown in Figure 3. Brunswick was the only company which immediately began production of their scoring system. The recent emergence of the microprocessor provided the technological advance necessary for making viable the implementation of a sophisticated automatic self-contained scorer system (Figure 4).

Additional electronic scorers have been introduced since the demonstration of those first ones. They included the semiautomatic Scortronic System by Sharp, the Automatic Scorer by Ikegami Tsushinki, the Meltas system by Mitsubishi Electric, the Automatic Bowling System by Kinetic Systems and the automatic Rapid-Score System by RCA. During this period AMF began marketing a semiautomatic scorer (i.e., EasyScore) on an interim basis to bridge the gap until the viable fully automatic MagicScore bowling Scorer system became ready for production. Pinfall data is entered by hand through keyboards with the semiautomatic systems in contrast to the automatic systems where data can be keyed in by hand if need be but which data normally is entered electrically from suitable pin-detectors. All recently introduced systems have self-contained player consoles, except for the RCA system which uses a central processor and a central printer; all these systems use CRT display devices for clarity and simplicity of operation. The AMF and RCA systems provide for a manager console by which various administrative control functions can be performed over player consoles, such as game monitoring, establishing a practice mode of operation, and displaying the statei of these consoles.

It is generally acknowledged today that bowlers prefer automatic to hand scoring primarily because it gives more time to socialize and to relax. Hand scoring is viewed by many bowlers as a disagreeable task which requires concentration and makes the scorekeeper subject to criticism for making an error. Of hand scoring's two major elements, doing the arithmetic is more objectionable than recording the pinfall, particularly among women. The reasons why arithmetic is disliked are the concentration required, the fact that some bowlers feel inadequate regarding arithmetic, and the fear of making a mistake. This last reason also applies to recording pinfall. Hand scoring is considered a nuisance and a distraction from bowling involvement. It is not that scoring is unimportant, it is simply that bowlers feel involved in the game without manually keeping score.

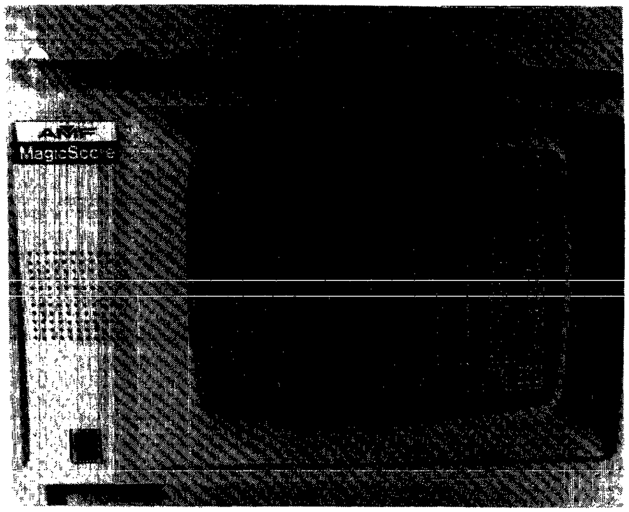

Figure 5—Close-up view of the CRT display, showing display format and character font

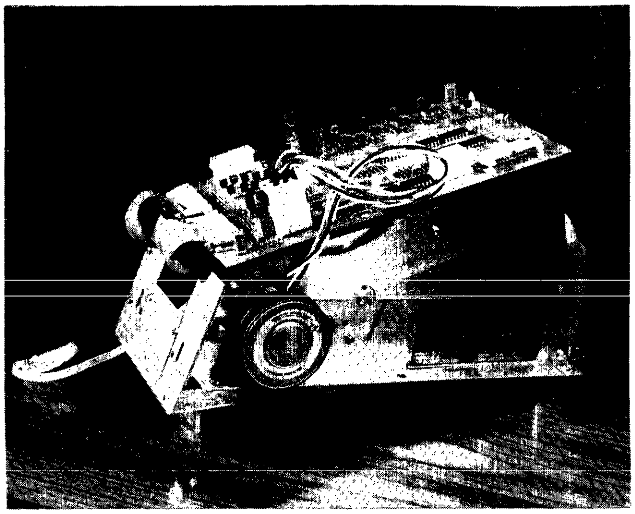

Figure 7a—Photograph of thermal printer, revealing thermal print-head subassembly, paper-advance stepping motor

OUTLINE OF FUNCTIONAL SUBSYSTEMS

The basic format of the bowling score sheet, as approved by the American Bowling Congress, best depicts the progress of a game of bowling. Accordingly, it was decided that the bowling scorer display subsystem emulate its key features, (Figure 5) as well as the printer subsystem (Figure 6) with which permanent records of games are produced. A cathode-ray tube display medium was selected for its outstanding brightness and clarity. To maximize size of the pinfall-data characters (Figure 5), each bowler is designated by three letters and the frame-by-frame subtotals were omitted on the display. A novel thermal printer was found to be most cost-effective, reliable, and maintenance-free since it has only one moving part (i.e., the paper-feed stepping motor) and only requires replenishment of thermally-active blank paper (Figure 7); a total print-out, which includes running subtotals by frames (Figure 6), is produced after the game ends. Display characters are made up from dots of a 5×7 matrix with a non-interlaced horizontal raster-scan where the same pattern of dots appears on adjacent pairs of scan lines; in contrast, printed characters use 5×5 dot matrix. Extra print-head dot-elements are provided for producing the grid-lines of the print-outs.

Figure 6—Copy of Sample-Printout

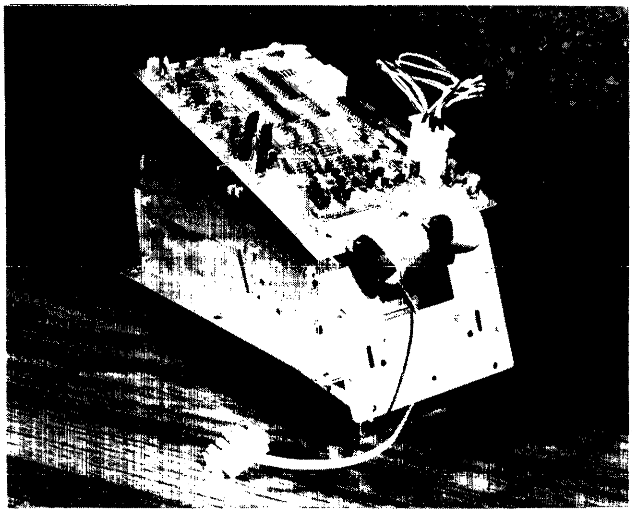

Figure 7b

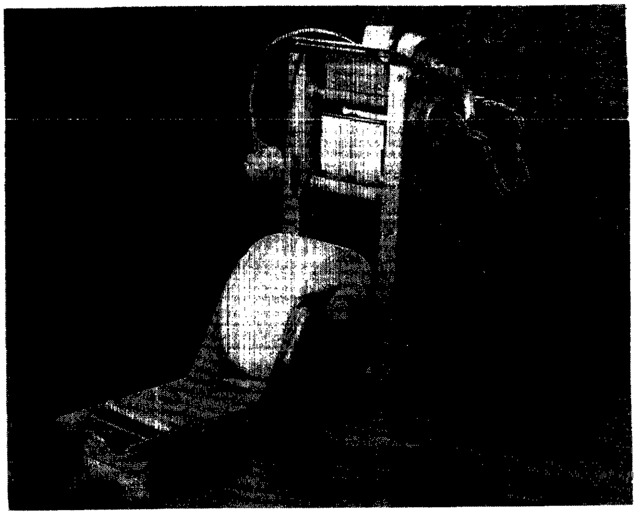

Figure 7c

The following data must be defined at the outset to initialize a game of bowling: names of the players in bowling sequence, handicap of each bowler, and the designation of pacers whose score is not added to the team totals or blind bowlers who will not physically bowl but whose game average score is entered during initiation. The scorer derives representative pinfall data from the average score entered, and displays it when it is the blind player's turn to bowl as if this player actually bowled. In addition, the system must be placed in either the open or league mode of sequencing; in the open playing mode the bowlers assigned to a lane bowl in a round-robin fashion, but in the league mode the bowlers of a pair of lanes are sequenced to bowl alternately on both lanes. Initialization of the scorer is performed through a center keyboard shared by the players of the pair of lanes served by the particular scorer (Figure 8).

Ruggedness, flat sealed construction, and tactile feel were guiding requirements for the development of this and the other scorer keyboards.

During the initialization operation, the operator first selects the sequencing mode (i.e. Open or League) which becomes indicated on the console by LED indicators. A particular player-row is then chosen by designating left or right side, if the proper side has not already been selected, followed by selecting the proper row. This selection will be visually acknowledged by a cursor that appears over the number of the display row. Next, the field is selected in which data will be entered from the keyboard. Depressing the Player Name key produces a cursor on the bottom row below the 6th player row where the next name character entered will be displayed. Up to 16 characters are accepted and displayed on the bottom row; but only the first and the next two characters that are preceded by a space are displayed in the name field of the player row selected. In contrast, the full 16 character name appears in this name field of the print-out. All cursors are removed when a new side selection is made; no cursors are reproduced on the print-out since they are used only to cue the bowlers during data entry. Sequence mode selection becomes inhibited when the first pinfall data is entered; at that time, a player cannot be unbinded or un-pacered.

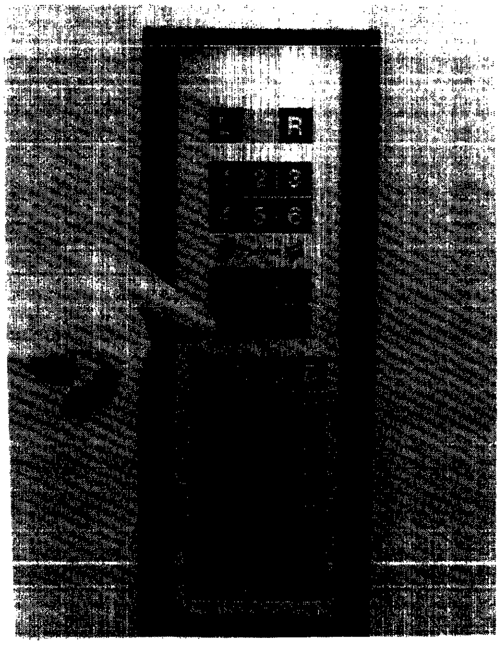

Figure 8—Close-up view of the center section of the keyboard

Being fully automatic, the bowling scorer begins cueing players to bowl once the system has been initialized with the data of the first players. The players who are to bowl are called by their full names which are displayed on the bottom display line on the lane-side they are to bowl on. In addition, arrows appear in the fields where the next pinfall data will be entered, pointing to the lanes from which the data will be taken.

Two extra keyboards, dedicated each to one lane-side, are available to provide for out-of-order player-sequencing and error correction of pinfall-data (see Figure 9). Forcing a player in out-of-sequence is accomplished by depressing the desired row-number key on the home-side of the team the player belongs to.

The MagicScore bowling scorer can be operated as an option in the semiautomatic mode by setting a concealed switch to that mode. In this mode pinfall data is entered by way of the score-key array located on the

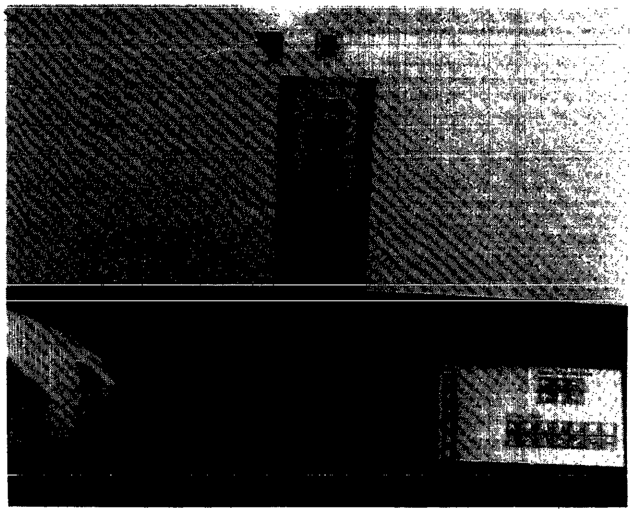

Figure 9—Close-up view of the Console Keyboards, showing center keyboard and dedicated additional keyboards

lane-side where the pinfall data originated. Other than that, the keyboards serve the functions outlined above.

OUTLINE OF THE ELECTRONIC LOGIC

The electronic scorer logic is contained on two printed-circuit boards which are mounted behind the key-board subassemblies on the front panel hinged for ease of access (Figure 10). The printer drive electronics is contained on a printed-circuit board mounted on top of the printer subassembly itself to make it even more of a readily replaceable functional unit. The electronic logic is partitioned onto a microprocessor board (left side board as seen in Figure 11) and a display processor board (right side board of Figure 11). The overall logic schematic is shown in Figure 12.

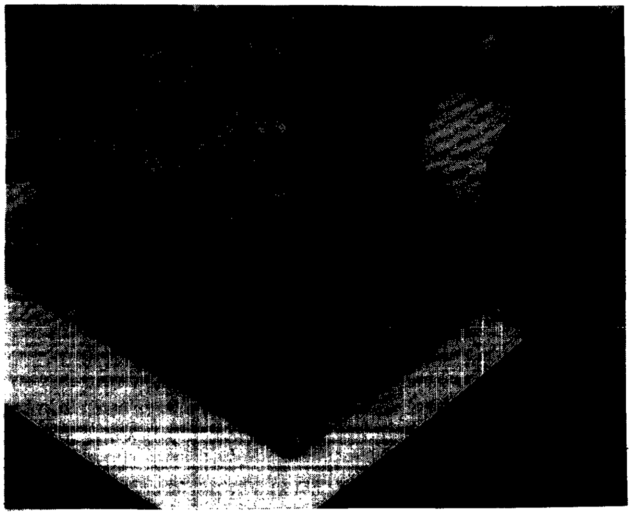

Figure 10a—Console open, revealing printing subassembly, power-supply, MPU electronics board Display Processor electronics board

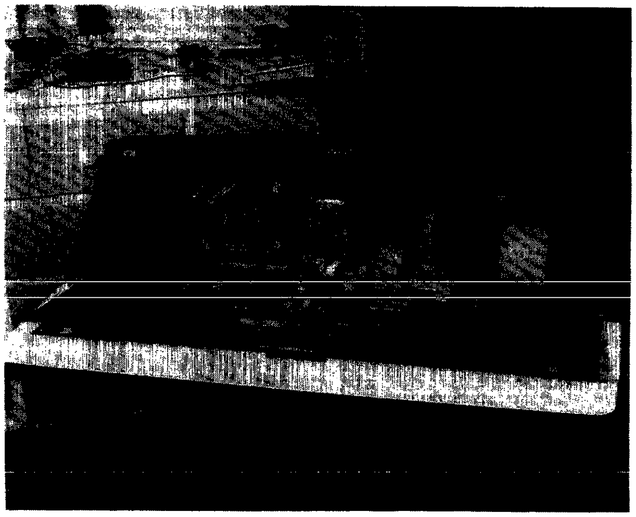

Figure 10b

The microprocessor board contains an M6800 type microprocessor with three Peripheral Interface Adapters of the M6800 family of components, one Asynchronous Communications Interface Adapter which connects to a common serial communications bus, and five 2000×8 bits read-only memories which store the scorer control software. It also includes a six-position DIP switch array by which each scorer can be assigned

Figure 11—Close-up view of the MPU electronics board (left) and Display Processor board (right)

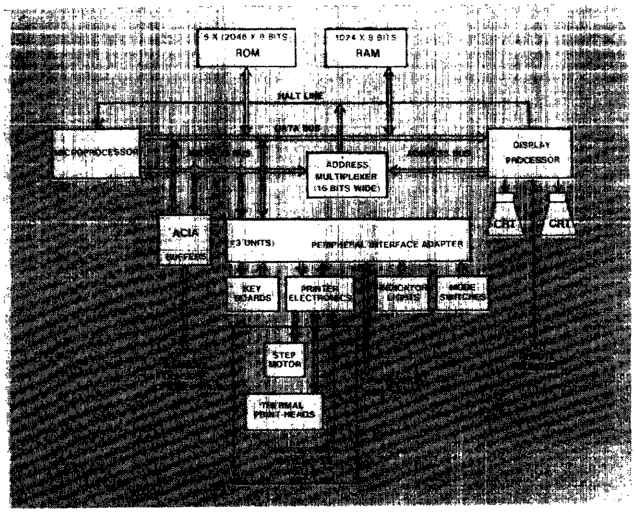

Figure 12—Simplified block diagram of the MagicScore bowling scorer logic

a unique address which it uses to recognize messages on the communications bus. The display processor board contains the random-access memory of the scorer in addition to the circuits that produce suitable video signals for the display monitors (Figure 13). A rechargeable standby battery is provided for these random-access memories to preserve pinfall data for many hours during power failures.

The scorer software, whose flow-chart is shown in greatly simplified form in Figure 14, provides for processing score data from the keyboard (Figure 9), the pinsensor, and the manager console. The pinsensor receive routine creates a compatible pinfall data word from the incoming width modulated data (i.e., a binary zero is represented by a pulse of duration 10×8 ms, the left-lane delimiter pulse by a pulse of duration 16×8 ms, and the right-lane delimiter by a pulse of duration 22×8 ms; binary ones and zeros are serially accumulated in a shiftregister as they arrive and this word is forwarded to the pinfall-data processing routine when a delimiter is detected), executes the manager-console subrouting (i.e., read, interpret, and execute data received by the asynchronous communications interface adapter), increment timers (e.g., time-out for clear key-activation and for indicator flash control), and activate indicators. An executive program sequentially performs such functions as producing signals for the printer, calculating score subtotals, computing the next bowler to play and cueing him, etc.

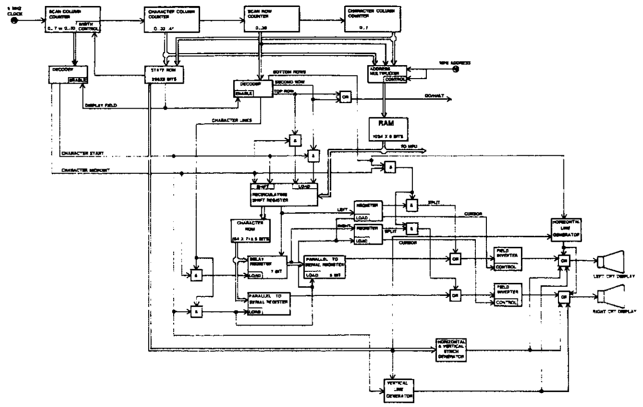

Figure 13—Block diagram of the Display Processor

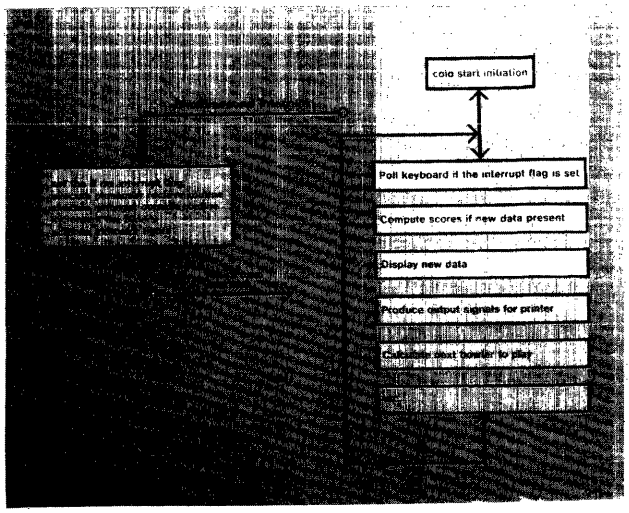

colo start initiation
Poll keyboard if the interrupt flag is set
Compute scores if new data present
Display new data
Produce output signals for printer
Calculate next bowler to play

Figure 14—Flow chart of the software

During program execution the microprocessor deposits display and other data in the random-access memory of the Display Processor board and retrieves such data from this memory. Concurrently, the display processor electronics fetches data from this memory and processes it for display (Figure 13).

Each row of display characters is made up from 28 scan lines. A complete line of display characters from both display sides is transferred from the random-access memory into a recirculating shiftregister during the first two scan-lines of each character row, and recirculates there for the full duration of this row. The characters of the left screen are located at even addresses of the random access memory, those of the right screen at odd addresses; points to the left and right side display characters are similarly interspersed in that shift-register. A character column counter designates the column number of the character that is being scanned across by the cathode-ray tube beam at every instant. It is used to read the left-side data from the random access memory during the top scan line of each character row and the right-side data during the second scan line.

As the character count is advanced, the left-side character is converted into a suitable pattern of seven dots by means of a character read-only memory. This pattern is stored in the left-side buffer shiftregister. The same process is immediately repeated for the right-side characters. These dots are then serialized and outputted to the respective display monitors.

A state read-only memory is used to define the width of each character (i.e. seven counts when part of a string of characters and ten counts when followed by a vertical line), the presence of a horizontal gridline, the presence of a horizontal synchronization signal, etc.

Means are also provided for selectively directing either the left-side video signals or the right-side signals to a video bus of the manager console. When both sides are selected, this is decoded to blank out the display monitors. This switching function is provided by the manager console which has access to all of addressable space (including RAM and peripheral interface adapters) through the microprocessor by way of the asynchronous communications interface adapter.

The component efficiency afforded by a microprocessor is evident (Figure 11). Not so is the extent by which the use of a microprocessor facilitated the developmental task: operational aspects of the control software were defined as the hardware was being developed, and operational refinements were incorporated while the system was being tested. The flexibility of a microprocessor based design made incorporation of ancillary functions both compelling and practical. The manager console feature is a case in point. It was decided to provide flags in random-access memory by which a manager can remotely control the bowling scorer consoles via a serial communications bus. The functions made available through these consoles include blanking out scorers, monitoring lane activity through respective display, disabling the clear function at a console so as to preserve the count of games and frames bowled, and projecting messages onto an individual display screen.

Operational details are described in the User Instructions attached to the MagicScore Bowling Scorer which will be demonstrated during the presentation of the paper at the conference.

QLISP—a language for the interactive development of complex systems

by EARL D. SACERDOTI, RICHARD E. FIKES, RENE REBOH,

ABSTRACT

This paper presents a functional overview of the features and capabilities of QLISP, one of the newest of the current generation of very high level languages developed for use in Artificial Intelligence (AI) research.

QLISP is both a programming language and an interactive programming environment. It embeds an extended version of QA4, an earlier AI language, in INTERLISP, a widely available version of LISP with a variety of sophisticated programming aids.

The language features provided by QLISP include a variety of useful data types, an associative data base for the storage and retrieval of expressions, the ability to associate property lists with arbitrary expressions, a powerful pattern matcher based on a unification algorithm, pattern-directed function invocation, "teams" of pattern invoked functions, a sophisticated mechanism for breaking a data base into contexts, generators for associative data retrieval, and easy extensibility.

System features available in QLISP include a very smooth interaction with the underlying INTERLISP language, a facility for aggregating multiple pattern matches, and features for interactive control of programs.

A number of applications to which QLISP has been put are briefly discussed, and some directions for future development are presented.

INTRODUCTION

An important byproduct of research in artificial intelligence (AI) has been the development of programming languages that permit instructions to be given to a computer at a very high level. A second important byproduct has been the development of highly sophisticated, supportive interactive programming environments. Tools of this kind are very important for developing AI programs, which tend to be large, complex, and subject to frequent alteration. As the needs of the computing community grow, and the ability of hardware to perform more calculations in a given time improves, we believe the programming tools that have been a necessity to AI will become important tools of general applicability.

This paper will present a functional overview of the capabilities and features of QLISP, one of the newest of the current generation of very high level AI languages that includes MICROPLANNER,[1] SAIL,[2] CONNIVER,[3] POPLER,[4] and others. As such, it will serve both to introduce the language to the computing community, and to provide a brief overview of the features available in the new generation of AI languages. A more extensive treatment of QLISP is available elsewhere.[5]

QLISP is both a programming language and an interactive programming environment. It grew out of the QA4 language[6] that was developed at the Stanford Research Institute from 1969 through 1972. Many of the basic concepts of the language are derived from the QA4 work. QLISP embeds an extended version of QA4 in INTERLISP,[7] a widely available version of LISP with a variety of sophisticated programming aids. In addition, it provides many new features not present in other languages.

In the following section, we will describe the language features of QLISP, with special emphasis on those not available in other languages. (Bobrow and Raphael[8] give a comparative description of a number of these languages.) Then we shall describe the programming environment provided by QLISP and the underlying INTERLISP. Finally, we shall give some examples of the ways in which the language has been used to create complex software systems.

LANGUAGE FEATURES

This section will discuss the more notable features of the QLISP language. Most of these are derived from features present in QA4. Some are derived from other languages. Most have been extended for greater ease of use, compatibility with the underlying INTERLISP language, or increased generality.

Data types

QLISP provides a very rich set of data types and facilities for manipulating them. In addition to the range of types provided by INTERLISP (including numbers, arrays, strings, list and binary tree structures), QLISP provides data of type TUPLE, VECTOR, BAG, and CLASS.

A tuple is similar to a LISP list, but can be accessed via associative retrieval as described below. A vector is like a tuple, but is treated somewhat differently when evaluated.

A bag is a multi-set, an unordered collection of elements with possible duplicates. For example, (BAG A A B C) is equivalent to (BAG A C B A) but is different from (BAG A B C). Bags are particularly useful for describing the argument lists of associative commutative relations. For example, if we defined the relation PLUS to take a bag as its argument, then the expressions (PLUS A A B C) and (PLUS A C B A) (which would both be stored internally as (PLUS (BAG A A B C))) would be equivalent by definition.

A class is an unordered collection of elements, without duplication. For example, (CLASS A A B C) is equivalent to (CLASS C B A).

Associative data base

Expressions composed of any of the data types mentioned above may be placed in a data base. The data base is designed for *associative retrieval*, the fetching of data by content rather than by name or address. A request for an item of data may specify values for any of its constituent elements, leaving the rest to be matched by the values in the retrieved item. The data base is maintained in the form of a discrimination net, a tree-like structure in which the nodes represent tests to apply to an expression, and the branches represent the values returned by the tests. In general, these tests are set up to find the first difference, scanning left to right, between two expressions.

Canonical representation of expressions

By storing all data in a common discrimination net, QLISP can represent equivalent expressions uniquely. In the QLISP net, only one instance of an expression may occur. Before an expression is entered into the net, it is transformed into a canonical form. A new datum will not be created if the expression already occurs in the net. Thus, continuing our example about the PLUS relation, (PLUS A A B C) and (PLUS A C B A) are not only equivalent; they are exactly the same pointer into the data base.

Property lists

Arbitrary expressions are represented uniquely in QLISP, just as atoms are represented uniquely in LISP. Therefore it is possible to assign properties to QLISP expressions in the same way as LISP atoms. For instance, we may execute the command

```
(QPUT (PLUS A B (MINUS A))
   SIMPLIFIESTO B),
```

which will put the value B under the indicator SIMPLIFIESTO in the property list of the expression (PLUS A B (MINUS A)). If this expression, or any equivalent expression (such as (PLUS B (MINUS A) A)), is ever encountered again, we can look on its property list and find a simplification for it.

One particular indicator on the property lists of expressions is used to represent truth value. When this indicator, MODELVALUE, has a value T, the system interprets that expression to be "true." Similarly, a value of NIL represents a "false" expression. Special statements exist for manipulating this particular property. For example, the statement

```
(ASSERT (AT SRI MENLO-PARK))
```

would simply place the attribute-value pair (MODELVALUE T) on the property list of the tuple (AT SRI MENLO-PARK)*. The semantics of the statement is that SRI is in Menlo Park. Similarly, the statement

```
(IS (AT ←THING MENLO-PARK))
```

would cause a search of the data base for something that was known (i.e., was in the data base with MODELVALUE equal to T) to be in Menlo Park.

The unification pattern matcher

An important activity in AI programs is the construction, modification, and analysis of complex symbolic expressions. The most powerful tool for this is a *pattern matcher*, an algorithm that allows one expression to be used as a template to break up another expression into components. QLISP extends this facility by providing a *unification* pattern matcher in which each of two expressions may act as templates for the other.

Some examples at this point are appropriate. The

* This paper will avoid almost all need for the reader to cope with QLISP-specific syntax. It suffices to say that in QLISP statements, the elements of expressions are presumed to be constants unless identified as a variable by the prefix ← or $. The ← prefix indicates that the variable is to be assigned a new value; the $ prefix indicates the previous value of the variable.

QLISP statement MATCHQQ invokes the pattern matcher directly. The statement

```
(MATCHQQ (←X←Y) (A B))
```

will match X to A and Y to B. The statement

```
(MATCHQQ (←X←X) (A B))
```

will fail, since X cannot be bound simultaneously to A and B. The statement

```
(MATCHQQ (A←X) (←Y B))
```

will match X to B and Y to A. The statement

```
(MATCHQQ (A (B←X) ←Y)
    (←X←Z (A(B C))))
```

will match X to A, Y to (A (B C)), and Z to (B A).

The QLISP pattern matcher is based on an extended unification algorithm that can deal with the variety of data types available in the language. The matcher is not complete for complex expressions containing bags and classes. However, it is adequate for the kinds of expressions that are almost always used. Pattern matching is used in QLISP for several central purposes. It is used to bind variables and decompose expressions, as we have mentioned. It is used to control associative retrieval. It is also used to invoke functions for specified purposes, as we will now show.

Pattern-directed function invocation

Many of the AI languages provide a feature, first proposed by Hewitt,[9] whereby functions can be invoked not only by naming them, but also by checking to see if they are appropriate for a given argument. This check is performed by matching a pattern associated with each function with the given argument. For example, we might write some functions for an algebraic simplifier that looked like this*:

```
PLUSSINGLE:  (QLAMBDA (PLUS←X) $X)
PLUSZERO:    (QLAMBDA (PLUS 0 ←←X)
             ('(PLUS $$X)))
PLUSMINUS:   (QLAMBDA (PLUS←X
             (MINUS←X) ←←Y)
             ('(PLUS $$Y)))
```

The PLUSSINGLE function says: given an argument of the form PLUS followed by any single element, return that single element. The PLUSZERO function says: given an argument of the form PLUS followed by any number of elements, one of which is 0, return the form PLUS followed by all the other elements of the argument.

At the user's option, if a function's pattern can match an argument in more than one way, all possible matches may be attempted in turn. When one match leads to a failure, an alternative match is attempted. The function itself will not fail until all possible matches have been tried. For example, the following program will find two friends of JOE who are father and son:

```
QLAMBDA (FRIENDS JOE (CLASS←F←S
         ←←REST))
        (IS (FATHER $S $F))
        BACKTRACK)
```

The program will cycle through all pairs of elements from the class of JOE's friends and see if one is the father of the other.

Teams of functions

Functions to be invoked by pattern are typically defined for application toward a specified purpose. Some functions are to be used for consequent reasoning: when a particular consequence or goal (characterized by the function's pattern) is desired, invoke this function to achieve it. Some functions are to be used for antecedent reasoning: when a particular antecedent condition (e.g., an assertion in the data base) (characterized by the function's pattern) occurs, invoke this function to cause further effects on the data base.

Typically, all the consequent functions are tried when a goal is to be achieved, and all the antecedent functions are tried when the data base is updated. Only the ones that have a pattern that matches the goal or assertion will actually be invoked, but a great deal of overhead must be expended to attempt to match the patterns of all functions.

This practice is inefficient since many functions may already be known to be inappropriate, and yet their patterns will all be checked. QLISP provides a feature whereby, with each of many kinds of statements that can invoke functions by pattern, a so-called *team* of functions can be specified from which applicable ones may be drawn. So, in our simplification example, we could cause one simplification to occur with a statement that calls for consequent reasoning:

```
(CASES (PLUS A 4 (MINUS A))
    APPLY (PLUSSINGLE PLUSZERO PLUS-
    MINUS . . . )).
```

The list after the keyword APPLY is the team of functions associated with the particular CASES statement. The system will attempt to match the patterns of only these functions with the particular PLUS expression.

Similarly, a team of functions may be specified with any ASSERT, DENY, DELETE, or QPUT statement to perform antecedent-type activities. For example, in

* The doubled prefixes (e.g., $$) indicate that the variable refers to a fragment of the expression containing it rather than a single element. The quote mark (') indicates that the following expression is to be instantiated (following the semantics of QLISP) rather than evaluated (following the semantics of LISP).

a computer system modelling the operation of a library, a team of functions might be associated with assertions that modelled a book being checked out. These functions might assert that the book was due in three weeks from the current date, update a count of books in circulation, or even cause the original assertion to fail, and provide appropriate other action to be modelled if the person checking out the book had overdue books outstanding. This activity could be initiated by a QLISP statement of the form:

```
(ASSERT (CHECKEDOUT (The Odyssey)
        James.Joyce (4 JAN 1918))
        APPLY $LIBRARYFNS
```

where $LIBRARYFNS was bound to the list of relevant antecedent functions.

Contexts

The previous discussion has presumed that all expressions were stored in a single, monolithic data base. In fact, the data base is factored into different segments, called *contexts*. Contexts may be thought of as corresponding to the block structure of ALGOL-like languages. Whenever a QLAMBDA function or a user-defined block is entered, the current context is set to be a descendent of the previous context. Variable bindings and assignment of properties (including, in particular, truth values) to expressions that are local to a context are perceivable only from that context or some descendent. Thus, contexts may be regarded as particular viewpoints on the data base.

In addition to a default structuring of contexts based on the structure of the flow of program control, QLISP provides facilities for manipulating contexts explicitly. For example, to prove a proposition of the form:

(P or Q) implies R,

one could set up two parallel contexts with P true in one and Q true in the other, and try to prove R in both contexts, as suggested in Figure 1.

Contexts are actually constructed from more elementary entities, which we shall call *contags*, for want of a better term. Contags, which are similar to the "situation tags" of PLASMA,[10] correspond to particular points in time in the evaluation of a program (typically when QLAMBDAs or blocks are entered). A context is an ordered list of contags, typically corresponding to the stack of active function and block invocations. For the user with sophisticated needs for data base manipulation, we have provided a set of QLISP statements that permit a user to construct his own contexts, or viewpoints on the data base, from the underlying contags. These statements allow the creation of a context that is a descendent of a number of independent contexts, a context that is the subset of a given context not retrievable from a second context, and a context that revises a given context to appear as if it were descendent of another arbitrary context.

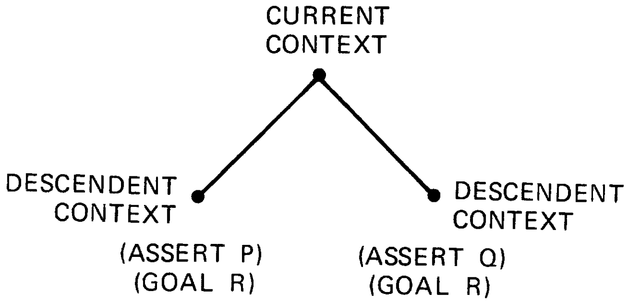

Figure 1—Using contexts to prove a disjunction

Generators

The data retrieval statements of QLISP are designed to find a single instance of a given pattern. To cause the pattern matcher to continue its search and obtain other such instances, a user's program must return to the query statement via the backtracking mechanism (i.e., by failing).

To allow a more natural and inexpensive method of retrieving multiple instances of a pattern, we have extended the CONNIVER[3] approach of using *generators*. For example, the IS statement that was introduced earlier specifies the retrieval of one instance of a given pattern. There is a generator version of the IS statement called GEN:IS that finds multiple true instances of a given pattern. Each time a statement such as GEN:IS is called, it produces a number of instances matching the pattern. These expressions are put on a "possibilities list" along with a "tag" that indicates how the generator can be restarted when more instances are requested, and this possibilities list is returned by the generator as its value.

If the function TRY:NEXT is called with a possibilities list as an argument, it will remove the first instance from the list and return it as its value. If the list contains no more instances, the tag is used to restart the generator. Since calls to TRY:NEXT can be made from anywhere in a program, this form of generator separates the retrieval of data elements from the processing that is done on them in a way that is not possible in a strict backtracking regimen.

The generator retrieval statements are implemented using INTERLISP FUNARGs. A FUNARG is a data object that conceptually represents a copy of a function together with that copy's private data environment.

Extensibility

QLISP statements that are not part of the underlying INTERLISP language are processed by the

INTERLISP error handling mechanism, as will be explained below. User-oriented tools for accessing the LISP translation mechanism are provided so that new QLISP-like statements can be defined easily. Once the statements have been defined, they are treated by the interpreter and compiler exactly like other QLISP statements. Typically, the extension facility has been used to provide alternative control structures for invoking the standard QLISP statements, or to provide special syntax for user-defined QLAMBDA functions.

SYSTEM FEATURES

QLISP is more than just a programming language; it is an interactive programming environment for the development of very complex collections of software. In this section we shall discuss the major features of this environment that are unique to QLISP.

Integration with INTERLISP

The major advantage of QLISP as a programming environment, as compared with other new AI languages, is its ease of use. It is easier to edit functions, create symbolic files, trace execution paths, break into computation paths, and debug programs in QLISP. This is primarily due to the choice of INTERLISP as the host language for QLISP, and the care that has been taken in the implementation of QLISP to preserve the many supportive features of INTERLISP.

QLISP is implemented via the error handling mechanism of INTERLISP. A valid LISP expression will never be seen by the QLISP processor. Thus, programs or portions of programs that use only LISP constructs will run as fast in QLISP as in INTERLISP.

When the INTERLISP interpreter encounters an ill-formed LISP expression, it calls an error routine that in turn invokes an error analyzer. If the expression is recognized as a valid QLISP form, it is translated to an equivalent LISP form that is returned to the interpreter for evaluation. The translation is stored with the original expression so that the translation need be done only once.

A similar mechanism causes QLISP code to be translated into equivalent LISP code when it occurs within a function being compiled. Since the translation occurs at compilation time, the QLISP interpreter need never be invoked at all when running compiled QLISP code.

Aggregation of pattern matches

The "apply team" mechanism provides a good means of reducing the number of unneeded pattern matches during pattern-directed function invocation. However, there may still be a lot of wasted effort as the function invocation mechanism attempts to match each pattern in turn to the argument. For example, the simplification functions described in the preceding section all begin with PLUS. They might even be segregated into a specific team of functions to simplify expressions beginning with PLUS. And yet every pattern will be matched against the argument, and the matcher will succeed at least as far as matching up the PLUS's.

An option is available to allow the patterns of QLAMBDAs to be aggregated together in a tree structure. For example, the tree for the simplification functions listed earlier appears as in Figure 2. A single operation against the tree can determine the set of all the QLAMBDA functions that are good candidates to successfully match a given argument. (The tests that are applied are cruder than those applied by the pattern matcher itself, so that the set of functions may contain some whose patterns won't actually match when the matcher is invoked.) This set can then be intersected with the particular "apply team" to determine which functions to invoke.

The tree structure that is used is actually the discrimination net that is used as the associative data base. For "apply teams" of more than fifteen functions or so, this feature provides significant efficiencies.

Interactive program control

Since the QLISP backtracking mechanism is implemented using INTERLISP's error facility, there are a number of ways in which the standard INTERLISP interactive facilities won't work properly. For ex-

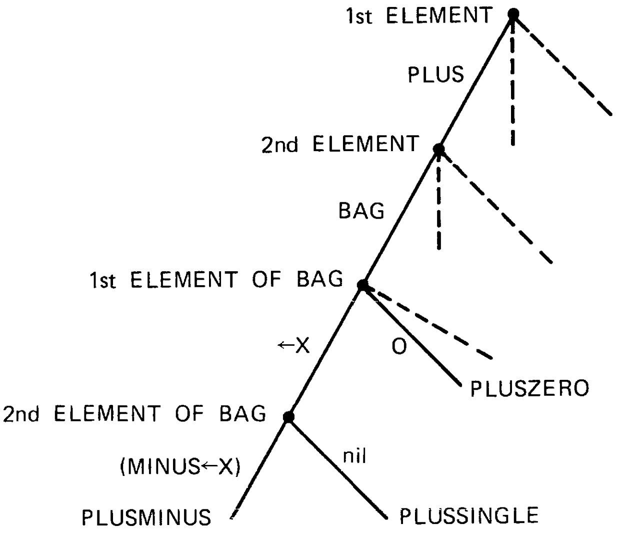

Figure 2—Pattern selection tree for simplification functions

ample, the INTERLISP function tracing facility is implemented as "break the computation, then print, then continue." But INTERLISP errors, which are generated by QLISP to cause backtracking, are trapped at a break. The solution we adopted to this particular quandary was to implement a QTRACE facility that did not generate a break when it printed information about a function invocation. Similar care was taken with breaks in computation, the package for manipulating symbolic files, and many other system components to allow a QLISP user to believe that the total system was behaving exactly as the underlying INTERLISP would.

APPLICATIONS

To provide some perspective on the utility of QLISP, we will briefly describe some of the applications to which it has been put. The common characteristics of these applications are that the programs and the concepts underlying them could not be specified without a sustained cycle of programming the best current ideas about what the program should be doing, observing the program's behavior, and then modifying or extending the ideas.

Program verification

The first major QLISP program was the program verifier of Waldinger and Levitt.[11] The verifier was originally written in QA4. The program includes over 100 functions each encapsulating a specialized piece of knowledge about the semantics of the language of the programs being verified. The QLISP version ran about 30 times faster than the original QA4 program.

Automatic programming

Subsequent work by Waldinger has used QLISP for the generation of simple programs from output specifications. This work makes strong use of the unification feature of the pattern matcher to combine the knowledge that is distributed in various QLAMBDA functions. For example, one function may say, in effect, to produce a list with some X as its CAR, perform (CONS X something), where the something is unspecified. Similarly, another function may say, to produce a list with some X as its CDR, perform (CONS something X), where the something is again unspecified. So if the system were given the goal of producing a list with A as its CAR and B as its CDR, the first function would return (CONS A something), the second would return (CONS something B), and by unifying these results the system can produce the correct code (CONS A B).

General problem solving

A system developed by Sacerdoti[12] generates complex plans, monitors their execution, and recovers from unexpected events that cause the execution to deviate from the expected course of action. This is a large system (about 60 pages of code) and almost all of it is in the underlying INTERLISP language. However, the pattern matching and context mechanisms of QLISP are central to its operation, and the ease with which the representation of knowledge could be changed was important in the system's development.

The semantics of the actions that the system plans for are written in a language extension of QLISP that has QLISP's semantics but is evaluated very differently. Strong use of the pattern matcher and of the extension feature allowed the action language to be readily changed as the scope of the program increased.

Deductive retrieval

A deductive retrieval package was written by Fikes[13] to allow arbitrary deductions to be fired off by a QLISP-like query. In addition to simply causing associative retrieval from the data base, Fikes' queries can fire off arbitrary programs to deduce the answer to the query from other available information. These query statements, implemented as a language extension of QLISP, make strong use of the generator facility. Capabilities for modelling state changes, also part of this package, make strong use of the ability to associate an arbitrary property list with an expression.

Computer aided design

The first general-purpose program for computer aided design that uses AI techniques in a substantial way has recently been completed. It works by generating a model of the object to be designed in stages of increasing detail. As each stage is generated, appropriate user-supplied design constraints are applied. The system employs sophisticated backtracking techniques to minimize the search for an object that satisfies all the constraints. The program in its current form[14] is written completely in INTERLISP. The development of the program was carried out in QLISP, and the code was gradually cut over to pure INTERLISP as design ideas gelled and execution speed became important. The pure INTERLISP version runs about ten times faster than the original QLISP version. The development of the system was greatly facilitated by the early use of QLISP and the resulting ability to easily change internal representations and control strategies.

Econometric modelling

A system has been developed that integrates a quantitative computer model with an overlay of heuristic judgmental rules.[15] The heuristic overlay is intended to facilitate interactive use of the econometric model by making it easy to alter parameters and adjust boundary conditions. The underlying quantitative model was implemented in a mixture of INTERLISP and FORTRAN. The heuristic model was implemented in QLISP as an ASSERT team, a set of functions applied after an assertion has been made in the model. The user interface was implemented in QLISP because of the ease of interaction it provides.

CURRENT STATUS

QLISP has been in active use at SRI for nearly two years. The version at SRI is implemented in INTERLISP on a PDP-10 computer using the TENEX operating system. It is available for use over the ARPAnet by other users on the network.

A version of QLISP is also available for INTERLISP-370, a version of INTERLISP that runs on IBM 360 and 370 series computers.

QLISP is not intended to be a performance language. The programming tools that it provides are of general purpose. Thus a program written in QLISP will run slowly compared to a version of the program written in a language that provides a more restricted set of data types or less flexible control structures. But it has been our experience that, when the programs to be written are large, complex, and subject to frequent alteration as development proceeds, then the inefficiency in the program's execution time is more than compensated for by efficiencies in the programmer's development time.

FURTHER WORK

While QLISP is a useful tool for many purposes, further work will be required to augment the power of the language to reflect the growing needs of AI programming. The current version provides an associative data base that must be entirely contained within the program's core image. Systems that operate on substantial knowledge bases are a focus of current research interest in AI, and the amount of data that these systems will use will require that at least part of the associative data base be resident on secondary storage. This will require a new data storage and retrieval mechanism, since those of existing AI languages, including QLISP, tend to distribute data randomly throughout the store. The distribution of data needs to be at least partially based on semantic criteria, instead of being totally on a syntactic basis as is done now.

Another inadequacy of QLISP and other AI languages is that the pattern matcher returns too little information. Given two patterns to match, it replies either with an exact matching between the patterns or with a report of failure. It would often be extremely useful to have a measure of how "close" the match was to succeeding. Obviously, this would be an expensive feature, but this kind of "fuzzy" matching would provide a user with the powerful ability to begin to deal with expressions on a semantic basis.

A third area for further development is in the general category of multiprocessing. While many languages support the use of multiple interdependent processes, the level of command that they provide is typically quite low. Typically they are on the level of "start process," "suspend process," and "wait on semaphore." It would be very advantageous to have higher level commands available that would allow the language system itself to keep track of many processes at many levels of function calls. Such a mechanism could be easily tied to the existing "APPLY team" facility of QLISP.

CONCLUSIONS

We have given a brief overview of the capabilities and features of QLISP. While it is not practical for use as a production language, it is a time-saving tool for use in the construction of complex systems that are subject to significant change during the course of their development.

ACKNOWLEDGMENTS

The basic features of QLISP are derived from the QA4 language, developed at SRI by Jeff Rulifson, Richard Waldinger, and Jan Derksen. The initial implementation of QLISP was done by Rene Reboh and Earl Sacerdoti. Subsequent development was carried on by Daniel Sagalowicz and Mike Wilber. Rich Fikes developed the generator package, and was instrumental in straightening out the context mechanism. Mal Newey wrote the pattern matcher, based on a problem reduction algorithm of Richard Waldinger. Richard Waldinger has been a major force in setting the goals of the language development. Warren Teitelman has provided much help in generalizing the features of INTERLISP that permit the clean interface to QLISP.

User interface design issues for a large interactive system

by RICHARD WILLIAM WATSON
Stanford Research Institute
Menlo Park, California

ABSTRACT

User interface design issues are discussed for a large interactive system. The assumptions about the user environment are explicitly described. Issues discussed include command language syntax, command recognition and completion, subsystem organization, user extension capabilities, user options, and various forms of prompting, help and feedback. These issues are discussed within the context of an existing system, the NLS system.

INTRODUCTION

The large interactive system user interface issues discussed in this paper reflect experience at Stanford Research Institute (SRI) over the past twelve years in the evolution of the user interface to the NLS system. NLS is a prototype collection of tools in a growing workshop of tools and services to aid knowledge work.[1,4] NLS provides facilities to support activities such as document creation, study and publication, message handling, information filing and retrieval, and software engineering. We expect the number of tools and the vocabulary that controls the use of these workshops to grow. We further expect that the use of such workshops will spread throughout those occupations involved with information in various forms and that there will be infrequent and casual users of such systems, along with many people who will spend large fractions of their day using such workshops. One goal is to match the speed of system responsiveness to the natural speed and flow of man's thought processes. It is from these basic expectations that our user interface work has developed.

The sections below enumerate several assumptions and areas of concern around which the NLS user interface has developed to date. A key point to mention is that we do not consider the NLS user interface a static, finished product. It will change, based on analysis of usage experience, and the technology and media available.

The user interface has two sides: the input side by which the user inputs information, indicating by various conventions and controls what he wishes accomplished; and the output side by which the machine provides feedback and other assistance to the user in command specification, and provides various forms of information portrayal. Man has many motor and other capabilities that could be the basis for input and command specifications; similarly he has his full range of senses that could be targets for system output.

To date, computer information systems make use of only a few motor and sensory capabilities in their man-machine dialog. An important area of research involves exploring the advantages to be gained and the techniques to be used to extend this range. There is interesting research going on in areas of speech, eye movement, brain wave control, hand written script, and video graphics that will undoubtedly be integrated into the truly multimedia systems to be built in the near future.

We call the user's collection of input-output equipment, and arrangement of work tables and work space, the workstation. At the present time, input to interactive systems centers around various types of keyboard devices: standard typewriter-type, function button, keyset (chord), and graphical pointing devices (mouse, electronic pen-tablet, light pen, joystick). The dominant output means are teleprinters and displays of varying capabilities.

The present NLS user interface has been developed around this equipment, although many of the principles used in its design can be easily extended for use with other media.[3] The prime motivation for the use of the mouse for pointing and two keyboards (standard typewriter-like and keyset) as the input devices for the display version of NLS (DNLS), are described in References 2 and 3. NLS can also be used from typewriter terminals (TNLS). In this paper, we concentrate on describing some of the motivations behind the design of the NLS command language and the forms of information portrayed to assist the user in command specification. Forms of general NLS information portrayal are described in Reference 1.

HIGH LEVEL ASSUMPTIONS UNDERLYING THE DESIGN OF THE NLS USER INTERFACE

First we describe a few high-level assumptions about the system usage environment that affect the user interface design and then discuss some of the lower level issues and the specific techniques used to deal with them.

Coordinated set of user interface principles

There will be a common command interaction discipline, over the many application areas in the workshop, that shapes user interface features, such as the language, control conventions, methods for obtaining help, and computer-aided training.

This commonality has two main implications. One, it means that while each domain within the core workshop area or within a specialized application system may have a vocabulary unique to its area, this vocabulary will be used within language and control structures common throughout the workshop system. A user will learn to use additional functions by increasing vocabulary, not by having to learn separate "foreign" langauges. Two, when in trouble, he will invoke help or tutorial functions in a standard way.

Grades of user proficiency

A once-in-a-while user with a minimum of learning will want to be able to get at least a few straightforward things done. In fact, even an expert user in one domain will be a novice in others. Users will be clerical workers, information specialists, executives, engineers, and others. Attention to novice-oriented and to tutorial help features is required.

Users also want and deserve the reward of increased proficiency and capability from improvements in their skills, their knowledge, their conceptual orientation to the problem domain and to their workshop's system of tools, methods, conventions, etc. "Advanced vocabularies," short concise control notation and conventions in every special domain will be important and unavoidable.

A corollary feature is that workers in the rapidly evolving augmented workshops should be involved continuously with testing and training in order that their skills and knowledge may most effectively harness available tools and methodology.

Ease of communications between subsets and addition of workshop domains

One cannot predict which domains or application systems within the workshop will want to communicate in various sequences with which others, or what operations will be needed in the future. Thus, results must be easily communicated from one set of operations to another, and it should be easy to add or interface new domains to the workshop. A corollary is that the total workshop may contain a very large number of tools and services. Some users may have access to only a subset of its capabilities while others will have access to many or all capabilities.

As described below, we expect the workshop to be embedded in a computer network and thus communication between tools and between users must take place across both process and host boundaries according to well specified conventions and protocols.[5,6]

User programming capability or user interface extensibility

There will never be enough professional programmers and system developers to build or interface all the tools that users may need for their work. Therefore, it must be possible, with various levels of ease, for users to add or interface new tools, and extend the user language to meet their needs. They should be able to do this in either a variety of programming languages with which they may have training, or in the basic user-level language of the workshop itself.

Range of workstations and symbol representations

The range of workstations available to the user will increase in scope and capability. These workstations will support use of text with large, open-ended character sets, pictures, voice, mathematical notation, tables, numbers, and other forms of knowledge. Even portable hand-held consoles will be available. Indeed the multiplicity of possible terminals raises the question of whether a consistent set of control and portrayal conventions is possible.

As hardware decreases in cost, more and more capabilities will be placed in the workstation both in the form of user interface aids and facilities, and in the form of frequently used tools.

Distributed nature of the user interface processes

The collection of facilities to support interfaces with the system of tools can be conceived of as a single service as seen by the user. These facilities may all reside in a processor in the workstation or be distributed in two or more processors, depending on the level of their sophistication and state of the art with respect to cost, hardware capability, and so forth.

Tools embedded in a computer network

The computer-based tools of a knowledge workshop will be provided in the environment of a computer network, such as the ARPANET.[7] For instance, the core functions will consist of a network of cooperating processors performing special functions, such as editing, publishing, exchanging documents and messages, data management, and so forth. Less commonly used but important functions, such as a compiler, might exist on a remote machine. The total computer-assisted workshop will be based on many geographically separate systems.

Once there is a "digital-packet transportation system," it becomes possible for the individual user to reach out through his processor to other people and other services scattered throughout a "community." The "labor marketplace" where he transacts his knowledge work will be literally independent of geographical location.

Specialty application systems will exist in the way that specialty shops and services now do—and for the same reasons. When it is easy to transport the material and negotiate the service transactions, one group of people will find that specialization can improve their cost/effectiveness, and that there is a large enough market within reach to support them. And, in the network-coupled computer-resource marketplace, there will be a growth of specialty shops, such as application systems specially tailored for particular types of analyses, or for checking through text for spelling errors, or for doing the text-graphic document typography in a special area of technical portrayal, and so on. There will be brokers, wholesalers, middle men, and retailers.

The key point to emphasize is that even when hardware costs decrease to the point where a user can perform 90 percent of his work using tools and information that operate in the processor in his work station, he will want to have access to a computer network to:

(a) Communicate in various forms with others
(b) Access very large or special databases
(c) Access special tools that run elsewhere

Problem orientation of the command language and tolerance for ambiguity

The user has a task that he wishes performed by the system. Depending on the nature of the task and operations available to him on the system, he may be able to express what he wants accomplished in a single "statement" or command to the machine, or it may require a series of commands.

One of the goals of the designers of the command language and system is to understand the nature of the user's application domain so that the user can express his needs with constructs that are similar to his thought processes, natural problem solving vocabulary, and language forms. The machine will then break down the request into smaller steps as required for internal processing.

If there is ambiguity in the user's command, the machine should recognize it, if possible, and prompt appropriately for clarification. There is still much research and development required to fully meet this goal.

Many people hope to allow natural language to be used in making statements to the machine. This capability will require models of the user and task domains for understanding.

Even when systems are able to interpret commands given in natural language, the precision and usage efficiency of appropriate artificial languages will make the latter's continued use preferable, especially for skilled users.

Given the above general considerations as background, we can move on to examine features of the NLS user interface in more detail.

SOME COMMAND LANGUAGE CONSIDERATIONS

A command language must allow unambiguous specification of what the user wishes accomplished. The operation to be performed, and the entities or information items (arguments) to be acted upon, or used to determine what is to be acted upon, must be specified. These can be specified in a variety of ways: by typing them in full or in some form of abbreviation, by pointing at them on a screen, by pronominal reference, by implication from context, or by use of default values automatically assumed by the system where appropriate. The order of their specification, the syntax or grammar of the language, can have various forms. For example, operational command-words can be specified, followed by the arguments, or vice versa. Arguments can be in fixed positions or explicitly named and occur in any order. Some arguments or command-words can be optional and require special characters to indicate their presence. Arguments or command-words can have defaulted values under certain conditions. Pronominal references can be allowed to refer to previous occurrences. Arguments may be given types by the system and language designer for more extensive error checking and feedback.

Arguments and keywords can be specified by complete or partial typein (there are a variety of forms of command recognition that are discussed later) or designated by pointing to representations on a display or by use of specially coded function keys. Or, the machine may ask questions and the user just fill in the blanks.

Depending on the characteristics of the computer and communications system, it may or may not be possible to provide command word or keyword completion, prompting or other feedback, argument checking, default value fill in, and so forth, during the command specifications.

For example, in line-at-a-time, half-duplex systems, the user usually must complete the entire specification of the command before transmission to the system, while in character-at-a-time, full-duplex systems, the system can react to each character received and provide more extensive aids to the user during command specification.

The above discussion outlines just a few of the many choices available to the language designer. As the purpose of this paper is not to be a complete tutorial on all possible choices available and their advantages and disadvantages, the following discussion gives only the main NLS command language features and the motivation for their adoption.

THE NLS COMMAND LANGUAGE

The NLS command language generally has the following form, where angle brackets group meta symbols:

⟨operation specification⟩ ⟨operand specification⟩ ⟨command completion⟩

The fields in a command are of a fixed order, although some commands have optional fields that can be specifically requested. Other fields can have a system-supplied default value. Because NLS operates from a character-at-a-time, full-duplex system, several levels of help are available, as described later, for giving cues and prompting, explicitly listing options or syntax, and giving full documentation on what the system expects next during command specification. It was not felt that much would be gained for novice users by allowing fields to be specified in any order by using explicit field names. Novice users do not need to be aware of optional fields.

As much as possible NLS makes the operational specification of the form verb-noun followed by arguments and possibly other keywords. We have also tried to maximize the fullness of the verb-noun matrix.

This approach seemed to be natural, and follows normal English imperative forms to aid learning. The choice of verb-noun form seemed to fall out naturally when considering such important areas as editing. A given verb or operation, such as DELETE, can naturally be applied to many entities, such as STATEMENT (a paragraph, title, equation), CHARACTER, NUMBER, TEXT, FILE etc. Learning is easier if the user can form a model of how the system works that can be consistently applied. In this case, a user can learn n verbs and m nouns and understand that generally, if it is meaningful, they can be used in pairs. Having learned n+m vocabulary terms, he can apply them in the form of n×m commands. For example one can command DELETE STATEMENT, DELETE NUMBER, DELETE FILE etc.

We have tried to pick command keywords that have normal usage related to the operation described. A synonym capability would be easy to implement.

Four forms of command keyword recognition are provided to enable the user to choose the one most appropriate to his terminal type, system response, previous system experience, and present NLS experience level. We have worked to pick an operational vocabulary for the present system that guarantees keywords to be unique in a maximum of three characters:

(1) A single-character mode allowing high-speed single-character recognition of the most commonly used command keywords; less commonly used command keywords require an escape character followed by enough characters for unique recognition: With large and expanding command sets one cannot choose keywords with mnemonic value and guarantee uniqueness in the first character. This mode is generally preferred by experienced users because of the conciseness and speed with which frequently used operations can be expressed. We find that experienced users are very concerned that commands be formed with the minimum number of input operations, and that commands have the richness needed to specify adjective or adverb type operations as needed. There is thus some conflict in certain commands between these goals for the experienced user and the need for command simplicity for the novice.

(2) A demand mode requiring a special character to initiate recognition: This has proved to be popular for new users of typewriter terminals, particularly those with experience using the TENEX operating system, under which NLS currently runs.[13]

(3) An anticipatory mode requiring the user to type just enough characters for the command to be uniquely specified; the system then automatically fills in the remainder of the command word.

(4) A fixed mode that guarantees recognition on entry of three characters.

Given the implementation approach outlined later, it is quite easy to add other recognition modes, such as allowing the user to choose keywords from a menu displayed on the screen. However, experiments have shown that the time it takes to point to an item on the screen is equivalent to several keystrokes and thus would be disadvantageous to skilled users, although possibly of value to novices.[2,3]

Modes 3 and 4 have turned out not to be heavily used.

Operand argument specification is contained in a number of fields that are variable with the type of command. All commands of a similar type have the order of the operands as consistent and as natural (relative to normal English usage) as possible. Infrequently used operand fields are optional and novice users need not be aware of their existence.

Related to argument specification is the problem of choosing argument delimiters. There is a need for the following delimiting functions.

(1) Delimiting command words

(2) Delimiting arguments
(3) Delimiting optional arguments or command word fields
(4) Delimiting commands
(5) Selecting arguments from a display screen, and confirming the selections

One could choose separate characters (codes) to represent each of these functions. To do so seemed to us to add an unnecessary complication for the user. Therefore, except for using a special character to indicate an optional argument, or command word, a single code is used for the other functions in NLS. We call this code "Command Accept" (CA) even though it is used for other purposes as well. The system allows the user to define which keyboard character is to serve this function if he finds the system default to be inconvenient. One of the buttons on the mouse also serves this function.

Arguments can be typed in, defaulted where appropriate, or specified by pointing to appropriate entities on the display screen.

There are three flavors of command completion.

(1) Command Accept: Completion of the command indicating execute the command and return to the base state to await input of the next command. The default indication for this form is one of the buttons on the mouse in DNLS, which is translated into a control character. Command completion is defaulted to be CR in TNLS. The use of CR in TNLS is quite natural and generally does not conflict with textual input as most text in NLS is typed in without explicit CRs and is appropriately formatted by the system for various output devices. If the TNLS user wishes to input an explicit CR in his text file, he must precede it with an escape character. If he has need to enter many CRs in his text string, he can redefine the completion character, Command Accept, to be some other character.

(2) Repeat: Completion of the command and return to an appropriate intermediate command state for quick repetition of the command. Repetition mode continues until explicitly commanded to escape out of it. This mode is very useful when a delete or other operation is repeated several times.

(3) Insert: Completion of the command and entry to insert-statement mode for addition of new paragraphs or other text statements. This mode is like command repeat above except that it always takes you to the insert command. It is used frequently when one adds, replaces, or moves text, and then wants to follow it with new statements. It speeds text input when inserting sequences of paragraphs.

The system is to be used from a variety of terminal types, including both typewriter-type terminals and displays. The two-dimensional displays are to be the preferred workstation types whenever a design decision must be made between language forms possibly favoring one type or the other.

We decided to make the command language syntax for the TNLS version and the DNLS version as close as possible, except where the difference between the one-dimensional and two-dimensional media would clearly prohibit this or would seriously limit one or the other version. This decision allows people working in environments consisting of both typewriter and display terminals to move back and forth with ease.

The system has been organized into clearly defined subsystems with uniform rules for their entry and exit. Any subsystem can be entered from any other, either to "execute" a single command with automatic return or to perform a chain of commands. The user can return either to a specifically named subsystem in the path of subsystems traversed, or enter a new subsystem. The issue of how to group commands into subsystems has to do with training and patterns of use rather than system constraints. It relates to learnability and, to some extent ease of command specification using single characters as switching subsystems switches vocabularies, and to "knowing where you are" in a command or operational space.

One could construct a system where all commands were in a single subsystem. Study of the command set of a large system particularly conceived of as a set of tools shows that operations tend to group together in such a way that to perform a given task, such as sending a message or calculating a budget, generally require several related suboperations. Certain operations, such as moving in information space or seeking help, tend to be used as suboperations of many or all tasks. This latter observation has led to "universal" commands available from within any subsystems. One can also imagine certain commands to be needed frequently in just two or more subsystems and thus implemented in each subsystem having the need. There are now no instances of this case in NLS. The ability to execute a single command in another subsystem with automatic return has been very useful.

Provision has been made for options that the user can control as he wishes for the amount of prompting, feedback, recognition mode, and for setting other user interface parameters whenever it seemed a standard interface might not be appropriate to some significant class of users.

A mechanism is implemented that enables the user, or someone acting in his behalf, to create a file stating what options he wants to run with. The system thereafter automatically sets these options when he enters. This facility can also be used with small extensions to subset commands. This user option capability, when coupled with the ease by which the user interface can be redefined using the Command Meta Language described below, makes possible tailoring the user interface to specific users or groups of users.

All operations that have a natural inverse command have been given one (although NLS still does not have an "undo" facility).[14] A general undo/redo facility has a number of technical difficulties and its value might be questioned. However, the ability to undo or redo the last one, two, or three commands would clearly be useful.

As indicated earlier the ability of the user to extend the system himself is important. There is a tradeoff between ease of extension specification and operational efficiency. In providing such a facility one does not have to be deeply concerned with efficiency if the task handled by the extension is performed infrequently. If the operation is performed frequently, then it should probably be inserted as a system feature and implemented efficiently by professionals. This area is ripe for much additional development. The extensions must be specified in some language to indicate what sequence of events is to take place, what arguments to collect, and so forth, when a given user action is performed.

NLS now offers two forms of extensibility. The first allows users with some basic programming knowledge to write programs in the Algol-like L10 language in which the system is implemented, calling NLS system primitives as needed. They can use the Command Meta Language to specify a user interface if desired.[12] These programs can be installed by the user as one of his default subsystems, loaded as subsystems as needed, or used as content analyzer patterns.[8]

The user can also write sequences of NLS commands and have these sequences executed at will. A specific sequence of commands can be automatically invoked when the user first enters NLS.

HELP, STATUS, AND PORTRAYAL FACILITIES

The user interface must implement a man/machine dialog. In this section, we discuss issues from machine to man. The discussion centers around the use of displays, with comments on how the problems are dealt with for typewriters. Let us examine some of the types of information that the user needs in order to keep his bearings.

There are three main areas or dimensions along which the user needs information to help him (a) to know where he has been, (b) to know where he is, and (c) to know where he can go from here. Clearly the command language and user interface must offer provisions to move in these spaces as well as obtain status.

(1) Information Space—The user needs to know where he is in his information space, and what view or portrayal of the many possible is being displayed to him. Generally he arrived at his present position from previous points and he may want to be able to return to previous points or views as well as to move on.

(2) Subsystem or Tool Space—In workshops containing many tools and commands, the user needs to know which tool or tools are active, which ones he was in previously and their order, and which ones he can enter from here.

(3) Command Syntax Space—During the specifications of a command, the user may need to know what he can or is expected to do next and how to back up to a previous point.

The NLS display screen is organized into windows, as described in some detail in Reference 9. These windows are arbitrary rectangles. Windows can be displayed essentially all the time or overlaid with others. Windows can grow dynamically. Some windows are allocated and displayed or not displayed under system control for status and feedback information. Others can be created and manipulated by the user for display of his information space. Items selected from the screen by pointing at them with the mouse are indicated with an appropriate feedback mark. With typewriter terminals, one does not have this two-dimensional random display capability. While the same information can be given to the user, less can be given automatically, or at least the information must be given in an altered form.

(1) Information Space—The present NLS information space is hierarchically organized. A user has a directory or directories within which there are files. A file can contain notes on many subjects stored under various headings, his mail, or single documents. Files in turn are hierarchically organized as a tree of information nodes containing text, graphics, or both.

Files can contain cross citations to specific points within other files or the same file, thus creating networks. NLS has appropriate commands for moving within and between files and for obtaining a display of the path over which one has traveled, and commands for backtracking along this path.[1]

Display screens have a limited number of lines within which to display information, and typewriters, even at 30 chars/sec or higher, cannot quickly and easily print out large documents. Also, the user often wants to see a summary or overview of a document or have it formatted in special ways to aid his understanding. To meet this need for easy control of information portrayal, NLS has a concept called "view specification." The user can change his "view" within the commands for moving in information space or by separate command. So that he can be reminded of his current view, the most commonly used view parameters are fed back to him in a small window in the upper right hand corner of the screen. When he is at a point in a command where it is permissible to change views, this fact is fed back both by prompt (if prompts are turned on) and by enlarging the characters in the view-feedback window. For more discussion on moving, viewing, and portrayal in NLS see References 1 and 4.

(2) Subsystem or Tool Space—NLS is viewed as a collection of tools (subsystems) that can be used cooperatively. Each subsystem contains a number of logically related commands and has a name, such as Base

(the collection of editing and file manipulating commands), Calculator, and so on. All the tools work on information in the same file structure and the user can move from one tool to another, or execute commands on a single command basis in any tool from any other tool, as mentioned earlier. The user can receive a display of subsystems available to him or an ordered list of the subsystems in which he has previously been.

The name of the current subsystem within which he is operating is fed back in a small window in the upper left-hand corner of the screen in DNLs and as a four-character prompt in TNLS.

(3) Command Syntax Space—Several levels of feedback and types of "help" are available to the user in formulating a command to the system. Each is described below. The Help database, to be described, clearly is also generally useful for understanding the system as a whole.

(a) Command-Word Recognition:
The options here were described earlier and this mode is primarily useful in minimizing keystrokes and in triggering additional feedback.

(b) Noise Words:
When the system recognizes a commandword or field, it generates what we call "noise words" set off in parentheses so the user can distinguish between what he has entered and what the system has added. For example, INSERT STATEMENT (to follow), MOVE WORD (from) aid the user to remember to designate a statement in the first case, or select the word to be moved. In the latter case, after selection, the characters (to) will be fed back to prompt for the destination of the move. The noise words aid the user in remembering what to do next. Novice users report that noise words are one of the most useful initial aids. As more experience is gained, the other aids take on more importance. This is an important point to note: users at different levels of experience value different forms of feedback. Usefulness is not only determined by the inherent characteristics of the aids, but also by how they are implemented.

(c) Prompts:
When the user completes the specification of a field in a command, he is prompted with some terse characters indicating the type of thing expected next and the alternatives available to him for specifying, selecting, or addressing the needed argument. In DNLS the prompts are displayed on the line below that used to feedback the state of the users command specification and appropriately positioned horizontally. In TNLS the prompts appear in the command specification feedback as appropriate. Users can turn prompts off, which some users of TNLS do when they reach a certain level of proficiency, although many highly skilled users always operate with them on. DNLS users tend to always operate with them on because the high speed of the display does not slow down work while providing useful information. Users can also specify terse prompting, in which case optional fields are not prompted for. Beginning users have indicated that prompting is useful, but would like prompts to be more mnemonic and of English type and word length.

(d) Next Options and Syntax:
If the noise words and prompts are not sufficient to jog a user's memory about what options are available to him next, he can strike a ? or a <Control-S>. If he strikes a ?, the system displays, in alphabetical order, all the command-words that are legitimate for the next field or more extensive information than is available in the prompts for other fields. If he strikes <Control-S>, the system prints out the syntax of the command from his present position to the end of the command. The ? facility is extensively used and is very useful in refreshing one's memory about infrequently used commands or new commands for a user with only a basic knowledge of command system concepts and vocabulary. The <Control-S> feature does not seem to be extensively used at present and may indicate that the ? facility is sufficient.

(e) Help Data Base:
If the above facilities are not sufficient because of uncertainty about a basic concept or vocabulary word or the user wishes more information about the effects or use of a command, he can enter the Help tool. Entry can be from the basic command level or from any point during command specification. In the latter case, the system utilizes the information input up to this point to take the user to an initial point that describes the specific command and field where he is located.[10]

Once in the Help Database, a simple set of command conventions and the organization of the database allow the user to easily examine related subjects or move to higher level descriptions.[10] There are many unanswered questions about the best structure of a help database, how to mesh online and offline documentation properly, and what forms of accessing mechanisms to provide for novices and skilled users. We are just beginning to review our experience with online help facilities to this point.

(f) Active Tutorial Help:
The next level of Help facility would be an active tutorial facility. We have not yet implemented such a facility but can see its value. An example of such a facility is the work going on at BBN on the NLS-Scholar system.[11]

ERROR MESSAGES AND RECOVERY

Error messages indicating an incorrectly spelled file name or improperly specified entity are fed back to the user in a window at the top of the screen. The user is left at an appropriate point within the command specification or, where necessary, he must start over again to respecify the command. The text of error messages is important and should be as specific to the problem as possible. This has implications within the system design for trapping error conditions as early as possible and determining the appropriate message for the specific error and total context of the user. While we have made progress in this area, there is much more that could be done to meet the need stated above.

There are now no automatic error correction mechanisms built into the system, such as spelling correction or "Do What I Mean" type facilities.[14] These would probably be useful to add when resources permit.

EDITING AND BACKUP DURING COMMAND SPECIFICATION

The user can perform certain simple editing and backup operations during command specification. At any point during command specification he can do a "command delete," which will take him back to the basic command level. This is useful if he gets confused and wants to return to a known state or changes his mind about which command to perform next.

The user can delete the last character input or last selection made on the screen with a "backspace character" keystroke or button push on the mouse. He can repeat this process and continue the incremental backup process to the basic command state.

He can also delete the last word input, or the field specified to date, with a "backspace-word" keystroke or button push on the mouse. He can also repeat this process backwards to the basic command state as well.

IMPLEMENTATION

The mechanisms and data bases needed to implement the user interface have been modularized and isolated as a "Frontend" that can run on a separate computer, such as a minicomputer close to the user, and communicate with the basic tool information processing routines ("Backend") over a communication network. The Frontend consists of terminal handling capabilities, a command language interpreter, and two data bases; a Grammar representing the language syntax and noise words; and a User Profile indicating how the user wants various parameters set for him, such as his prompt and command recognition modes, keyboard key translations, and so on. The Grammar is generated from a high-level description of the user interface written in a language special for this purpose we call Command Meta Language.[12]

Given this particular system organization, it is easy to tailor, subset, or modify the user interface for individuals or groups, or to create interfaces for new tools.

Furthermore all the levels of help information, except the Help Data Base, are derived from the Grammar, which guarantees their correctness as the system changes and is debugged. Various forms of hard copy documentation, such as command summaries, are also derived from the Grammar representation.

Terminal transparent display language (TTDL)

by CARL E. KREBS, C. BUMGARDNER and T. NORTHWOOD
INCO, Inc.
McLean, Virginia

ABSTRACT

Terminal Transparent Display Language (TTDL) is a software language that implements complete and effective communications in an on-line computer system containing two or more different types of terminals. TTDL integrates differing terminal display techniques into a common language, freeing the application programmer from the specifics of terminal data handling and allowing him to concentrate on his primary function of providing a service to the terminal user.

INTRODUCTION

INCO, INC. developed and is currently implementing Terminal Transparent Display Language (TTDL) as part of the Terminal Oriented Support System (TOSS) Research and Development project for the Rome Air Development Center (RADC). The purpose of TTDL is to provide a software language and support system which will allow communications to different terminal types without reprogramming. See Figure 1. Under TTDL, terminal differences become "transparent" and do not require consideration by the programmer.

TTDL was specifically designed for use on Digital Equipment Corporation (DEC) PDP-11 series minicomputers that are terminal-oriented. TTDL provides the capability to operate any number of different terminal types on this system because it approaches terminal transparency from a functional standpoint. TTDL was designed to support the logical functions required by the intelligence analyst, rather than the specific terminal devices he might wish to use. For example, TTDL allows the programmer to specify an "accentuation level" to emphasize a particular section of text. This level is then mapped into a specific terminal's physical characteristic; this may be blinking on one terminal, but may be reverse video on another terminal.

This paper addresses four specific areas of the TTDL system. Firstly, it describes the Display Specification Language, the primary communication tool of the application programmer.

Secondly, it describes the seven most important functional features of TTDL. They are:

- Screen Area
- Command Line
- Select Menu
- Screen Formatting
- Data Checking
- Control Input
- Display Library

Thirdly, it describes the separate software modules which drive the system. And lastly, it details the control and flow of data through the system.

By describing TTDL in terms of its user functions, this paper hopes to present a more meaningful software description; one from which the reader can understand TTDL's operation as well as its theory.

DISPLAY SPECIFICATION LANGUAGE (DSL)

TTDL defines displays using the Display Specification Language (DSL). This language is designed for use with either FORTRAN or MACRO-11 (PDP-11 assembly language). DSL is clear and concise and allows great flexibility in designing displays. Displays can be defined in three ways: statically, not changing during the program; dynamically, using data from the execution of the program; or a combination of both ways. DSL provides for naming a field or group of fields so that they can be referenced by routines which modify, extract data from, or dynamically accentuate such named fields. This accentuation can be applied to any or all fields in the display, either when the display is defined or later during program execution.

There are 16 levels of accentuation, including the normal level (no accentuation), and a "zero" or blank level (data input is not displayed). The blank level is useful for entering passwords or other classified information, and for entering error messages into the display, which can then be used merely by dynamically changing the accentuation level.

DSL provides formatting capabilities, which include:

- Floating tab positions (up to 16) which are set

according to actual data length for the fields and the width of the target screen display area.

- Right and left justification around a tab position.
- Center text on a line.
- End page.
- New line.
- Justify text against the right margin.
- Fill the space between two fields with dots.

DSL allows the programmer to specify data attributes for input fields, such as data type and length. Data types include:

- String fields which consist of any character in the print set. Specific string attributes include alphabetic, numeric, blank, and special characters (all other printing characters). Any combination of the four is also allowed.
- Integer fields.
- Real fields in which scientific notation is also supported.
- Minimum-maximum field where the integer entered must be between two limits.
- Two character choice fields consisting of one position where the user must enter one of two specified characters.

Any of the above fields may also be specified as mandatorily requiring input as opposed to optionally requiring input. Input fields can also be accentuated.

DSL thus frees the programmer from varying considerations of screen size, display techniques, accentuation techniques, input methods, and required hardware protocol.

FUNCTIONAL FEATURES OF TTDL

Screen areas

The terminal display device can be divided into multiple independent regions, each known as a Screen Area (SA). Each SA can be treated as a separate display, allowing multiple programs to be run simultaneously on a single terminal. SA's can be defined in any realistic size.

Command line

Each terminal has a one-line command line. Input on this line is passed to a command interpreter which checks the command against a list of system commands. The command is then dispatched to the appropriate routine for implementation. Error messages, either syntax errors from the interpreter or execution errors from the service modules, are displayed on the command line at the end of the entered command. Current commands include running and aborting tasks, and display paging commands.

Select menu

A common programming technique is to provide the user with a list of choices, or selection menu, for the user to select from. TTDL provides a select construct in which the programmer merely lists all the choices in the menu. The prompt line (e.g., ENTER DATA

. . .) is automatically generated by TTDL, a different prompt being available for each terminal type. This construct also allows the terminal user to make full use of any available input devices which the terminal supports. These may include light-pen, cross-hairs, function keys, or he may simply type in his choice. The choice made is echoed in the input field of the prompt line. The program sees only an integer denoting the choice selected.

Screen formatting

TTDL provides automatic display formatting by fitting the logical display to the target SA. The process includes breaking lines that are too long by backscanning for a blank and breaking at that point for a display-only field, or breaking exactly at the end of the line for an input field. The display is broken into pages if it cannot be made to fit on a single page. Efforts are made to fit the display on one page, such as ignoring "new line" codes for compression of selection menus. If the display must be paged, efforts are made to keep a logically connected field from being broken between pages by moving the entire field to the next page. Page information is also included at the bottom of each page, i.e., page number, whether there are more pages or not, and paging commands which can be entered by input devices—if they are available.

Data checking

TTDL provides automatic input editing to insure that data meets the restrictions assigned by the programmer. The user is not allowed to leave the current page until all errors are corrected. The number of errors is displayed on the bottom line of the SA. Fields requiring mandatory input must also be filled in correctly, although optional fields can be left blank. The fields are then marked to show the application program those that had data entered.

In the case of string fields, any spaces not filled in always appear as nulls to the programmer, no matter what character is used to reduce the limit of input fields on the terminal. Selection menu choices are checked for the validity of the total number of choices available.

Control input

Control sequences can be entered apart from normal data input. These sequences trigger control functions on the SA in which the programmer is working. These functions include:

- Command line—transfer to enter data on, and return from command line.
- Paging commands—page forward, page back, first page.
- Enter data—data is ready to be returned to the application program.
- Cursor control—move cursor up, down, right, left, home. Cursor only stops on unprotected areas.
- Tab—tab to next or prior input field, tab to next field containing incorrect data (flagged by data checking routines), tab to the first input field on the next line.
- Move to the next active SA.
- Erase input field.

Each function is declared valid or invalid and ignored pursuant to the status of the SA.

Display library

The user can store displays on disk through a display library capability, referring to them by a six-character name. Functions supported are store, retrieve, and delete. This capability frees the application program from the storage overhead of having the displays defined internally. Checks are made for duplicate names when storing. When retrieving displays, the actual display name is checked against the active displays; if it has the same name, it is renamed, and the new name is given to the program to use. This allows the same display to be used concurrently by different terminals controlled by the same program.

TTDL SOFTWARE MODULES

TTDL was designed using two kinds of software modules: primary modules, which drive the system; and support modules, which provides sub-processing and data support for the primary modules.

The primary modules are the Preprocessor, Postprocessor, Secondary Input/Output, and Primary Input/Output modules. They handle the actual transfer of data to and from the terminal.

- The preprocessor translates the DSL into a Terminal Independent Format (TIF).
- The postprocessor formats the data to fit the SA, and provides dynamic display paging support.
- The secondary input/output module translates common capabilities into terminal dependent functions.
- The primary input/output module transfers data to and from the terminal.

The support modules are Buffer Manager, Process Control, Field Routines, Application Interface, and Display Library modules.

- The buffer manager directs the storage and retrieval of TIF data.
- The process control module supports intra-task and inter-task communications.

- Field routines allow modification to and retrieval of data from the display by the application program.
- The application interface module provides a table-driven interface between the applications program and TTDL.
- The display library module handles the storage and retrieval of displays from disk.

The following paragraphs provide a complete description of each TTDL software module.

PRIMARY TTDL MODULES

Preprocessor (PRP)

The preprocessor is a finite-state compiler which translates the DSL specified by the application program into a Terminal Independent Format (TIF). Using state tables, the preprocessor translates the data from DSL to TIF, which is suitable for storage on disk and recall for retrieval on any type of terminal. The preprocessor is completely terminal independent, requiring no information about the display terminal.

As a finite-state compiler, the preprocessor uses a series of macros to conduct state-translation processing. This construction allows easy additions to the language by merely making the additions to the state tables and combining them with the appropriate processing macros.

Postprocessor (PSP)

The postprocessor formats the TIF produced by the preprocessor to fit the target screen area. It builds a transaction file correlating data in the TIF to locations on the SA. Algorithms break lines that are too long, and automatically pages displays which are too big for one SA. The resulting transaction file is sent to the secondary I/O module for further processing. The postprocessor is virtually terminal independent, requiring only SA size and the number of display characters required for certain functions.

Secondary I/O (SIO)

The secondary I/O module produces the actual data stream sent to the terminal. As input, it uses the TIF, the transaction file built by the postprocessor, and a set of terminal dependent protocol tables and routines.

The secondary I/O is table-driven, a feature which facilitates addition of new terminals to the system. Addition of a new terminal requires only the addition of protocol tables and those routines which are unique to the terminal or new to the system. As more terminals are added to the system, the number of new routines decreases; most routines are common to a class of terminals.

Specific functional capabilities of SIO include: adherence to hardware protocol for each terminal; display field accentuation; addition of dots for the DSL feature; compensation for differences between terminal types; and hardware simulation with software routines.

Primary I/O (PIO)

The primary I/O module handles the actual transfer of data to and from the terminal. Inputs to primary I/O from the SIO are the address of the data and its length. Important features include: interruption of a read to allow a write to occur, and restoration of the read at the exact point of interruption; queueing of other reads while a read or write is in progress; validation of control sequences entered by the user—invalid sequences are ignored; support of zero level accentuation by echoing blanks to the terminal when data is entered; and asynchronous operation, by processing requests on other terminals until recently issued I/O is completed.

The primary I/O is also table driven, having tables of write routines, read routines, etc., which are dispatched by terminal type.

SUPPORT MODULES

Buffer manager

TTDL uses dynamic storage for its work areas, the majority of which are used for TIF. The buffer manager is responsible for handling of these buffers.

TTDL uses 512 byte blocks of dynamic storage allocated by the Intertask Coordination Module (ICM) of TOSS. Using a logical-to-physical mapping algorithm, the buffer manager translates TIF addresses into a specific block of TIF. The buffer manager pages the buffers to disk on a demand basis when in-core storage runs short, using an extensive algorithm to determine which blocks to write out. A currency concept is also used, through which a certain buffer is kept current for the TIF being processed, with a pointer to the current character in the buffer. Functions include: set currency; get current character; put a character; access a block; deaccess current block; and map into current location. This last function allows the requesting module to directly access the current block.

Process control module

The process control module provides the control required by TTDL to permit the simultaneous support of multiple tasks, multiple terminals and terminal types, and multiple screen areas on each terminal. The process control module assigns a Process Control Block (PCB) to each individual process. The PCB contains all appropriate data for the process, including a stack area where data may be stored if the process is suspended. In addition to providing intra-task control, inter-task communication is achieved by queueing PCB's from one task to another.

The process control module also resolves resource contention by suspending a process until the required resource (such as nodes, buffers, or PCB's) is available.

Process control functions include: passing control to another process; suspending a process; spawning a new process; ending a process; and subprocess calling and return (analogous to subroutine call and return). These functions manipulate queues of process. A dispatcher module provides the control mechanism for dispatching processes to be run and identifying the task in which the process resides. The dispatcher also handles Service Request Blocks (SRB) which are requests for service issued by application programs through ICM.

Field routines

Field routines consist of a group of modules which allow the application programs to interact with the TIF for their display. Individual modules include: initialize a field to the null state; set fields to string, integer, or real values depending on field type; retrieve data from string, integer, or real fields; change accentuation levels of display fields; test the availability of input for input fields; and set origins for generated field names. The largest modular group is a set of routines to find specified fields in the TIF which the application programs desire to access. Since the processing performed by most routines is minimal, addition of new routines is easily accomplished.

Application interface module (AIM)

The application interface module is the entry point for all application calls. It checks the format of each call and formats a service request block for transmission to the appropriate TTDL task. The AIM is FORTRAN compatible, and addition of a new host language would require only a small system enhancement. TTDL task specifications would not be affected.

The AIM is table driven, so that a new call requires only the addition of two macros. The AIM also provides conversion functions for dynamic display definition from data provided during execution.

Display library

The display library module consists of two parts. One part performs the directory functions and allocation of disk storage. The second part, the external processor, performs the formatting of the display TIF and associated information for storage on disk.

A directory entry consists of a 6-character ASCII name, the virtual block number of the display, and the number of blocks allocated. Each directory has a header which contains a pointer to the next directory and the number of blocks allocated for a high block number. Each directory is one disk block long. A deleted directory entry is marked such that the blocks may be reused.

While the display library keeps track of display storage, the external processor formats the information in the TIF and additional information required when the display is reformatted. Parameters to the external processor include a buffer to store the information in and its length. The external processor can also be used to send displays to and from other systems.

DATA AND CONTROL FLOW

The following paragraphs describe the typical flow of data and processing to and from a terminal. This flow is illustrated in Figures 2 and 3.

Display definition and output

Operations start with a call to the routine DISDEF (display definition). DISDEF formats a request specifying the argument and passes it to the preprocessor. The preprocessor then maps into the application program and retrieves the DSL. The DSL is then converted into TIF and given to the buffer manager for storage.

Once the display is defined (by one or more calls to DISDEF) the program indicates its desire to output the display via the FLASH call. This is dispatched to the postprocessor which creates a transaction file based on the TIF and the size of the target SA. This transaction file relates TIF data to SA position.

Control is then passed to the secondary I/O module, which uses the TIF, the transaction file, and terminal dependent tables and routines to create the output stream. SIO also adds the hardware protocol for such features as protected/unprotected fields, emphasis (blinking, reverse video, etc.), code transliteration, and cursor positioning.

Finally the buffer containing the output stream is passed to the primary I/O module, which transmits it to the appropriate terminal.

Data input

After the display has been output, the SIO then prepares to input data. This data can consist of control sequences or input for the program. The SIO sends a request to the PIO for each field, stating how many

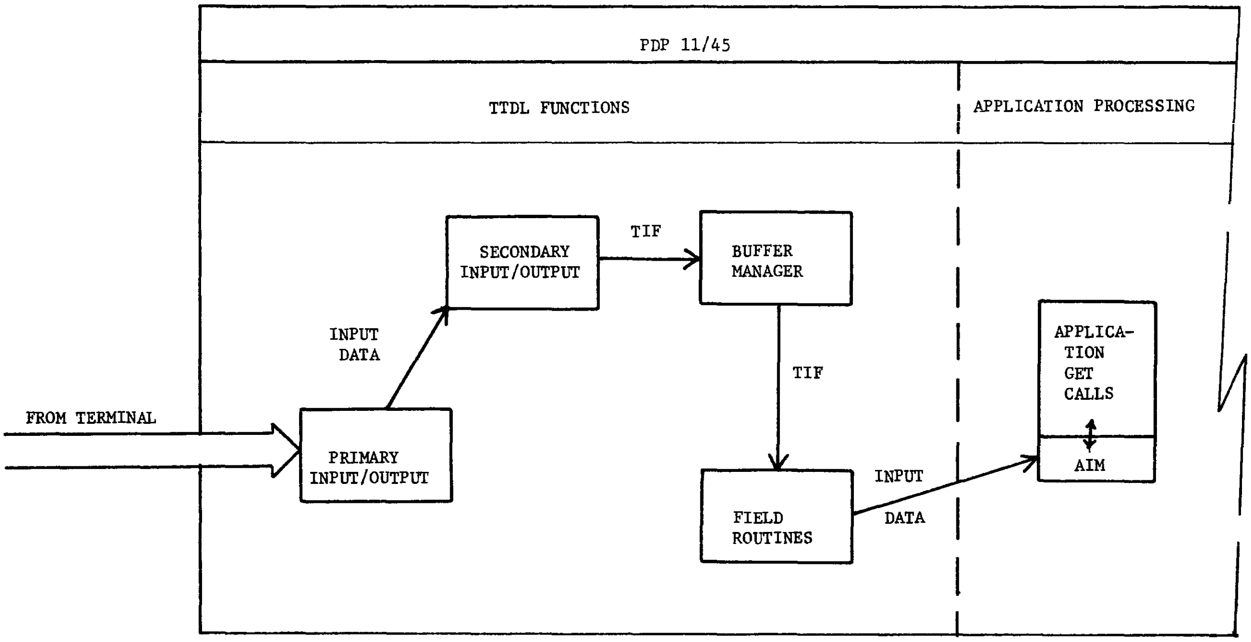

Figure 2—Input flow.

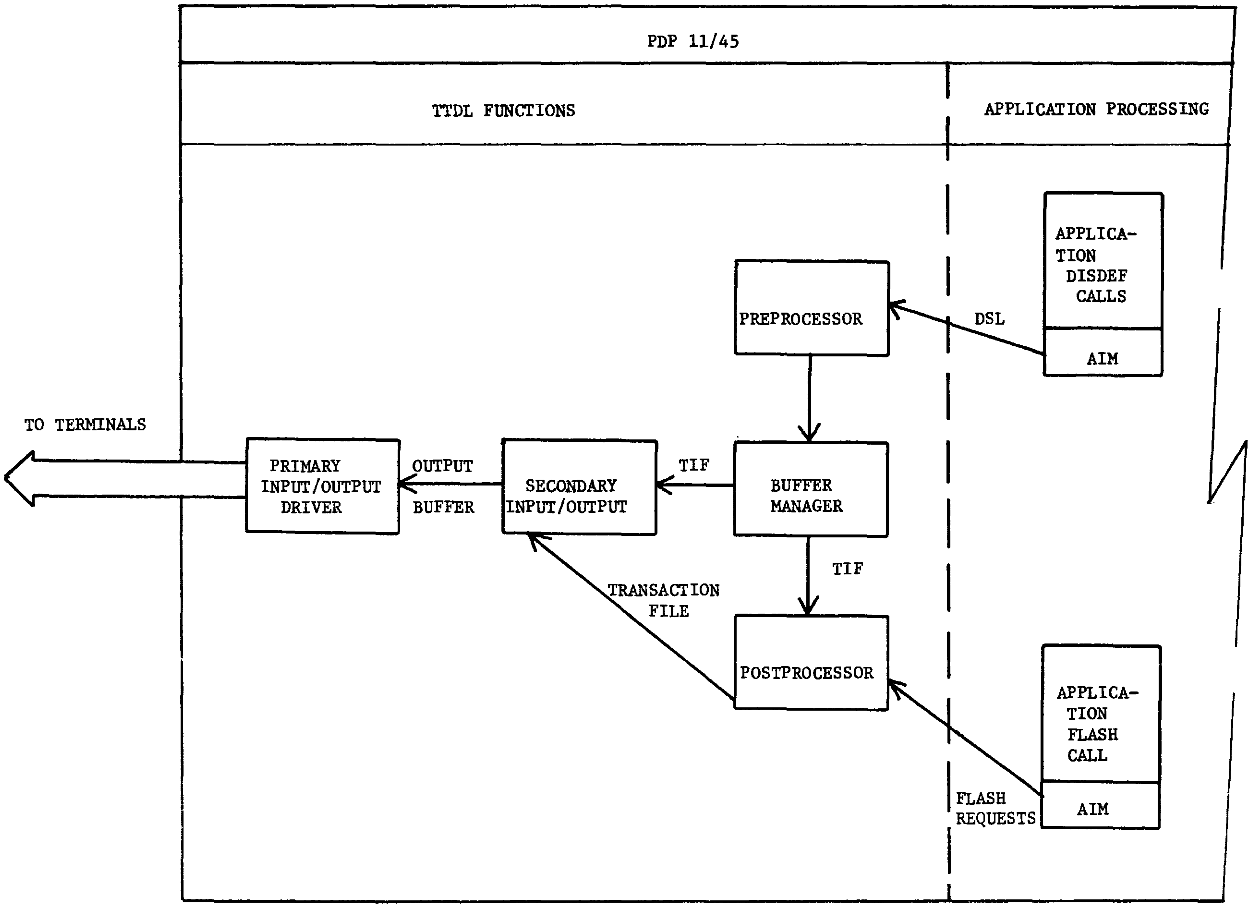

Figure 3—Output flow.

characters are required, any accentuation information, and buffer addresses for the input and output buffers. The PIO then returns control whenever the number of control characters or a valid control sequence is entered. The SIO then either goes to the next field, or processes the control sequence. When all the data is entered, the SIO returns control to the application program, which can then modify or retrieve the data entered.

SUMMARY

As can be seen from the above discussion, TTDL is a useful flexible language which can effectively facilitate communications among the many and various terminals of large data processing systems. Such a language delivers powerful capabilities to system users—capabilities which are necessary in the rapidly changing data processing environment.

Working set restoration—A method to increase the performance of multilevel storage hierarchies

by PETER SCHNEIDER
Siemens AG
Munich, Germany

ABSTRACT

The emergence of new storage technologies such as Charge Coupled Devices (CCD) and Bubbles with access times which lie in the access gap between semiconductor memories and rotating magnetic storage media is another important step toward implementing multilevel storage hierarchies.

However, a comparison between a three-level storage system, consisting of cache, page buffer and CCD main memory, and a conventional two-level main memory system will show that the three-level hierarchy using the transfer on demand strategy has an effective access time which is higher by about a factor of 2.

Yet, through better use of the program locality the access time of a three-level system can be reduced to that of the two-level cache/page buffer system. Using this method, the so-called working set restoration, the working set of pages of the next program to be run is loaded into the page buffer during execution of the active program. The required page transfer operations are executed concealed and are thus not time-critical for the processor. This means that for program processing only the access time to the two-level system becomes apparent.

The advantage of a three-level system of this type lies not so much in the improved performance but rather in the lower costs, since it permits the use of a large-capacity main memory on a technology level which is cheaper by a factor of 2 to 4 as compared with MOS RAM.

INTRODUCTION

In the planning of large computer systems, there is a pronounced trend toward increased use of multilevel storage hierarchies. The first step in this direction was the development of the software-controlled virtual memory.

The emergence of the various semiconductor technologies such as the bipolar and MOS technologies, which brought about random access memories of various densities, speeds and costs, led to the development of directly addressable two-level main memory structures. These consist of a cache designed in fast and hence expensive bipolar technology and a main memory designed in cheaper, albeit slower, MOS technology; see Figure 1. By making use of the locality of the active programs, the effective access time of the main memory system can be reduced to nearly that of the cache. The introduction of a two level main memory system in machines with a virtual memory was the next step toward a system enhancement through the use of storage hierarchies. Recent developments include new storage technologies such as Charge Coupled Devices (CCD) and Magnetic Bubble Domain Devices (MBD) of which some were announced as products. Their access times lie in the long-existing access gap between the semiconductor technologies used in the main memory and those of the secondary storage media. The per-bit costs are also estimated to fall in between the price categories of the two known technologies.

Because the new storage technologies have an operation mode different from that of the random access storages, they are called Block Access Memories (BAM).[1] Whereas with RAMs any bit can be addressed within an equally short time, BAMs require long access times for single bits while, for a sequence of bits, the longer access time occurs only at the beginning with the remaining bits following sequentially at a high data rate.

In the system considerations outlined in the following paragraphs, the CCD technology will be used as an example representative of the above-mentioned new technologies.

CCD TECHNOLOGY—ITS COST AND PERFORMANCE

The operation of Charge Coupled Devices (CCD) is founded on the basic concept of storing information in MOS capacitors in the form of charge packets and to

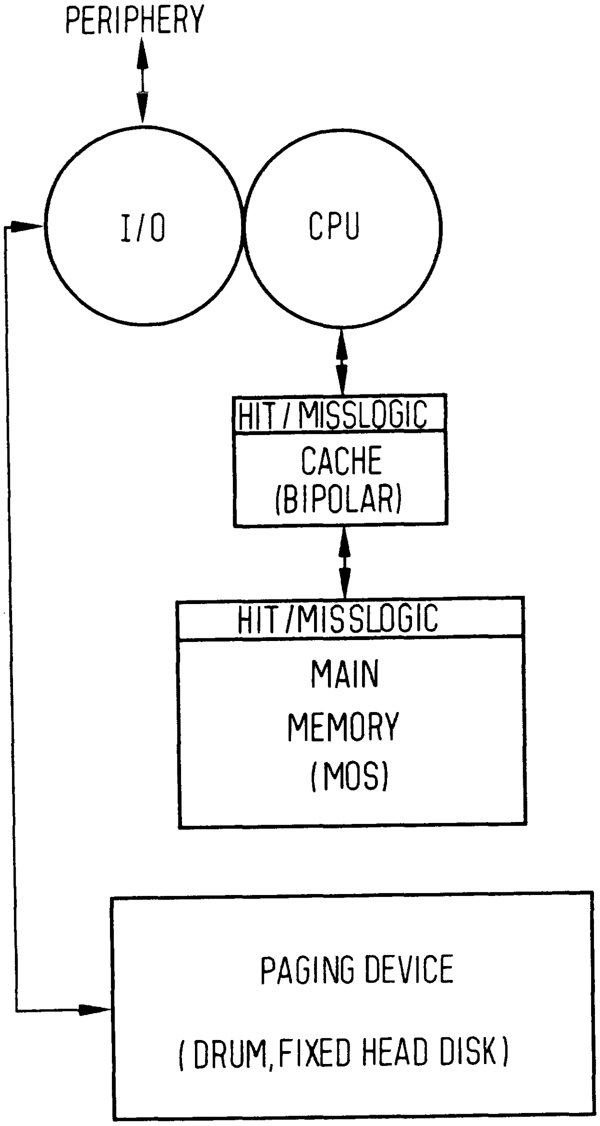

Figure 1—Two level working memory hierarchy with paging device

shift it at the semiconductor surface from one capacitor to the next. This technology is thus suitable for generating shift registers for the storage of analog as well as digital information. The inherent advantages of the CCD technology are that it is based on the tried MOS technology, storage locations can be extremely small and a high production yield is expected. As compared with MOS RAMs, memory densities greater by a factor of 2 to 4 and per-bit costs lower by a corresponding factor are anticipated for the CCD memory chips.

Memory chips implemented in this technology contain randomly addressable shift registers which are closed via read/write terminals. Since, in the CCD technology as well as in the conventional MOS technology, information is stored dynamically, a refresh of the entire information written is needed after several milliseconds. This is also done by the read/write terminal. Due to shift-frequency-dependent transfer losses, which occur when the information is shifted from one capacitor to the next, the length of shift register loops is limited. As an example, lengths of up to 256 bits are believed to be realizable for a shift frequency of 10 MHz.[3]

For the following system considerations, devices with a capacity of 65,536 bits, a setup of 256 loops with 256 bits each, and a shift frequency of 5 MHz are assumed. The time required for a complete pass of the information stored in a loop is then 51.2 μs; the mean value for accessing an arbitrarily chosen bit is after one half pass, corresponding to 25.6 μs. Memory chips incorporating these characteristics will be available in the near future.

Some system-engineers believe that these new technologies will challenge only drum and fixed-head disk storages, and thus solely consider the possibility that these technologies replace the conventional paging device in the virtual storage system. By contrast, a discussion in Reference 4 is based on the assumption that the use of a CCD main memory within a three-level directly addressable main memory might obviate the need for a paging device.

However, since the CCD technology, viewed price-wise, can probably compete with MOS RAMs but not with secondary-memory technologies, the following question arises: Can costs be cut maintaining the same system performance if a two-level main memory is replaced by a three-level main memory structure with a CCD main memory, assuming that the virtual storage concept with a conventional paging device is retained?

VIRTUAL STORAGE SYSTEM WITH THREE-LEVEL MAIN MEMORY

To clarify this question, we must first look at the functions performed by today's main memory.

To ensure efficient utilization of the central unit, it is necessary to keep the current pages, the co-called working set[5] of several programs in the main memory even if processing of these programs is interrupted due to secondary storage accesses. If, for instance, program pages are missing which have to be fetched from the paging device and entered in the main memory, processing of the active program has to be interrupted. The page entry takes several milliseconds during which time the central processor would have to wait with nothing to do if no other executable programs were available.

However, if several processes are in main memory, the central unit moves on to another process if the active process has to be displaced. Among the processes kept in main memory are those waiting for a page to be entered from the paging device. This ensures that, upon reactivation, processes will not have to be deactivated because pages are missing which were overwritten just before.

This holding of working sets of several programs plus the necessity of also having some operating system routines reside in main memory already require main memory capacities of 1 MByte or more for today's timesharing or multiprogramming environments. Due to the mounting storage requirements of individual users as well as the increased use of the installations for multiprogramming applications, an increased memory capacity of over 16 MByte will be needed.

This very fact presents a strong argument in favor of using a cheaper memory technology in the main memory. However, measures must be taken to guard against a loss of system performance. Due to the CCD memory access time which, compared with random access working memory, is longer by several orders of magnitude, an outright replacement of the main memory is not possible because resident operating system routines must remain readily accessible and the time of access to data of active programs must likewise not be adversely affected.

Considerable savings can, however, be achieved in terms of expensive random access storage capacity by dividing the main memory capacity into two categories using the following criteria:

(a) A large capacity memory, which will continue to be called main memory and is designed in CCD technology, for storing non-active working sets;

(b) a small-capacity random access memory, the so-called page buffer containing the currently active process as well as the resident and a small number of exchangeable operating system routines.

A strategy equivalent to the virtual memory's paging on demand might also be used here as a load strategy between main memory and page buffer. Pages could then be transferred to the page buffer each time they have been found missing by a built-in hit/miss logic. This method will be referred to as transfer on demand.

This division of the main memory results in a three-level main memory system consisting of cache, page buffer and main memory; see Figure 2. Originally, this division was made under the aspect of cost advantages alone, but we have to examine now whether a procedure of this kind will not result in a loss of performance vis-a-vis a conventional system.

TWO-LEVEL AND THREE-LEVEL MAIN MEMORY SYSTEM PERFORMANCE COMPARISON

For a comparison of the performance rate of different main memory systems, we use the effective access time for read operations

$$T_{eff}=h_1 \cdot t_1+(1\text{-}h_1)\cdot[h_2\cdot t_2+(1\text{-}h_2)\cdot t_3]$$

since only read operations are time-critical whereas write operations can in general be run concealed while the processor is busy. h_1 and h_2 are the hit probabilities for read accesses, t_1, t_2, t_3 the access times to the different hierarchy levels.

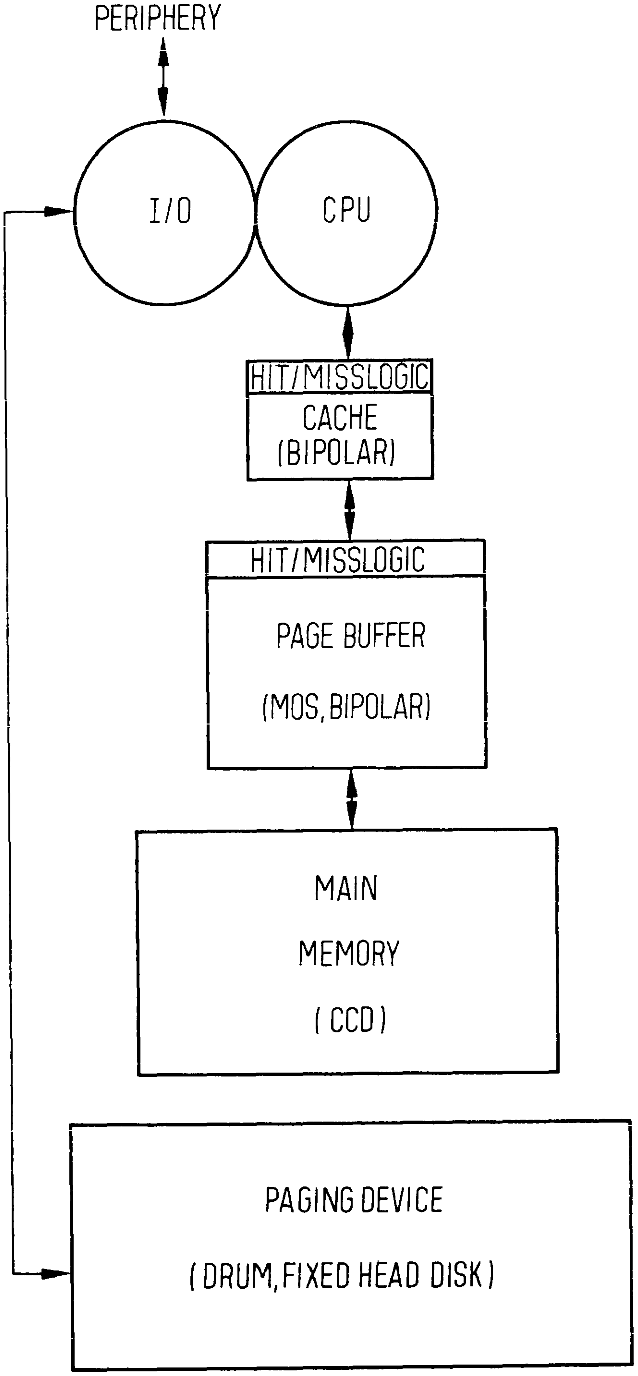

Figure 2—Three level working memory hierarchy with paging device

Let us first consider the two-level memory hierarchy cache/MOS main memory. Assuming

$$h_1=95\%, t_1=100 \text{ ns}, h_2=100\%, t_2=1000 \text{ ns},$$

the effective access time T_{eff} will be 145 ns. By comparison, a longer mean access time of 250 ns results for the three-level hierarchy with CCD main memory, page buffer and cache, when $h_2=95\%$ and $t_3=51.2$ μs.

Since the time of access to the CCD memory (t_3) is much greater than that of the page buffer (t_2), the effective access time of the overall memory is extremely susceptible to changes in the page buffer miss rate. If this increases heavily, the effective access time assumes values that are too high to be tolerated.

These considerations lead to the tentative conclusion that under adverse conditions the performance of the three-level hierarchy will be worse than that of its two-level counterpart when using the transfer-on-demand strategy assumed here, which works on the principle that pages are fetched from the main memory only after a page miss has occurred. In order to allow the cost-saving three-level hierarchy to be used without degradation, some means must be found to either prevent or at least significantly reduce page misses, which are responsible for longer access times. This may be achieved by use of the working set restoration method.

WORKING SET RESTORATION

This term will be used to designate a method designed to provide a program, upon its reactivation, with the specific memory environment it requires for optimum processing. This is where the locality of a program, referred to as working set of pages,[5] comes in. Under the conventional method, deactivated programs are, upon their reactivation, provided with that number of page frames for entering the pages which corresponds to the actually required number of pages during the preceding processing interval. In contrast to this, the method proposed here attempts to retrieve the actual pages addressed in the preceding interval rather than mere page frames.

A similar method is discussed by Tung[6] who suggests that shorter transfer times between two memory hierarchy levels be achieved by interleaving the main memory in as many ways as there are page frames in the page buffer, i.e., that the number of main memory modules should match the number of page frames in the page buffer. The interface width is equated with the page size. Nevertheless, there are processor wait times under this system during process changeover until a new process can be started. Besides, this concept would require a main memory with an extremely large capacity and the use of very wide interfaces would also pose a problem. Further, it should prove difficult to ensure an optimum distribution of all active pages over all possible memory modules—a necessity if the method proposed by Tung is to work properly. For these reasons, implementation of such a system cannot be advocated.

Since it does not make any difference in the time total whether all pages are transferred consecutively or individually upon request, it is suggested here to load the working set of a program concurrently with the processing of another process so that it does not occur time-critically for that process. To allow this, the page buffer capacity must be expanded by an additional area so that one area will always be available for program processing and another for loading the working set of the successor process. Further, the time available for concealed loading must be sufficient. However, it can be safely assumed that it is, because it is made up of the runtime section of the active program and the operating system execution time for the subsequent process change.

Through the use of this procedure, the access time of the three-level system is reduced to the access time of the two-level cache/page buffer system since the majority of page misses were forestalled in a non-time-critical manner. The third level will have to be accessed only when pages which reside in the main memory but not in the page buffer are added to the working set of the active program.

SYSTEM CONFIGURATION

Having explored the theories and facts suggesting that the use of the working set restoration concept as a load strategy between page buffer and main memory seems practical, let us proceed to discuss a sample system configuration and its management.

The memory system, Figure 3, has a cache with generally known characteristics and of conventional size at the top level. Since the cache is independent of the load strategy used between second and third level, it is excluded from the following discussions.

The 512 KByte (K=1024) page buffer is divided into four modules: Modules 1 and 2 are designated for program processing or for loading the successor process working set; Module 3 contains resident operating system routines; Module 4 contains various routines of the exchangeable operating system.

Each of these modules has a capacity of 128 KByte. At any given time, the active program is present in only one of the two modules slated for processing. Both modules contain the page buffer addresses from Ø to 31 (page size 4 KByte). This ensures that, during processing of a program in, say, module 1, the successor process can be entered in module 2 without affecting program execution. Besides this, the allocation of main memory and page buffer addresses is simplified in so far as all main memory addresses are always allocated to page buffer addresses 0 through 31.

The page size of 4 KByte is identical to that used in the virtual memory system. The storage technology employed in the page buffer must be able to accommo-

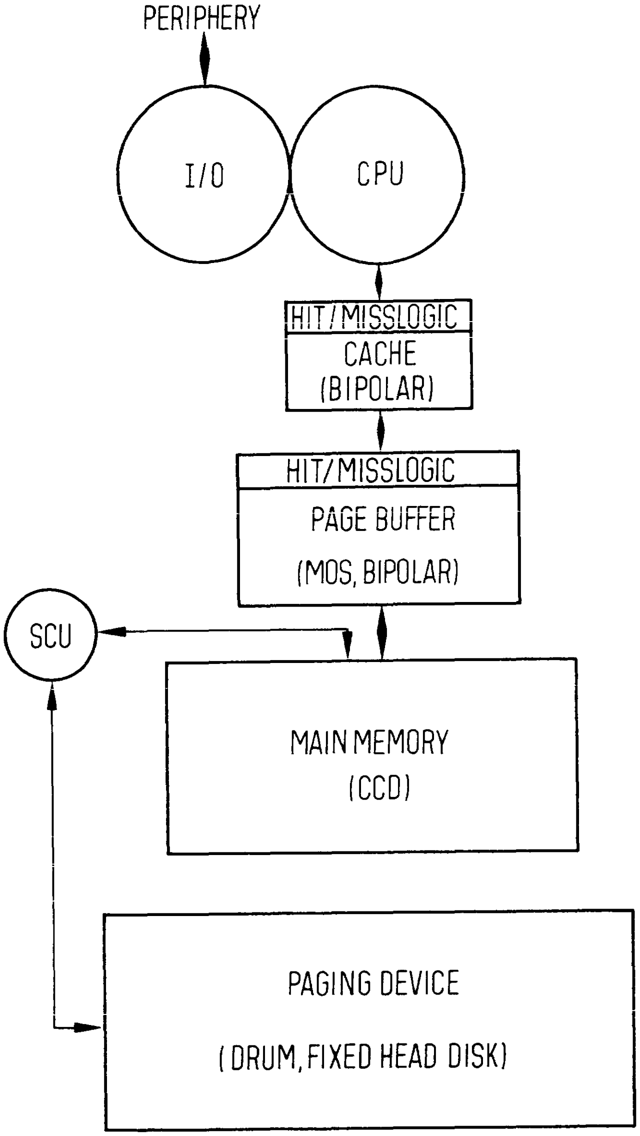

Figure 3—Scheme of the working memory system with direct paging between CCD-main memory and paging device

date the data rate transferred from the CCD memory over a data path with a width of, say, 8 Bytes.

A CCD memory of modular design is assumed as main memory: 144 CCD memory devices with a capacity of 65,536 bits contribute one bit each to a 16-Byte word which is transferred via the 8-Byte interface using the two-way streaming method. Consecutive words of a 4 K-Byte page are successively stored in the CCD loops; thus a page can be read out or written in 51.2 μs with one parallel cycle of all 144 loops. This corresponds to a data rate of 80 MByte/s. The module comprises 256 pages, i.e., it has a total capacity of 1 MByte, Figure 4. Depending on the desired system performance, the CCD main memory can be implemented with capacities from 1 MByte to 16 MByte or more with the aid of these modules.

A hit/miss logic implemented in the form of an associative memory is visualized as a means of checking whether the pages requested by the processor are entered in the page buffer. The associative memory always describes the specific page buffer module (1 or 2) containing the program (addresses 0 through 31), and module 4 containing the operating system (addresses 32 through 63). This ensures that the entries, by virtue of their being located in the hit/miss logic as they are, point to the page buffer address. Another section of the hit/miss logic—again with addresses 0 through 31—will be used for storing the working set table of the successor process. In addition to the main memory address entries, there will be a write bit which indicates whether a page entered in the page buffer was modified and therefore does no longer match the original in the main memory.

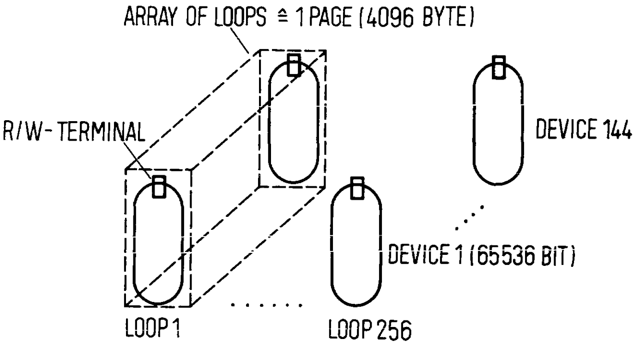

Figure 4—Scheme of a 1 MByte CCD-memory module

In the system discussed here (cf. Figure 3), the exchange of pages between main memory and paging device is not performed via the central processor as in so many existing systems, but rather via a storage processor (SCU) assigned to the memory. This processor has its own memory for storing the pages to be exchanged between main memory and page buffer until they can be entered without interfering with the processes taking place between main memory and page buffer. In addition, the storage processor is responsible for loading the working set of the successor process.

After this overview of the system's hardware components, let us now turn to the specific software requirements for working set restoration.

Each process will have a table assigned to it describing these pages (up to 32) that were entered in the page buffer by that process during the most recent processing period. These tables are stored in the memory of the storage processor according to their internal process code numbers and can be directly addressed by means of these numbers.

In the order to start the working set restoration procedure, the process requiring loading operations must be known to the storage processor. This information is extracted from the process queue maintained by the operating system and is passed by the central processor to the storage processor as soon as this interrupts a program and changes over to another one. This information enables the storage processor to control working set restoration proceedings.

FUNCTIONS

We will now discuss page miss handling and activities involved in working set restoration, Figure 5.

Page miss

After address translation in the central processor, a request address is sent to the memory system. In most cases, an access can already be satisfied in the cache. If a cache miss occurs, the address is switched through to the page buffer. The hit/miss logic then determines whether the requested address is present in the page bŭffer. If the desired page is not available there, it must be fetched from main memory. This is done by switching the address through to the main memory, after which page transfer is started. A processor-requested word within a page is switched through to the processor during page entry and, on the basis of the foregoing, will be received after a mean time of 25.6 μs.

In addition to pages which were read only, the page buffer also contains pages which were modified. Since these pages no longer match their original in the main memory, they must be written back to main memory before being overwritten. If both the requested page and the page to be written back are contained in the same module, this may require two page transfer times. In order to avoid such displacement procedures with page miss, one buffer page is always reserved into which the requested page can be loaded immediately. If the page released for overwriting by the replacement algorithm was modified, it is subsequently written back in non-time-critical fashion to main memory, and then becomes a new buffer page. Thus, 32 pages are active in the page buffer at all times. Yet, since one of these pages is being marked free, a page entry due to page miss can be handled in the shortest possible time.

Working set restoration

A working set is to be transferred from the CCD main memory to the page buffer whenever an active process is displaced. The central processor immediately switches over to the next process while the storage processor starts loading the working set of the next executable process; see Figure 5. The storage processor first reads out the 32 hit/miss logic entries describing the page buffer contents of the program just displaced, and updates the associated page table. In the course of this, it determines which pages have to be displaced from the page buffer and simultaneously checks to see, by way of a comparison with the successor process page table, whether any successor process pages fall into other modules than the pages to be displaced.

END

Figure 5—Flow diagram of the working set restoration activity

The page buffer and main memory addresses are then switched through by the storage processor to the memory control, which is instructed to handle page transfer. Transferred first are those pages that can be entered in the page buffer simply by overwriting unmodified pages.

Transferred next are pages which lie in other modules than the pages to be displaced. This is done in the following fashion: the memory locations are read out of the page buffer in the Read/Update/Write mode and transferred to the main memory, while data are simultaneously written in from another main memory module.

The last pages to be entered are the ones which lie in the same module as the pages to be displaced. Here too, the data are entered in the page buffer via Read/Update/Write, but the page to be displaced from the page buffer must first be transferred to the storage processor for intermediate buffering. Pages of this type are entered in main memory after working set restoration has been completed.

Concurrently with page loading, the main memory addresses of the respective pages are entered in the currently unused portion of the hit/miss logic at a location corresponding to their page buffer address such that, at process change-over time, not only will the pages be in the page buffer, but the pertaining address information will also be stored in the hit/miss logic.

After this discussion of the three-level storage hierarchy's structure and functions, let us now examine its capability as compared with other systems.

CAPABILITY

To measure the capability of the three-level memory structure, a simulation program was created which allows an examination of the page miss rate in the page buffer for the transfer-on-demand strategy as well as under working set restoration. The different handling of page fault interrupts as compared with other interrupts has been taken into account. When a page fault occurs, all pages already entered in main memory are retained, whereas with all other interrupt causes the number of pages found after reactivation will be less. This is where the size of the main memory comes in; it can be calculated as follows: Assume that 100 users are concurrently attached to a computer system. Five of these are to be in the active process queue at any given time. Based on measured values, a mean working set size of 100 KByte can be assumed, which adds up to a memory capacity of about 500 KByte for the processes in the active queue. The remaining 95 users share the rest of the main memory capacity. If main memory capacity is 4 MByte, each process will find an average of 40 KByte available upon its reactivation. If each process is to find a greater capacity available, the main memory capacity must be increased if the length of the process queue remains the same. A greater main memory capacity will then result in increased capability since pages have to be overwritten less frequently in main memory and some of the page faults for previously used pages can be prevented. This is taken into account by the simulation program.

The analysis covered address sequences of several different programs. Table I uses two typical address sequences (program A and program B) to demonstrate the impact of main memory size on the page faulting rate and the page miss rate in the page buffer for both load strategies.

These results yielded by simulation were used for calculating the effective access times of useful processor accesses. The term "useful access" is employed to define only the number of accesses used for actual program processing, whereas the time needed for accesses during operating system activity is viewed as waiting time and is thus prorated to the useful accesses. Using this effective access time, the systems illustrated in Figures 1, 2, and 3 were analyzed and compared. The effect of the cache was ignored because it is the same in all systems.

The following formulae yield the effective access times for useful accesses.

For a two-level system

$$T_{eff1}=h_{pf}\cdot t_{int}+h_{int}\cdot t_{int}+(1\text{-}h_{pf}\text{-}h_{int})\cdot t_2, \text{ and}$$

for a three-level system

$$T_{eff2}=h_{pf}\cdot t_{int}+h_{int}\cdot t_{int}+(1\text{-}h_{pf}\text{-}h_{int}\text{-}m_2)\cdot t_2+m_2\cdot t_3$$

The same formula applies for the three-level systems which differ only in the load strategy. Depending on the load strategy, different miss probabilities (m_2') or (m_2'') must be expected in the page buffer.

h_{pf} and h_{int} represent the page faulting and interrupt rates, respectively; m_2 is the miss probability in the page buffer and t_{int} (=1 ms) represents the operating system execution time for process changeover. t_2 (=1 μs) is the access time to the second level of the two-level system, and t_2 (=160 ns) and t_3 (=51.2 μs) are, respectively, the access times to the second and third levels of the three-level system. Figures 6a and 6b show the cost curves of the compared systems: cost

TABLE I—Effect of main memory capacity on page faulting rate and page miss rate

Program	Main memory capacity	Interrupt frequency h_{int}	Page fault rate h_{pf}	Page miss rate transfer on demand (m_2')	Page miss rate working set rest. (m_2'')
	MB	%	%	%	%
A	4	0.07	1.67	4.66	0.93
	8	0.07	1.27	4.51	1.13
	12	0.07	0.93	4.41	1.30
B	4	0.07	0.38	0.61	0.00
	8	0.07	0.24	0.60	0.00
	12	0.07	0.18	0.60	0.01

curve C_2 applies for the two three-level systems differing only in their load strategy, while C_1 represents the conventional two-level system. As is clearly demonstrated, the costs of the three-level main memory are substantially lower. The figures also plot the effective access time curve of "useful access" for all comparison cases as a function of main memory capacity.

The effective access time of a three-level system with working set restoration T^{WSR}_{eff2} is almost equal to that of the two-level system T_{eff1}, Figure 6a, or can, according to Figure 6b, even be lower if no page buffer misses occur and the page buffer's significantly shorter access time, as compared with a conventional main memory, can thus be made the most of. The effective access time of a system with transfer on demand T^{TOD}_{eff2}, on the other hand, is always less favorable.

(b) Simulation with program B

CONCLUSION

Through the use of the working set restoration strategy, a three-level system can in fact always achieve nearly the same performance level as a conventional two-level system, provided that systems with equal main memory capacity—points 1 and 2—are juxtaposed. If, on the other hand, systems with equal cost levels are compared, the three-level system will always offer a more favorable effective access time (cf. points 1 and 3) due to the lower page faulting rate resulting from the greater main memory capacity.

Performance and power dissipation analysis for CCD memory systems

by S. L. REGE
Burroughs Corporation
Piscataway, New Jersey

ABSTRACT

In CCD memory systems a tradeoff exists between the frequency at which the memory system is operated and the power dissipation. The higher the frequency of operation, the lower is the service time and the higher is the power dissipation. A close look at the initial cost of the CCD memory system and the cost of maintaining these memory systems will show that the cost of maintenance for a year is nearly equal to the initial cost. This high cost necessitates an analysis of the CCD memory system design for service time and power dissipation.

In this analysis three different states called the Access, Refresh, and Idle states are defined for a CCD memory system. Each state is characterized by a frequency and five different modes of operations are defined depending on the relation between the frequencies. Average service time and power dissipation equations are then derived and each mode is analyzed. Contrary to the normal belief that the power dissipation increases with access frequency, it is shown that for certain modes the power dissipation is constant and is independent of frequency. Finally, a figure of merit is defined and the different modes are compared.

INTRODUCTION

In the last few years, extensive work has been done on Charge Coupled Devices (CCD's). These devices have a potential of becoming basic building blocks to construct memories for digital computers. Many papers are available that analyze and propose designs for the basic component and its layout on the chip.[1-3] Very little analysis is available on the use of the chip in a memory system. It is predicted that the cost/bit for CCD memory systems will be 15 to 30m¢/bit[4] and power dissipation of 20 uw/bit. Using a rule of thumb of 1 m¢/uw/year for the operation of semiconductor memory systems stated by Morton,[5] it is evident that the initial cost and the operating cost for a year are equal for CCD memory systems even when operated at low frequencies. The situation would be still worse at higher frequencies.

Here we will analyze some aspects of the CCD's pertaining to their use in a memory system design. The analysis will show the tradeoffs of operating and using different devices and an insight into the design of the chip.

CCD CHIP PARAMETERS

Most common types of CCD chips being designed are of the closed loop shift register type. Therefore, we will analyze such a chip. A typical chip will have S shift registers with N_t cells in each shift register (Figure 1). The design of the device will determine the refresh time (t_r), which is the maximum allowable time before which a new refresh cycle must be started. Usually a refresh amplifier is available after every N_r cells, and N_t is an integer multiple of N_r, with N_r and

N_t being powers of two. Some typical values for S, N_t, N_r and t_r are given in Table I.

MODES OF OPERATION

With the above mentioned basic parameters for the chip a memory system can now be designed to operate in three different states. The three states are the Access state when the data is being accessed (read or written) from the chip, Idle state in which the chip is doing nothing and the Refresh state in which the data in the shift register is being refreshed.* The three states can be characterized by having three different frequencies: Access frequency f_a, Idle frequency f_i and Refresh frequency f_r. By definition, a memory system can be in the Access state and Refresh state at the same time if the frequencies for these two states are the same. A state transition diagram for the three states is shown in Figure 2.

Time to Refresh
Refresh complete and no access request.
Access State
Refresh State
Refresh not complete
Access not complete
Access Request & Refresh complete

Figure 2—State and transition diagram for the different states of CCD memory operation

In evaluating the performance of the chip, the following assumptions will be made:

(1) The refresh state has priority over both the access and idle state, whereas the access state has priority over the idle state.

(2) The data transfer in a shift register is always initiated from the bit addressed as the first bit. This is not always necessary and different assumptions can be treated as special cases and the analysis pursued here modified accordingly.

(3) A new access for data is not made when a previous access is pending. This assumption implies a buffer in which all the requests to the memory system are stored and serviced with some scheduling strategy.

(4) There is an equal probability that the refresh, idle or access states are started at any bit in the shift register.

(5) The power dissipation is proportional to the frequency at which the data cells are being moved.[6] Notice that the power dissipation of the peripheral circuitry, drivers and the shift register array is a function of the frequency.[1]

(6) The refreshing and accessing can be done simultaneously, if, and only if, the refreshing frequency (f_r) and the accessing frequency (f_a) are the same. This implies that the interface to the CCD memory system always transfers or receives data at the same frequency.

(7) Once a data transfer is started all the bits in a shift register must be transferred.

By choosing different values for the three frequencies f_a, f_r and f_i, the chip and hence, the memory system can be operated in five different modes (Table II) requiring one, two, or three clocks. Notice that the number of clocks required is an indication of the complexity of control required by the memory system and, therefore, in some sense defines the cost for control circuitry.

The five modes of operation and their implications are tabulated in Table II. Mode 5 is the most general mode of operation and the other modes can be considered as a limiting case of this mode. For example, mode 3 can be considered as a limiting case of mode 5, when f_i tends to f_r.

Before evaluating the different modes, the implications of the modes of operation on a memory system design are qualitatively discussed. In a semiconductor memory system design some major parameters of interest are: (a) power dissipation which influences the cost of maintaining the memory, (b) access and service times which influence the performance of the system, (c) the interface requirements such as, the data width and data rate, and (d) the control complex-

* The Access state may be further divided into an Aligning state and a Transfer state. Presently, we will not make any distinction and the analysis made here can be easily extended to that case.

MODE	FREQUENCY	METHOD OF OPERATION
1	$f_a = f_r = f_i$	Continuous Refresh Most common mode of operation in the near future.
2	$f_a \neq f_r$ $f_a = f_i$	Burst Refresh Possible low access frequency due to interface requirements.
3	$f_a \neq f_r$ $f_i = f_r$	Possible high Access rate. Useful when the memory is expected to remain idle for a large percentage of the time.
4	$f_a \neq f_i$ $f_a = f_r$	Zero idle frequency is possible. Minimum access frequency determined by the lowest allowable refresh frequency.
5	$f_a \neq f_i \neq f_r$	Zero idle frequency possible. Interface requirement of low access frequency can be satisfied.

TABLE II—Possible Modes of Operations for a CCD Chip

ity which determines the difficulty and the amount of overhead involved in the design of the memory system.

Mode 1 is a continuous mode of operation in which all the bits are moving all the time and has the simplest control circuitry. This will be the most common mode of operation in the early systems.

Mode 2 requires two frequencies and, therefore, has a control complexity higher than Mode 1. One method of operating in Mode 2 would be to use low idle and access frequencies and high refresh frequency. Such a mode is applicable when an external device with low data rate is interfaced with CCD's and real time transfers are made. Also, when memory is operated in a 'vertical mode',[7] as is recommended for CCD device,[8] it is necessary to shift the bits at a low frequency.

Mode 3 of operation has equal idle and refresh frequency and either low or high access rate. The control complexity is the same as in Mode 2. It is necessary that $f_r(=f_i) > N_r/t_r$. Intuitively, such a design is attractive only when the memory system is expected to remain in the idle mode for a high percentage of the time. Mode 4 of operation is again as complex as Mode 2 and Mode 3 and can be operated with burst refresh and zero idle frequency. Finally, Mode 5 is the most general mode of operation and will have the maximum control complexity. A practical application of this would be: (1) when the system is idle most of the time, (2) the external requirement necessitates low data rate, and (3) burst refresh is to be used to refresh the memory. The analysis later will show that only some of these modes are advantageous from the performance and power dissipation considerations.

On the following pages, equations for Mode 5 of operation will be developed. Then the equations for the other modes of operation will be determined as a limiting case of Mode 5.

ANALYSIS OF SERVICE TIME

Service time is defined as the time elapsed between the moment a request is made to the memory for some information to the moment when all the information is delivered.

When a request is made to a CCD memory system for particular information, the bits in the shift registers have to be shifted until the shift register is positioned at bit 1 under the read/write circuit. The time required to do this will be called the access time (t_a). Once the shift register has been positioned then the data may be transferred and the time required to transfer the data will be called the transfer time (t_t). The service time (t_s) is the time required to service a request and is given by

$$t_s = t_a + t_t$$

and the average value of service time ($\bar{t}_s$) is

$$\bar{t}_s = \bar{t}_a + \bar{t}_t$$

Assume that t_a is a random variable and can be determined as a sum of three random variables given below.

X_r = random variable that represents time spent in refreshing when a service request is made.

X_a = random variable that represents time spent in aligning the shift register to bit 1 when a service request occurs.

X_d = random variable that represents time lost when a service request cannot be satisfied because the refresh cycle has to be started before all the bits in the shift register are transferred.

Then

$$t_a = X_r + X_a + X_d$$

and because X_r, X_a and X_d are independent random variables, we have

$$\bar{t}_a = \bar{X}_r + \bar{X}_a + \bar{X}_d$$

We have to determine the values of X_r, X_a and X_d. The probability density function of X_r is given in Figure 3. From the figure

$$\bar{X}_r = \frac{1}{2}\left(\frac{N_r}{f_r}\right)^2 \cdot \frac{1}{t_r}$$

The value for X_a is simple to calculate and is given by

$$\bar{X}_a = \frac{1}{2}\frac{(N_t-1)}{f_a} \approx \tfrac{1}{2}(N_t/f_a) \qquad \text{[for large } N_t\text{]}$$

To calculate $\bar{X}_d$, notice that if a request arrives at a time when the shift register is at position N, then the minimum time required to access and transfer the block is given by

$$\frac{N_t + (N_t - X)}{f_a} = \frac{2N_t - X}{f_a}$$

Because the probability that a request occurs at any particular bit is the same, the expected value of X_d is (Figure 4) derived as

$$\bar{X}_d = \sum_{X=1}^{N_t} \frac{1}{N_t t_r}\left[\frac{1}{2}\,\frac{(2N_t - X)^2}{f_a^2} + \frac{N_r(2N_t - X)}{f_r f_a}\right]$$

$$= \frac{1}{2t_r f_a^2}\left[\frac{7}{3}N_t^2 - \frac{3}{2}N_t + \frac{1}{6}\right] + \frac{N_r}{N_t t_r f_r f_a}\left[\frac{3N_t^2 - 2N_t}{2}\right]$$

Notice that for large values of N_t

$$\left(\frac{3}{2}N_t - \frac{1}{6}\right) \ll \frac{7}{3}N_t^2 \text{ and } 2N_t \ll 3N_t^2$$

$$\bar{X}_d \approx \frac{7}{6t_r}\left(\frac{N_t}{f_a}\right)^2 + \frac{3N_t N_r}{2t_r f_r f_a}$$

Then the average value of t_a is

$$\bar{t}_a = \frac{N_t}{2f_a} + \frac{1}{2t_r}\left[\left(\frac{N_r}{f_r}\right)^2 + \frac{7}{3}\left(\frac{N_t}{f_a}\right)^2 + \frac{3N_t N_r}{f_a f_r}\right]$$

For a shift register of length N_t and transfer frequency f_a

$$\bar{t}_t = \frac{N_t}{f_a}$$

Therefore, the average value of the service time is

$$\bar{t}_s = \frac{3N_t}{2f_a} + \frac{1}{2t_r}\left[\left(\frac{N_r}{f_r}\right)^2 + \frac{7}{3}\left(\frac{N_t}{f_a}\right)^2 + \frac{3N_t N_r}{f_a f_r}\right]$$

ANALYSIS OF POWER DISSIPATION

In CCD's power dissipation is proportional to the frequency.[6] Amelio[1] gives equation for the average power dissipated (P_d) on chip for a data frequency f as

$$P_d = 2N(0.2 \times 10^{-12})f$$

where P_d is the power dissipated due to a shift register of N bits being shifted at a frequency f.

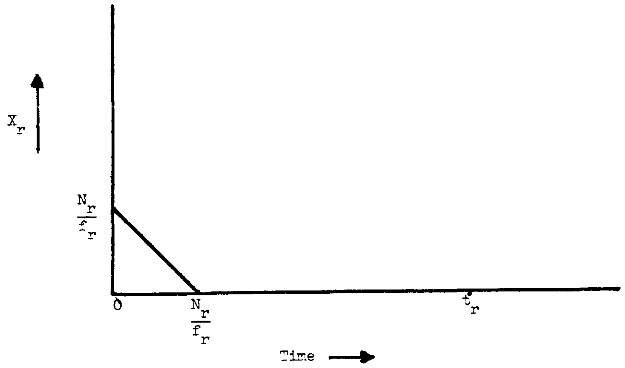

Figure 3—Probability density function of X_r

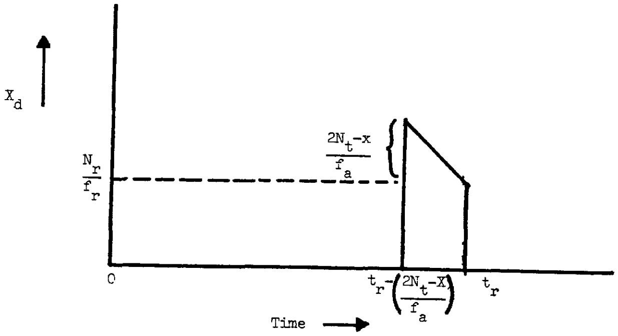

Figure 4—Probability density function for X_d when a service request is made at bit position x

Because the CCD electrodes have a large capacitive load, the power dissipated in the drivers is much larger and is given by

$$P_d = CV^2f$$

where C is the capacitive load, and V is the voltage applied.

We will represent the constant of proportionality between power dissipation and frequency as K. Usually the power dissipation due to the drivers is much larger than the power dissipation due to the shift register array and hence, $K=CV^2$.

Then if $t_1, t_2, t_3 \ldots t_n$ are different time intervals in which frequencies $f_1, f_2, \ldots f_n$ are applied to the chip, the average power dissipation is given by

$$\bar{P}_d = K\frac{t_1f_1 + t_2f_2 + \ldots\ldots\ldots + t_nf_n}{t_1 + t_2 + \ldots\ldots\ldots + t_n}$$

The three different states of the CCD memory systems will determine three different time intervals and three different frequencies.

These are:

(1) Total time spent in refresh state (T_r) and refresh frequency f_r.

(2) Total time spent in idle state (T_i) and idle frequency f_i.

(3) Total time spent in access state (T_a) and access frequency f_a.

Then the average power dissipation ($\bar{P}_d$) is given by

$$\bar{P}_d = K\frac{f_r\bar{T}_r + f_i\bar{T}_i + f_a\bar{T}_a}{\bar{T}_r + \bar{T}_i + \bar{T}_a}$$

To determine the average values for the different times we will consider a basic period as the time from the beginning of one Refresh cycle to the beginning of the next Refresh cycle. Then

$$\bar{T}_r = \frac{N_r}{f_r}$$

The remaining time in a cycle is the sum of the total idle time and the total service time. Therefore

$$T_a + T_i = \left(t_r - \frac{N_r}{f_r}\right)$$

$$\bar{T}_i = \left(t_r - \frac{N_r}{f_r}\right) - \bar{T}_a$$

To determine the average total time spent in servicing requests ($\bar{T}_a$) assume that in any given cycle there is a possibility of maximum of s accesses. Then let

p(j) = probability that j accesses are made

(j = 0, 1, 2 . . . s)

The average time spent when one access is made is already determined and is given by $\frac{3N_t}{2f_a}$ and, therefore,

$$T_a = \sum_{j=0}^{s} j\,p(j)\frac{3N_t}{f_a}$$

$$\text{Let } Q = \sum_{j=0}^{s} j\,p(j)$$

Intuitively Q represents the average number of requests per period.

Then

$$\bar{T}_a = \frac{3N_tQ}{2f_a}$$

and

$$\bar{T}_i = t_r - \frac{N_r}{f_r} - \frac{3N_t}{2f_a}Q$$

Adding the various terms and rearranging gives the average power dissipation for mode 5 of operation as

$$\bar{P}_d = K\left\{f_i + \frac{N_r}{t_r}\left(1 - \frac{f_i}{f_r}\right) + \frac{3N_tQ}{2t_r}\left(1 - \frac{f_i}{f_a}\right)\right\}$$

This general analysis for average service time and power dissipation can now be applied to each mode of operation.

ANALYSIS OF DIFFERENT MODES

In this section we will analyze each mode of operation. The service time and power dissipation equations for the different modes derived from the analysis of general Mode 5 are given in Table III. The graph in Figure 5 denotes the average service time and power dissipation for Mode 1 of operation and the graphs in Figures 6 to 10 denote the percentage improvement in average power dissipation and percentage degradation in service time for Modes 2 to 5 over that of Mode 1 of operation.

Mode 1 will be the most usual mode of operation in the near future. A plot of access frequency vs service

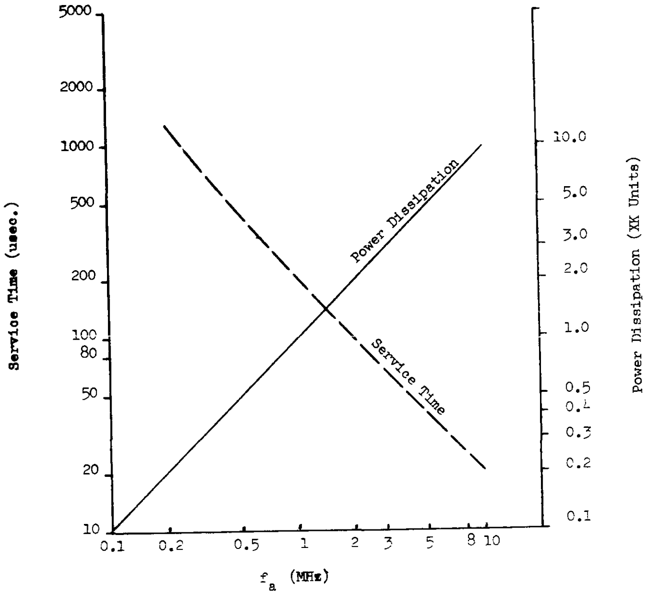

Figure 5—Graph of service time and power dissipation vs. access frequency for mode 1 of operation

MODE	FREQUENCY	SERVICE TIME	POWER DISSIPATION	REMARKS
1	$f_a=f_r=f_i$	$\frac{3N_t}{2f_a}+\frac{1}{2t_r}\left\{\frac{3N_r^2+7N_t^2+9N_tN_r}{3f_a^2}\right\}$	Kf_a	Power Dissipation directly proportional to frequency
2	$f_a\neq f_r$ $f_a=f_i$	$\frac{3N_t}{2f_a}+\frac{1}{2t_r}\left\{\frac{N_r^2}{f_r^2}+\left[\frac{7}{3}\ \frac{N_t^2}{f_a^2}\right]+\frac{3N_tN_r}{f_af_r}\right\}$	$K\left\{f_a+\frac{N_r}{t_r}\left[1-\frac{f_a}{f_r}\right]\right\}$	Very little advantage over Mode 1 for both service time or power dissipation
3	$f_a\neq f_r$ $f_r=f_i$	Same as Mode 2	$K\left\{f_r+\frac{3N_tQ}{2t_r}\left[1-\frac{f_r}{f_a}\right]\right\}$	Values of f_i=1 to 3Mcycles/sec. are advantageous from both service time and power dissipation considerations
4	$f_a\neq f_i$ $f_a=f_r$	Same as Mode 1	$K\left\{\left[1-\frac{2N_r+3N_tQ}{2f_at_r}\right]f_i+\frac{2N_r+3N_tQ}{2t_r}\right\}$	For f_i = 0 and a given value of Q, the power dissipation is constant
5	$f_a\neq f_r\neq f_i$	Same as Mode 2	$K\left\{f_i+\frac{N_r}{t_r}\left[1-\frac{f_i}{f_r}\right]+\frac{3N_tQ}{2t_r}\left[1-\frac{f_i}{f_a}\right]\right\}$	For f_i=0 and a given value of Q, the power dissipation is constant. No advantage over Mode 4 unless $f_a\neq f_r$ due to interface requirements

TABLE III—Service Time and Power Dissipation Equations for Different Modes of Operation

time is given in Figure 5. The dominating factor for service time in the equation given in Table III is $3N_t/2f_a$. At small values of access frequency (f_a=200KHz) the contribution due to the second term is quite high (about 40 percent), whereas at moderate values (f_a=1MHz) it is about 10 percent and at high values it is negligible (less than 1 percent). The second term can be decreased by increasing t_r. N_r has no appreciable influence on the service time. The power dissipation is seen to be directly proportional to frequency.

Again, for Mode 2, the dominant term for service time is $3N_t/2f_a$. The power dissipation equation shown in Table III has two terms. The first term is the same as Mode 1 and the second term can be made negative by making $f_a>f_r$.

Figure 6 shows the percentage improvement in power dissipation and percentage degradation in service time over Mode 1 vs the access frequency for different values of f_r. The results show that either the degradation in service time is quite high or power dissipation improvement is quite low. A similar analysis for various values of N_r will show the same conclusion. Therefore, this mode of operation has little advantage over Mode 1. The service time equation for Mode 3 is the same as that for Mode 2 but the power dissipation equation is different.

Figure 7 shows the percentage improvement in power dissipation and percentage degradation in service time vs the access frequency for various values of Q. Service time is independent of Q but the improvement in power dissipation is reduced as Q increases. The difference in $\overline{P}_d$ improvement between the lowest and the highest value of Q is quite small and is of the order of 10 to 15 percent. Note that there is a rapid improvement in power dissipation from 1 to 5MHz and then the improvement tapers off. The worst case service time degradation is about 8 percent. Therefore, a good cut-off point for this mode of operation is around 5MHz when the service time degradation is about 5 percent.

The variation of percentage improvement in power dissipation and degradation in service time vs the access frequency for various values of f_r is shown in Figure 8. It shows that high values of f_r are disadvantageous from both power dissipation and service time point of view. Generally, this mode is better than Mode 2 of operation.

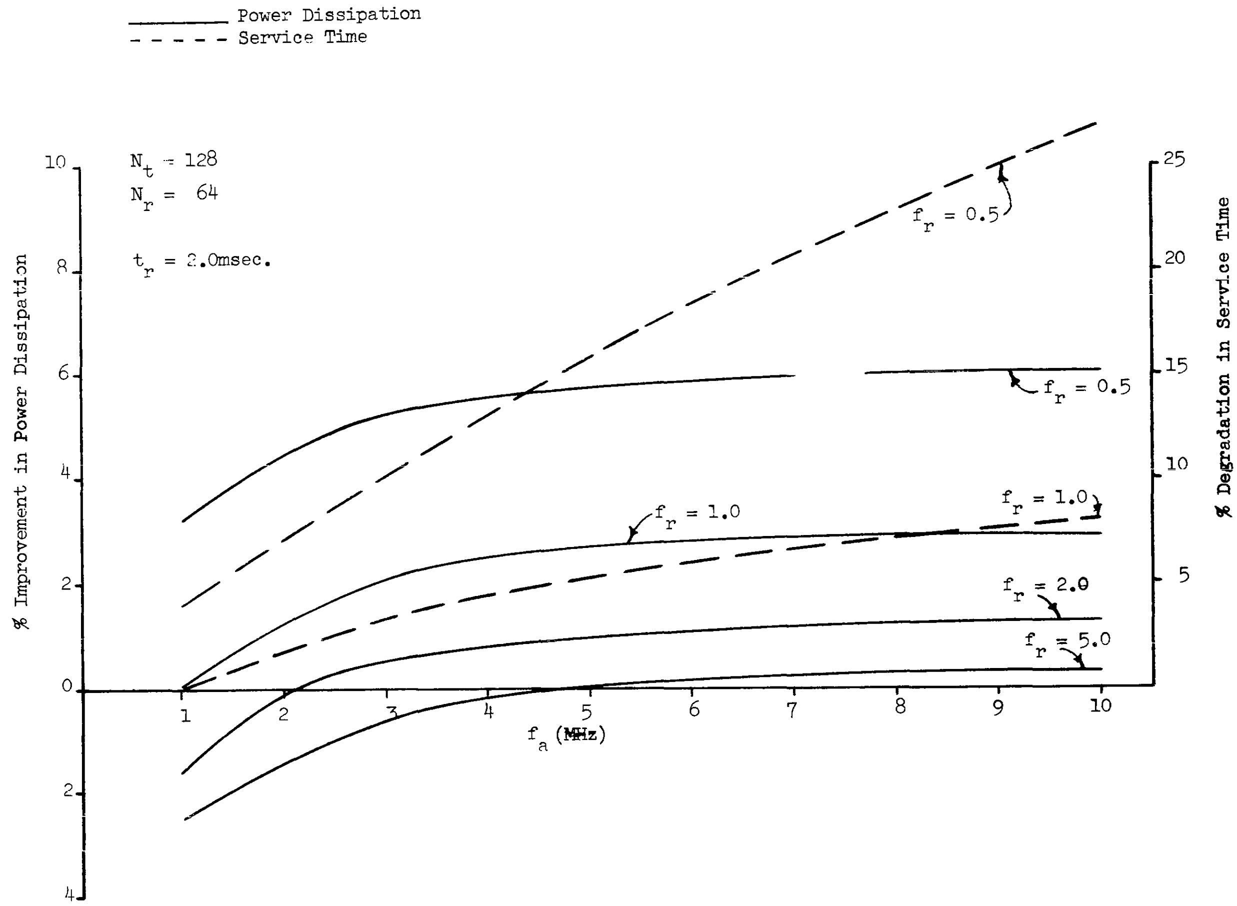

Figure 6—Percentage improvement in power dissipation and percentage degradation in service time vs access frequency for mode 2 of operation

In the Mode 4 of operation the average service time equation is the same as Mode 1. Physically, this is understandable due to two reasons: the idle frequency moves the information bits without doing any useful work and there is an equal probability of a service request at any bit.

Power dissipation equation has two terms, one proportional to the frequency f_i and the other a constant. By making f_i zero, and if the different parameters of a chip (e.g. N_a, t_r, etc.) are given, then power dissipation is only dependent on Q and is independent of the access frequency. Notice that increasing t_r reduces the power dissipation. This is again physically understandable, since the chip will have to be refreshed less regularly. The power dissipation also can be decreased by decreasing N_r or N_t. Notice that the second term can never be negative. Therefore, the minimum value of power dissipation occurs when $f_i=0$. Because the most interesting point is $f_i=0$, we will further analyze this mode at this operating point. With $f_i=0$ the power dissipation for Mode 4 and Mode 5 are the same.

Figure 9 shows the percentage improvement in power dissipation and percentage degradation in service time vs the access frequency for various values of Q for Modes 4 and 5. The percentage improvement in power dissipation increases as access frequency increases. Increase in the value of Q decreases the percentage power dissipation. For smaller values of access frequency ($f_a=1$ to 3MHz) the slope of the power dissipation curve is quite high (40) whereas at higher values it is small (2). The power dissipation improvement for values of f_a greater than 3.5 to 4MHz is marginal. Therefore, an optimal point of operation is $f_a=3$MHz for small values of Q and $f_a=4.5$ to 5MHz for large values of Q.

Finally, the following observations can be made:

(1) It is possible to operate a memory system at the highest possible frequency with about 90 percent improvement in power dissipation over Mode 1 of operation.

(2) It is advisable to make the time between refreshing (t_r) as large as possible both to decrease the average power dissipation and service time.

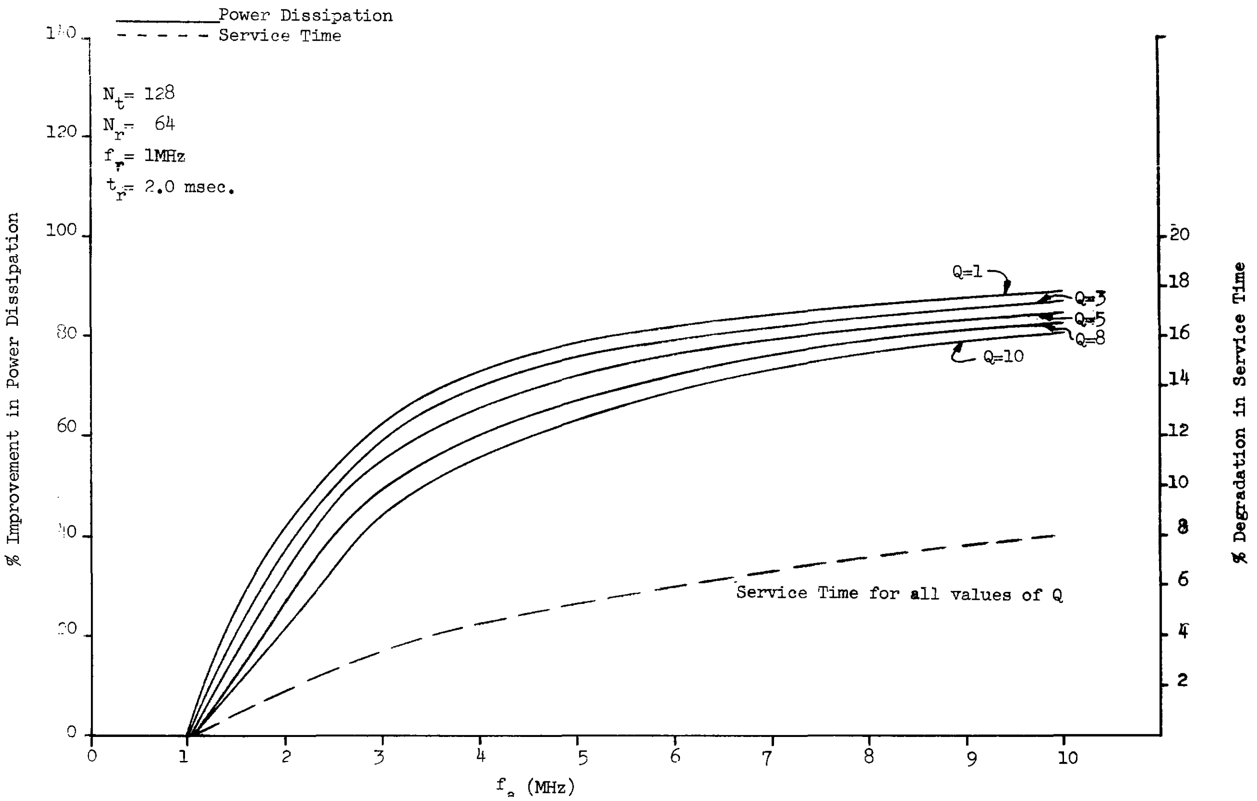

Figure 7—Percentage improvement in power dissipation and percentage degradation in service time for various values of Q for mode 3 of operation

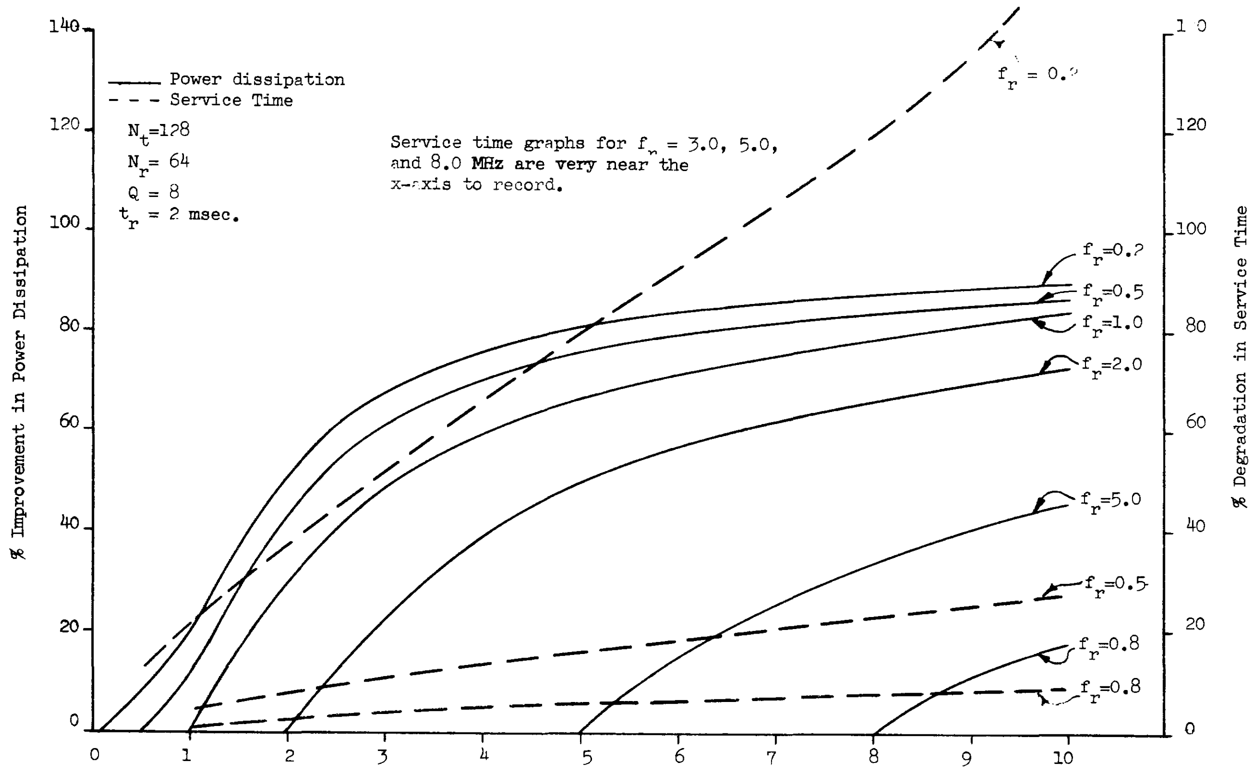

Figure 8—Percentage improvement in power dissipation and percentage degradation in service time vs access frequency for various values of f_r for mode 3 of operation

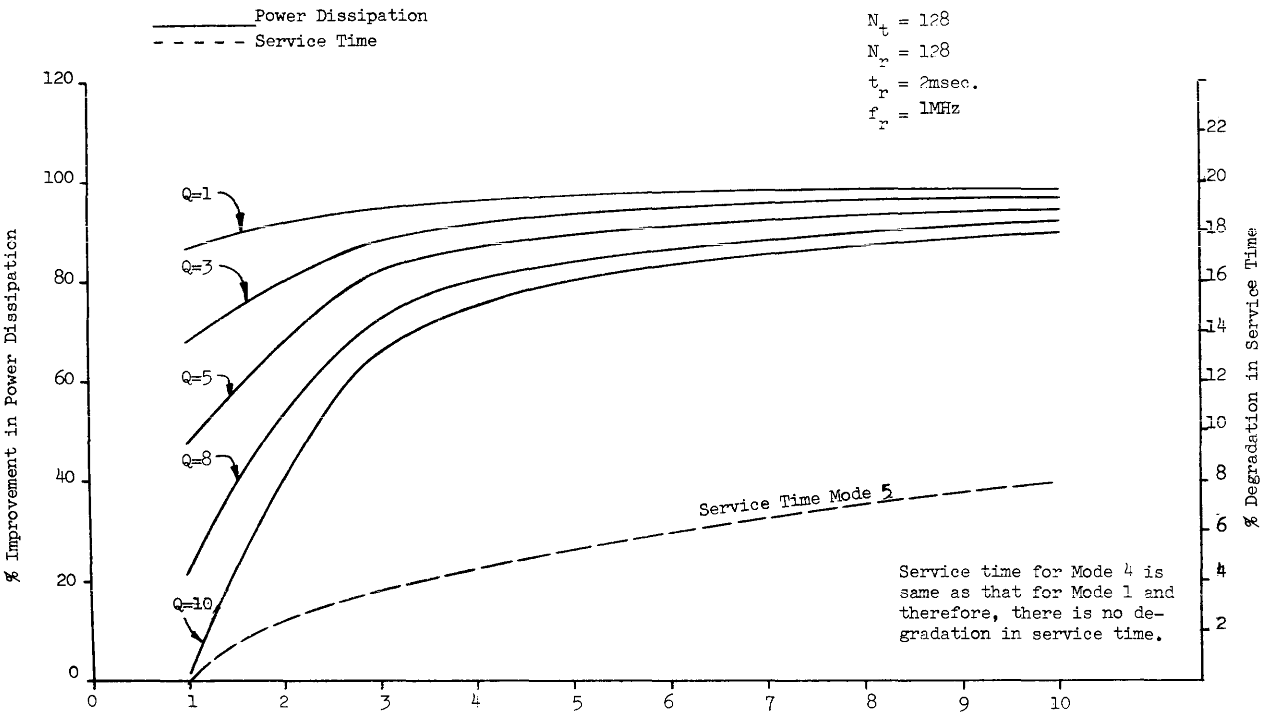

Service time for Mode 4 is same as that for Mode 1 and therefore, there is no degradation in service time.

Figure 9—Percentage improvement in power dissipation and percentage degradation in service time for mode 4 and mode 5 of operation

(3) The interesting modes of operation are derived by making idle frequency zero. This is intuitively valid because moving the bits in a shift register during idling does not have any advantage either from performance or from power dissipation viewpoint.

COMPARISON OF DIFFERENT MODES

In this section we will compare the different modes of operation. To make a comparison we will define a figure of merit (Fgm) as the number of possible services per unit time per unit power dissipation.

$$\text{Fgm} = \frac{1}{\text{average service time} \times \text{average power dissipation}}$$

Thus, a mode that has higher Fgm is better than one that has a lower Fgm.

In Figure 10 we draw a graph of Fgm vs. Access frequency for various modes. The typical values chosen for N_t, N_r, and t_r are 128, 64 and 2msec. The Refresh frequency, whenever it is different from Access frequency is chosen as 1MHz. The Mode 1 and Mode 2 are independent of Q, whereas Modes 3, 4, and 5 are dependent on Q and, therefore, graphs are drawn for various values of Q.

Mode 2 has the worst Fgm for all access frequencies and, therefore, is the worst mode of operation. Mode 1 has a typical Fgm of about 5 and is constant over all frequencies. For values of $f_a > 1$MHz Modes 3 and 4 and Mode 5 are better than Mode 1 for all values of Q up to 10. For $f_a = 1$MHz and values of Q=1,5, Mode 1 of operation is better than Mode 3. Also, for Q=10 Mode 1 is better than Mode 4 or Mode 5. But notice that for Q=10 Mode 3 is the best mode of operation for small values of f_a. At higher values of f_a Mode 4 is the best mode, closely followed by Mode 5 for all values of Q. The Fgm for Modes 3, 4 and 5 is reduced as Q increases. The reduction for Modes 4 and 5 is much higher than that for Mode 3.

Table IV lists the various modes and a qualitative comparison of these modes with respect to control complexity and cost of design.

CONCLUSIONS

Memory systems built with CCD's are shown to have three states of operation: The Access state, Refresh state and Idle state and each state has a frequency associated with it. Three different modes of operation are defined and average service time and average

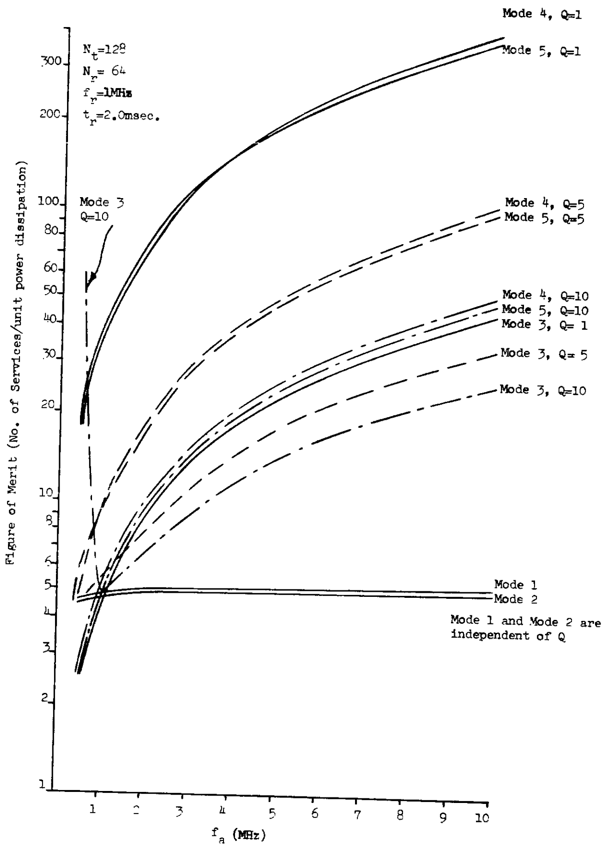

Figure 10—Figure of merit vs access frequency for various modes of operation

TABLE IV—A Qualitative Comparison of Different Modes of Operation

MODE	NO. OF CLOCKS REQUIRED	CONTROL COMPLEXITY	COST OF DESIGN	REMARKS
1	1	Minimum	Minimum	Simplest mode of operation
2	2	Moderately Low	Moderate Lower than Mode 4 if $f_i \neq 0$	Worst mode of operation
3	2	Moderately High	Moderate	For small f_a (f_a <1MHz) . A good mode of operation
4	2 if $f_i \neq 0$ 1 if $f_i = 0$	High if $f_i \neq 0$ Low if $f_i = 0$	Low if $f_i = 0$	For f_a > 1MHz the best mode of operation
5	3 if $f_i \neq 0$ 2 if $f_i = 0$	Maximum	Maximum	Best mode of operation except for mode 4

power dissipation equations for a general case of operation are derived. Equations for each mode are then derived as a limiting case of these general equations. The different modes are analyzed individually and, finally, a comparison between the different modes is made by defining a figure of merit. An interesting result derived is that the power dissipation is constant and is independent of Access frequency for Modes 3 and 4 when they are operated with $f_i=0$. Mode 4 is shown to be the best mode of operation. A simple qualitative comparison is finally made for the cost of implementation.

ACKNOWLEDGMENT

I would like to thank Dr. Bob Woo for extensive discussions during the development of this work, Mr. Paul White for comments that improved the quality of the paper, and Marie Golden for typing this paper.

Intelligent memory

by MURRAY EDELBERG and L. ROBERT SCHISSLER
Sperry Research Center
Sudbury, Massachusetts

ABSTRACT

The intelligent memory is a computer memory formed of circulating serial storage loops and distributed processing logic. In addition to the basic information storage function, the memory performs off-line sort processing, associative searching, updating and retrieval. The memory is also capable of dynamically varying its loop size to accommodate varying data requirements.

A number of memory configurations which trade performance for economy are possible. The options range from single record per loop and on-chip logic (aimed at CCD technology) to multiple records per loop and off-chip logic (aimed at magnetic bubble memories). The latter option is made possible by a new sort algorithm named "gyro sort" in which loop contents are caused to "precess" at appropriate intervals.

As one component of a storage hierarchy, the intelligent memory offers potential performance gains ranging from one to three orders of magnitude over random access memories at comparable cost.

STRUCTURE

The memory contains one or more identical modules. Figure 1 gives a block diagram of such a module, including $n \geq 2$ storage loops labeled $L_1, L_2, \ldots, L_n$ and n processing elements labeled $PE_1, PE_2, \ldots, PE_n$, where n is even. Each storage loop is a circulating shift register. All storage loops are shifted synchronously using a common clock. Processing element PE_i is incident with storage loops L_i and L_{i+1}.

There are two loop connection states possible within a processing element. Referring to Figure 2, the loop connection state indicated by the solid lines within processing element PE_1 is the *thru* state and isolates storage loop L_1 and L_2. The dashed lines indicate the *interchange* state which, if held for one complete rotation of loops L_1 and L_2, effects an interchange of the contents of these loops. The interchange connection, if held indefinitely, effectively joins the two incident loops into a single loop of double length. By causing $k-1$ contiguous processing elements to hold the interchange connection, a storage loop of size k times the basic loop size is formed.

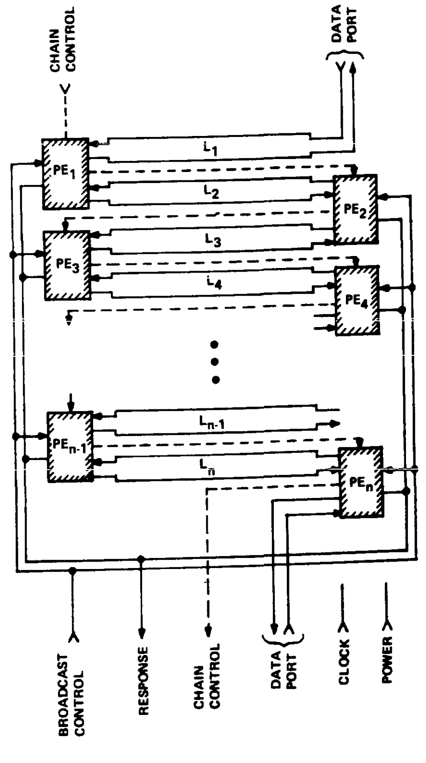

Figure 1—Intelligent memory module block diagram

A processing element is *inactive* if it is simply maintaining the interchange connection indefinitely and *active* otherwise. The pattern of active (denoted A) and inactive (denoted I) PEs is restricted to be of the form:

$$\underbrace{\underbrace{\text{II}\ldots\text{I}}_{k-1}\ \text{A}\ \underbrace{\text{II}\ldots\text{I}}_{k-1}\ \text{A}\ \ldots\ \underbrace{\text{II}\ldots\text{I}}_{k-1}\ \text{A}}_{n/k}$$

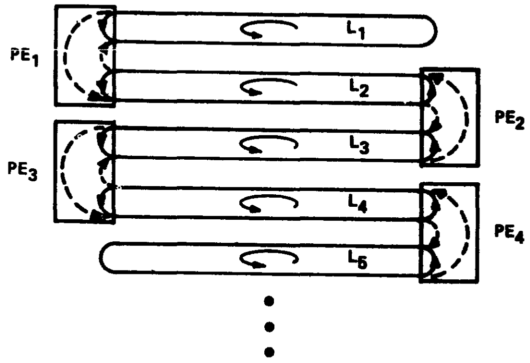

Figure 2—Loop connection states

Active PEs fall into two phases: the odd phase consists of the 1st, 3rd, 5th, . . . active PEs and the even phase contains those remaining.

Figure 1 shows distribution of control signals to PEs within a module via chain control lines (shown dashed) and broadcast control lines. Broadcast control lines send the same information to all PEs; chain control lines send information which may be modified by PE_i before being passed on to PE_{i+1}. Activity status is assigned to PEs via chain control lines. Certain broadcast control signals are made operative only at active PEs. Moreover, broadcast control signals designated odd (even) are made operative only at active PEs belonging to the odd (even) phase. A response line ORs together responses from all active PEs in the module. When two or more modules are used in a memory system, identical broadcast control signals are presented to each, and response signals from each are OR'ed together. Modules are connected in series with respect to their chain control lines and data ports; special terminations at the extremes are required.

Table I lists broadcast control modes. Table II lists individual broadcast control, chain control and response signals at the module level.

Figure 3 shows a block diagram of the general processing element PE_i. Signals internal to PE_i are identified in Table III.

In Figure 3, inputs from (outputs to) loops L_i and L_{i+1} are labeled x_i, x_{i+1} (y_i, y_{i+1}) respectively. Four main components of PE_i are shown: loop control (maintains appropriate loop connection state between loops L_i and L_{i+1}), activity and phase control (maintains activity status and computes phase for PE_i), static retrieval control (determines whether PE_i is a first responder during search operations), and the comparator (performs serial comparison and computes internal control signals).

We estimate PE complexity using MOS logic to be roughly 100 FETs.

TABLE II—Module-Level Signals

BROADCAST CONTROL:	
KFE	KEY FIELD - EVEN
KFO	KEY FIELD - ODD
KTUE	KEY, TAG, UPDATE - EVEN
KTUO	KEY, TAG, UPDATE - ODD
MODE	(Assumes one of the eight states listed in Table 1)

SS	SEARCH SUCCESSFUL
INT	INTERCHANGE
RF	REPLACEMENT FIELD
RD	REPLACEMENT DATA
A_i	PE_i ACTIVE
SS_i	SUCCESSFUL SEARCH BY PE_j, FOR SOME $j \leq i$
ER	ENABLE RESPONSE
RC	RESET COMPARATOR
RL	RECONFIGURE LOOPS
R_i	RESPONSE FROM PE_i

OPERATION

The intelligent memory provides six primary modes of operation: sort, load/unload, search, retrieve, update and reconfigure. These are described below; performance expressions are given with respect to the following memory parameters:

Loop Size	l	bits
One Bit Transfer Time	t	sec.
Loop Cycle Time	$r=lt$	sec.
Number of Loops	n	

In the paragraphs below, reference is made to signals KFE, KFO, KTUE, and KTUO. Signals KFE (Key Field-Even) and KFO (Key Field-Odd) define the bit positions on which a sort or search is to be made or which are to be updated. There are two such signals because PEs always are divided into two groups or phases, even and odd, which receive any specified group of bits at times separated by half a loop rotation. Signals KTUE (Key, Tag, Update-Even) and KTUO (Key, Tag, Update-Odd) must also be divided into two phases. These signals have multiple uses. During a sort, they are not used; during a search, the part of KTU gated by KF provides the search key, and any "ones" in KTU outside of KF define a tag field, in which the result of the search (signal SS—Search Successful) is deposited. During an update, KTU supplies the update data.

Sort

In sort operation, control inputs to the memory consist of sort key field definition signals KFE and KFO, and broadcast control mode signal equal to SORT<, or SORT>. These control inputs are generated by a memory controller (not described in this paper). The externally specified sort key field may consist of any contiguous block of 1 to l bit positions. The operation of an active processing element PE_i during one complete cycle of its incident loops L_i and L_{i+1} is as follows. The cycle begins when the key field portions of the data records (stored one record per loop) enter PE_i, high order bits first. As long as the two bit streams remain equal, PE_i maintains the thru connection state. The first mixed pair of bits causes PE_i to assume either the thru state or the interchange state, whichever routes the 0 bit to L_i if SORT< is specified, or to L_{i+1} if SORT> is specified, and to maintain that connection state for the remainder of the cycle. Equal key fields cause PE_i to maintain the thru connection for the full rotation. At a given instant of time during the sort, a data record may be distributed over as many as three contiguous loops. The memory correctly performs a stable sort of its contents on the specified key field, either ascending or descending, and provides a done signal at output R upon completion. Maximum sort time is nr/2 sec. Multiple key and non-contiguous key sorts are performed by repetition of the basic single-key stable sort.

The algorithm underlying sort operations of the memory is a circulating, interleaved version of a sorting network construction known as odd-even transposition sort (see Knuth[1] for a description).

Load/unload

To load a file into the memory, one of the two data ports is chosen as load port; the other is appropriately shorted. The memory is cleared. Memory loading is accomplished by invoking the appropriate sort operation with a key field spanning any data field known to be non-zero (perhaps the entire record). The file is presented serially at the input terminal of the load port.

Memory unloading is performed is a similar manner. An appropriate constant, 0 or 1, is presented at the input terminal of the unload port, a sort operation is initiated, and the file appears serially at the output terminal.

Loading or unloading the full memory requires nr sec. Concurrent loading and unloading is possible whenever the load file has a data field whose values are uniformly less than (or greater than) the values assumed by the corresponding data field in the unload file. This condition may be enforced by dedicating a single bit in each file to this purpose. Concurrent load/unload of the full memory requires nr sec.

Time to load and/or unload may be further reduced by partitioning the memory into a number of segments and loading (unloading) the segments in parallel from the same number of data sources (sinks).

Search

In search operation, control inputs to the memory consist of search key field definition signals KFE and

KFO, search key signals KTUE and KTUO, and broadcast mode signal equal to SEARCH=, SEARCH<, or SEARCH>. The externally specified search key field may consist of any contiguous block of 1 to *l* bit positions. The operation of an active processing element PE_i during one complete cycle of its incident loop L_i is as follows. PE_i compares the data on L_i to the key on line KTU during the interval defined by KF, and classifies the data according to whether it is $=$, $<$ or $>$ the key. The classification is registered via the internal state of the comparator (see Figure 3). If this classification agrees with the broadest control mode, signal SS is raised. In either case, after KF drops, SS may be written into loop L_i as a response or tag bit in any field specified by KTU. Average search time is 3r/2 sec., including writing the response bit.

By invoking appropriate sequences of search operations, compound and multiple key searches can be performed. For example, three search operations implement a "between-limits" search. The search operations provided form a functionally complete set. If S_1 and S_2 are any two search operations or sequences of search operations that can be performed by the memory, and if t_1 and t_2 are the corresponding response bits, then logical operators $-$ (NOT), $\wedge$ (AND), and $\vee$ (OR) applied to S_1 and S_2 may be implemented by secondary search operations as follows:

$$S_1 \wedge S_2 \quad t_1t_2 = \text{'11'}$$
$$S_1 \vee S_2 \quad t_1t_2 > \text{'00'}$$
$$-S_1 \quad t_1 = \text{'0'}$$

Direct hardware interpretation of complex data base queries is an important potential application.

Retrieval

There are two classes of retrieval problems to consider: unique response retrieval and multiple response retrieval. In the former case, responding records, if they exist, are known to be unique; in the latter case they need not be.

Unique response retrieval

Immediately following a successful search the responding record is routed directly and persistently to memory output R. Total average response time is 3r/2 sec.

Multiple response retrieval

The memory provides two options for retrievals in this class.

Static retrieval

The name of this option reflects the fact that no inter-loop data movement is involved. After a suitable waiting period T following a search operation, the output ER of the static retrieval control (see Figure 3) is equal to 1 for at most one processing element PE_i. If such a PE_i exists, it is the processing element having smallest index among those performing a successful search. The responding record on loop L_i is routed persistently to memory output R. The waiting period T must be at least as large as the time for a signal to propagate asynchronously through the full chain of static retrieval controls, conservatively taken to be nt sec. Total response time is $3r/2+nt+r=nt+5r/2$ sec. Retrieval of successive responses is triggered by pulsing the NR input.

Static retrieval response time can be substantially reduced by segmenting the memory at retrieval time and polling the memory segments for a response. In this case, total response time for the first retrieval is approximately $nt/s+5r/2$ sec., where s is the number of equal-length memory segments. This is minimized by choosing $s=\sqrt{n}$.

Dynamic retrieval

A sort operation is invoked following a search operation, using the search response bit as sort key. One of the two memory data ports is chosen a priori as the retrieval port, and the appropriate sort operation is used to drive responding records to the output terminal at this retrieval port. Minor additional logic at the retrieval port allows resetting the response bit in a responding record as it arrives at the output terminal, and reloading the modified record via the input terminal at that same retrieval port. This assures that all responding records will be both retrieved and preserved within the memory for subsequent operations. Average total response time for the first retrieval is approximately nr/4 sec.

As in the static case, response time for dynamic retrieval can be shortened by segmenting the memory at retrieval time.

Update

A replacement update may be performed in parallel on all records responding to any sequence S of one or more search operations and tagged, say in bit t. A search operation for t='1' is performed in order to cause the appropriate comparators to assume the = state. This is followed by a mode transition to UPDATE. The update itself is broadcast on lines KTUE and KTUO, along with update field information on lines KFE and KFO. Average total update time is 5r/2 sec.

Reconfigure

In a reconfigure operation the "shape" of the memory is transformed to accommodate various record sizes. With n basic storage loops of size l bits, reconfiguration to n/k loops of size kl bits for any k, $1 \leq k \leq n$, is possible. The activity and phase control (see Figure 3) implements this structural change to the memory. Sort, load/unload, search, retrieve and update operations apply to all memory shapes.

PACKED-LOOP VERSION

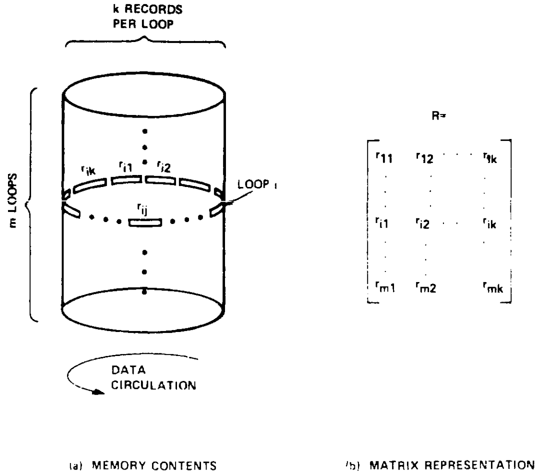
As originally conceived, the memory stores one data record per loop, and is capable of dynamically altering its loop size to accommodate varying record length requirements.

There are cost and technology dependent reasons why alternatives to short (e.g., 32 character) storage loops and on-chip processing elements (PEs) are of interest. For example, while on-chip logic is reasonable for CCD memories, it does not appear feasible for magnetic bubble memories at present. Off-chip logic implies long storage loops in order to maintain reasonable pin counts. Also, longer storage loops imply lower ratios of PE chip area to storage loop area and thus lower memory system cost per bit.

Extension of the intelligent memory architecture to accommodate long loops into which multiple data records are packed is straightforward, except for the sort mode of operation which presents a problem. A new sort algorithm named "gyro sort" was conceived to solve this problem.

Gyro sort

Suppose we have $k \geq 1$ records per loop and $m \geq 1$ loops (see Figure 4) for a total of n=mk records. Let r_{ij} denote the jth record on loop i, and let $R=[r_{ij}]$ be the m×k matrix representation of the memory contents.



(a) MEMORY CONTENTS (b) MATRIX REPRESENTATION

Figure 4—Packed-loop memory

One pass of gyro sort consists of the following two steps:

(1) sort columns
sort the columns of R, say in increasing order from top to bottom

(2) precess rows
for i=1,2,...,m, apply a circular (say right) shift of (i−1) mod k record positions to row i

Figure 5 illustrates the idea of row precession in step (2). In Figure 5(a) we are looking down on a stack of m=7 loops, each divided into k=5 record areas. The top loop is outermost. The numbered circles identify record areas. Figure 5(b) shows the rearrangement of record areas performed by the row precession. The dotted line shows the spiral movement followed by record area 1. This movement, superimposed on the loop rotation movement, motivated our choice of the terms "precession" and "gyro" sort.

We further illustrate gyro sort with a numerical example in matrix form. In this small example, m=6, k=3, and records consist of a single integer. Matrix R_2 below results from matrix R_0 after one pass of gyro sort. Matrix R_1 results from step (1) and R_2 from step (2).

$$\underset{R_0}{\begin{bmatrix} 8 & 3 & 12 \\ 11 & 9 & 2 \\ 5 & 14 & 6 \\ 18 & 1 & 7 \\ 10 & 17 & 13 \\ 16 & 4 & 15 \end{bmatrix}} \underset{R_1}{\begin{bmatrix} 5 & 1 & 2 \\ 8 & 3 & 6 \\ 10 & 4 & 7 \\ 11 & 9 & 12 \\ 16 & 14 & 13 \\ 18 & 17 & 15 \end{bmatrix}} \underset{R_2}{\begin{bmatrix} 5 & 1 & 2 \\ 6 & 8 & 3 \\ 4 & 7 & 10 \\ 11 & 9 & 12 \\ 13 & 16 & 14 \\ 17 & 15 & 18 \end{bmatrix}}$$

Step (1) may be accomplished for general records by the odd-even transposition sort algorithm as provided in the basic intelligent memory architecture. This is subject to a restriction on sort key field position and is discussed further in a later section. The column sort proceeds in parallel on all columns, and requires at most m/2 loop rotations to complete. Step (2) requires a modest amount of additional "precessing logic" and takes one loop rotation to complete if loops can be independently clocked, and several loop rotations otherwise.

Gyro sort consists of k such passes, after which the contents of row i are the records which form the ith block of k records in the final ordered file. Thus a sort of the file into buckets of size k records has been accomplished. There is no particular ordering among the row i records.

Continuing with the example, the second pass yields:

$$\underset{R_3}{\begin{bmatrix} 4 & 1 & 2 \\ 5 & 7 & 3 \\ 6 & 8 & 10 \\ 11 & 9 & 12 \\ 13 & 15 & 14 \\ 17 & 16 & 18 \end{bmatrix}} \underset{R_4}{\begin{bmatrix} 4 & 1 & 2 \\ 3 & 5 & 7 \\ 8 & 10 & 6 \\ 11 & 9 & 12 \\ 14 & 13 & 15 \\ 16 & 18 & 17 \end{bmatrix}}$$

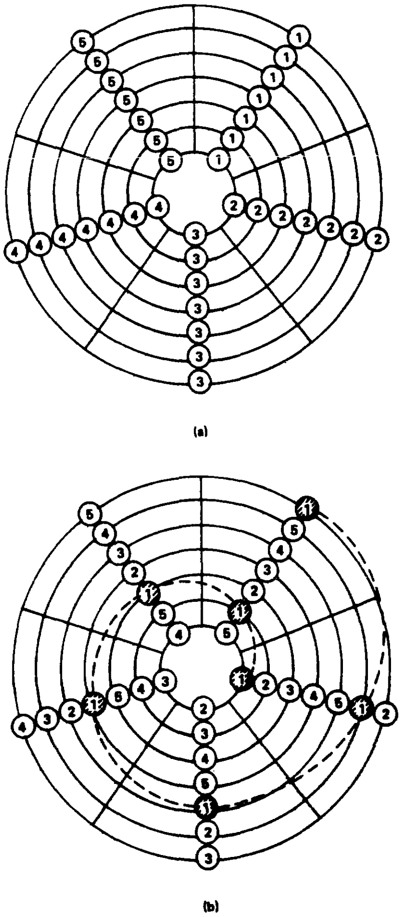


Figure 5—Loop precession

On the third pass we obtain:

$$\begin{bmatrix} 3 & 1 & 2 \\ 4 & 5 & 6 \\ 8 & 9 & 7 \\ 11 & 10 & 12 \\ 14 & 13 & 15 \\ 16 & 18 & 17 \end{bmatrix}$$
$$R_5$$

as claimed. That is, the first three records occupy row 1, the next three row 2, and so on.

We have proven that this claim is true in general.

Precession subsystem

Storage loop contents circulate under control of a loop clock. We distinguish between two types of loop clocking:

(a) Differential loop clocking—the clock signal may be selectively applied to some loops and not to others.

(b) Uniform loop clocking—the clock is applied uniformly to all loops.

Differential loop clocking is feasible in some technologies, e.g., CCD memories, and not in others, e.g., magnetic bubble memories. In the latter case, a rotating magnetic field is typically used to perform uniform loop clocking.

Figure 6 shows the block diagram of a loop precession subsystem. Three elements are represented in Figure 6: a collection of m storage loops $L_1, L_2, \ldots, L_m$, a precession register, and a precession control.

Figure 7 illustrates successive states of the precession register for $m=12$ and a loop packing factor of 5. For each state of the precession register, storage loops L_i for which $Z_i=1$ are advanced one record position relative to storage loops L_j for which $Z_j=0$.

In the case of differential loop clocking, this is accomplished simply by using Z_i to gate the loop L_i clock signal. This is done by precession control cell i.

Figure 8 illustrates precession control cell i for the case of uniform loop clocking, i.e., all storage loops are clocked uniformly. In this case, storage loop L_i is comprised of two sub-loops, the main loop and the auxiliary loop. Total capacity of loop L_i is l bytes; this is apportioned into l-δ bytes for the main loop and δ bytes for the auxiliary loop, where l is an integer multiple of δ.

Precession control is effected by a 2-input, 2-output loop switch at the junction of the main and auxiliary loops which either isolates these sub-loops as in Figures 8(a) and (b) or interconnects them as in Figures 8(c) and (d).

The state of the loop switch in precession control cell i is determined by the logical expression $P \cdot Z_i$ as indicated in Figure 8. When the memory is in precession mode $(P=1)$ the loop switch assumes the isolate state when $Z_i=1$ and the interconnect state when $Z_i=0$. At all other times $(P=0)$ the loop switch maintains the interconnect state.

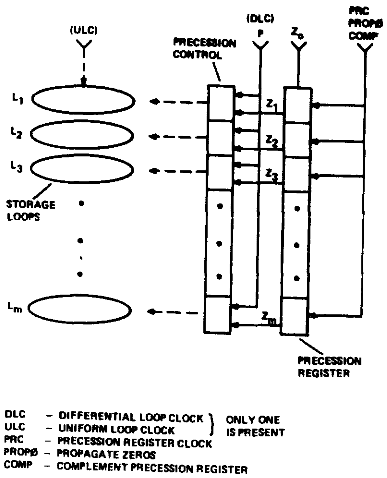

Figure 6—Loop precession subsystem block diagram

Z_1	Z_2	Z_3	Z_4	Z_5	Z_6	Z_7	Z_8	Z_9	Z_{10}	Z_{11}	Z_{12}
0	1	1	1	1	0	1	1	1	1	0	1
0	0	1	1	1	0	0	1	1	1	0	0
0	0	0	1	1	0	0	0	1	1	0	0
0	0	0	0	1	0	0	0	0	1	0	0
1	0	0	0	0	1	0	0	0	0	1	0
0	1	1	1	1	0	1	1	1	1	0	1

Figure 7—Precession register states k=5, m=12

Figure 8 illustrates the phase difference introduced in precession mode between a loop for which $P \cdot Z_i = 1$, (a) and (b), and a loop for which $P \cdot Z_i = 0$, (c) and (d), during a time interval $(l\text{-}\delta)t$, where t is the one-byte shift time (in sec.). The triangular marker in Figure 8 points to an arbitrary but fixed reference position relative to the loop contents. The reference position at time 0 is shown in (a) and (c), and at time $(l\text{-}\delta)t$ in (b) and (d). A phase difference of δ bytes has been introduced.

In (b) the auxiliary loop contents occupy the same position relative to the main loop contents as in (a). A transition to $Z_i = 0$ at time $(l\text{-}\delta)t$ will terminate the differential phasing while preserving the original ordering of stored data. If Z_i is held at 1 for an integral number (say s) of time intervals, each of length $(l\text{-}\delta)t$, then a total phase differential of $s\delta$ is introduced in loop L_i with respect to a loop L_j for which $Z_j = 0$ over that time interval.

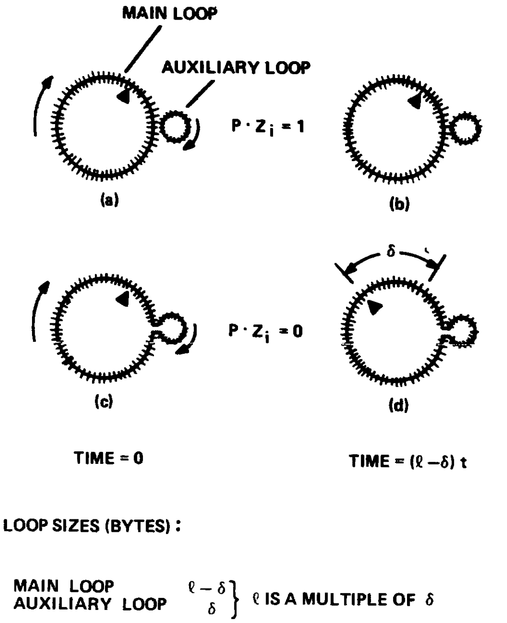

Figure 8—Loop L_i precession control uniform loop clocking

Operation

The same processing element may be used in both the packed-loop and single-record-per-loop memories. This imposes several restrictions on the operation of the packed-loop version vis-a-vis the single-record-per-loop version. The restrictions may be removed at the expense of increasing PE complexity.

In particular, for packed-loop operation, there is no provision for internal memory within each PE to store the current record packing factor k and separate status information about each of k records. Thus, PE actions such as interchanging records, or depositing a tag bit or posting an update following a successful search operation must be completed during one record interval, and not deferred to the next loop rotation. For sorting, this means the sort key field must occur at the head of the record. It may be of any length, however, up to the full record length. For searching, response bits cannot be written ahead of the search key area.

Concerning performance, with a record packing factor of k, gyro sort takes roughly k times longer than with one record per loop, but uses fewer processing elements by a factor of k. A similar tradeoff applies to packed-loop memory search and update operations.

Cost comparison

We assess the cost attainable with the packed-loop intelligent memory as compared with single-record-per-loop. Again we assume n=mk records, m loops, and k records per loop. We let q be the record size in bytes and $l=kq$ be the loop size in bytes.

Suppose we let a_s denote the chip area (say in nanoacres) for one byte of storage and a_p the chip area for one processing element (PE). Then the total chip area for the packed-loop case is

$$nqa_s + ma_p.$$

The *PE-overhead,* defined as the ratio of total PE area to total storage area is

$$\frac{1}{k}\frac{a_p}{qa_s}.$$

For the one-record-per-loop organization, total chip area is

$$nqa_s + na_p.$$

This assumes that a_p is the same in both cases. PE-overhead is

$$\frac{a_p}{qa_s}.$$

Thus the packed-loop organization cuts overhead by a factor of k, and reduces total chip area.

We define the PE-complexity α as follows:

$$a_p = \alpha \cdot a_s.$$

Thus a PE requires chip area equal to that of α bytes of storage. Then the ratio of one-record to multiple-record total chip areas is:

$$\frac{nqa_s+n\alpha a_s}{nqa_s+\frac{n}{k}\alpha a_s}=\frac{q+\alpha}{q+\frac{\alpha}{k}}$$

The PE-complexity α is fixed by the PE design and the technology used. A conservative estimate for α using CCD technology is 18.75 (equivalent to 150 bits of storage). Figure 9 is a plot of cost ratio (one-record-per-loop to multiple-record-per-loop) as a function of the record length q and the packing factor k, using $\alpha=18.75$. Figure 10 is a similar plot, using $\alpha=187.5$ as a representative figure for off-chip MOS PEs and magnetic bubble storage.

SUMMARY

We have described the structure and operation of an intelligent memory subsystem which combines the economy of new serial storage technology with the performance of highly parallel execution of data processing primitives. For a CCD/MOS realization with fundamental loops of size 256 bits, we estimate subsystem cost at 0.5¢ per bit; performance figures are given below, alongside rough comparable estimates for a single CPU and RAM. A memory-resident file of 32,000 32-character records is assumed in both cases. A 10 MHz shift rate is assumed for the intelligent memory; a 1 μs. cycle time is assumed for the CPU-RAM.

	Intelligent Memory	CPU-RAM
LOAD/UNLOAD	1 s.	1 s.
SORT	0.5 s	15 s.
SEARCH	40 μs.	75 ms.
SEARCH AND RETRIEVE	100 μs.	75 ms.
SEARCH AND UPDATE	65μs.	75 ms.
RECONFIGURE	4 ms.	—

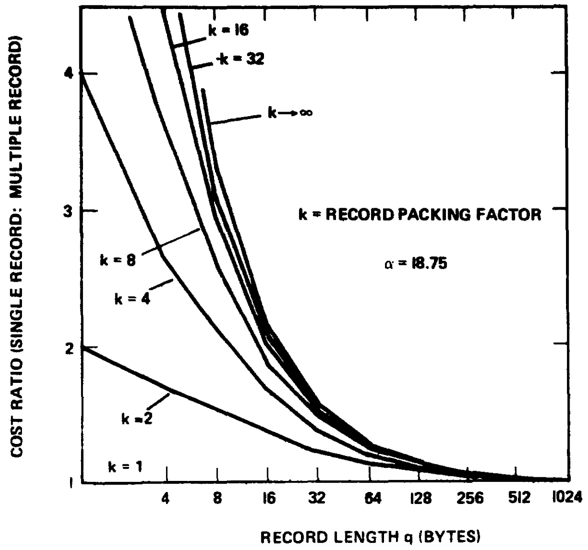

Figure 9

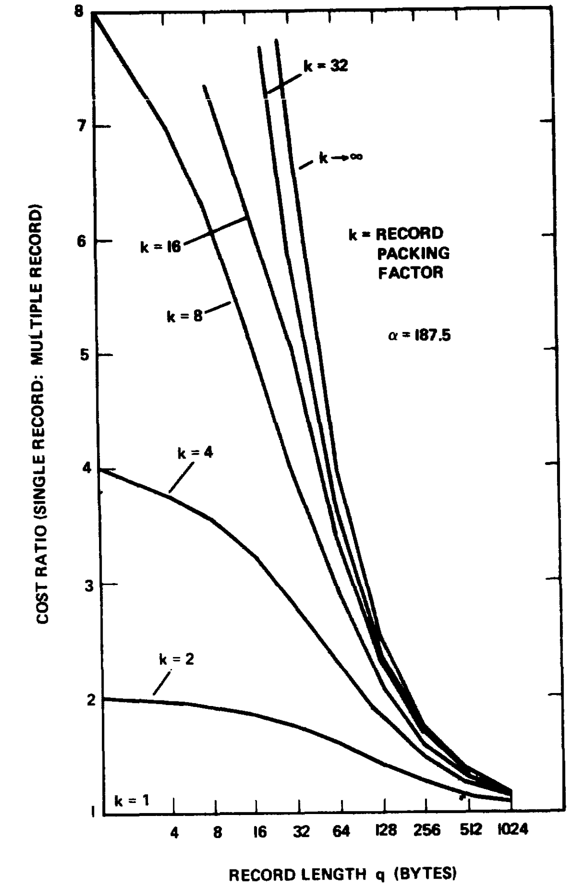

Figure 10

We have shown how performance can be traded for economy by extending the memory architecture to accommodate packed-loop operation. This is aimed at realizations using long storage loops in which lower subsystem cost (we estimate 0.05¢ per bit for magnetic bubble storage and off-chip MOS PEs) may make large capacity intelligent storage subsystems feasible for future data-oriented computer systems.

ACKNOWLEDGMENT

The authors would like to acknowledge the contributions of T. Bonn to this work. The idea of extending the intelligent memory to operate with multiple data records per loop, and the idea of precessing loops as part of a packed-loop sort strategy are due to him.

Los Angeles, California

*To the ingenious designers and programmers
of the first generation
Who made their machines work in spite of
most contrary components
And inspired their successors to continue
striving for reliable computing*

ABSTRACT

Approaches to the attainment of reliable computer operation are considered in this paper. The goal is to assure correct execution of programs using less than perfect components. The discussion includes design methodology, fault classification, redundancy techniques, reliability modeling and prediction, and examples of fault-tolerant computers. The last section identifies some relationships between reliability methods for hardware and for software.

HISTORICAL PERSPECTIVE

The problem of reliability has confronted both the designers and the users of computing systems since the building of the first computers in the 1940's. First-generation digital computers used large numbers of vacuum tubes, relays, and other electromechanical devices which were notably failure-prone. Various methods of failure detection and recovery were incorporated in the hardware of these machines. For example, duplicate arithmetic-logic units were used in the EDVAC and UNIVAC computers; various error-detecting codes were used in many others, including RAYDAC, IBM 650, NORC, etc.[1]

The advent of transistor technology in the second generation led to a very large improvement in component reliability. This improvement, in turn, led to a deemphasis of failure detection techniques in the hardware. The remaining exceptions were parity checking and related techniques in storage and I/O equipment. All failures, however, were not eliminated, and the absence of hardware checking led to the rapid development and extensive use of diagnostic programs. The diagnostics were employed to perform periodic checkouts of computers and to assist maintenance specialists by identifying failed parts during repairs. Widespread use of diagnostics began in the late 1950's and has continued into the present, with microdiagnosis largely superseding diagnosis in the middle to late 1960's.

Diagnosis-aided manual repair, however, proved in many cases to be an insufficient solution because of at least three reasons: (1) the unacceptability of the delays and interruptions of real-time programs caused by manual repair action; (2) the inaccessibility of some systems to manual repair; and (3) the excessively high cost of lost time and of maintenance in many installations.

Since the early 1960's the scope of computer applications has steadily expanded, encompassing numerous areas of critical importance. These applications include real-time control of communication and transportation systems, manned space flights, automated factories and power plants. At the present, use of computers is being considered for the monitoring of critically ill patients in hospitals. The reliability requirements for computers in such applications far exceed the requirements established for the computing systems of the 1950's and 1960's. The expected great benefits of computer use are balanced against the potentially disastrous costs of their failure.

Another relevant development of the past decade has been the wide distribution of computing systems throughout the entire planet and their use in space. Instead of being concentrated in a limited number of population centers, computers are now performing important, and even critical tasks in many locations that are remote from the service and repair facilities and personnel. Computers have been employed in space

* This work was supported by the National Science Foundation, Grant No. DCR 72-03633 A03

vehicles orbiting the Earth and the Moon, or traveling to the other planets of the solar system. In these applications fully automatic detection of faults, program restart, and self-repair are either absolute requirements, or economic necessities in order to provide reliable computing at an acceptable cost or risk to the user.

In the most general sense, reliable computing means "the correct execution of a specified set of algorithms", and encompasses all the following elements:

—correctness and completeness of software specifications;
—testing and verification (proofs) of programs;
—elimination of hardware design errors;
—continued correct execution of programs and protection of data in the presence of hardware failures;
—protection of the computing system against error-induced disruption or deliberate invasion of programs and data.

Attempts to meet the requirement for reliable computing, especially when external assistance by maintenance specialists is too slow, too costly, or not available, have utilized the two complementary approaches of *fault-intolerance* and *fault-tolerance*.[2] These approaches are applicable to all parts of the computing system, including its hardware elements, microprograms, system programs, and user programs.

In the "fault-intolerance" approach the reliability of computing is assured by *a priori* elimination of the causes of unreliability, i.e., of faults. This elimination takes place before the normal computing process, and the resources that are allocated to attain reliability are spent on perfecting the system prior to its field use. Since in practice it has not been possible to assure complete *a priori* elimination of all causes of unreliability, the goal of fault-intolerance is to reduce the unreliability (expressed as the probability of system failure over the duration of the specified computing process) or the unavailability to an acceptably low value. To supplement this approach, manual maintenance procedures must be devised which return the system to an operating condition after a failure. The cost of providing readily available maintenance and the cost of the disruption and delay in the computing process also are parts of the overall cost of using the fault-intolerance approach.

In the "fault-tolerance" approach the reliability of computing is assured by the use of protective redundancy. The causes of unreliability are expected to be present and to induce errors during the computing process, but their disrupting effects are automatically counteracted by the redundancy. Reliable computing is made possible despite the remaining program and hardware design errors, hardware failures, and external interference with computer operation. The resources allocated to attain reliability are spent on protective redundancy. The redundant parts of the system (both hardware and software) either take part in the computing process or are present in a standby condition, ready to act automatically to preserve its undisrupted continuation. In contrast, we note that the maintenance procedures in a fault-intolerant system are invoked after the computing process has been disrupted, and the system remains "down" for the duration of the maintenance period.

It is evident that the two approaches are complementary and that the resources allocated to attain the required reliability of computing may be divided between fault-tolerance and fault-intolerance. Experience and analysis both point to the conclusion that a balanced allocation of resources between the two approaches is most likely to yield the highest reliability of computing. An overview of past practice shows that fault-intolerance has been the dominant choice in both hardware and software in the 1950's and 1960's. In recent years the fault-tolerance approach has been making significant inroads in hardware system design; its application in software has remained very limited. The cost of redundancy has been the main argument against the use of fault-tolerance techniques in computer systems. The evolution of component technology into large-scale integration, the decreasing cost of mass-produced hardware elements, the very high cost of software testing, and the increasing reliability requirements all favor increasing use of fault-tolerance in computer systems of the future. The resistance to its wider use frequently originates with the practitioners of the current fault-intolerance and manual maintenance methods.

DESIGN METHODOLOGY FOR RELIABLY OPERATING COMPUTERS

This section and the subsequent sections address the issue of providing undisrupted computing while using less than perfect hardware components. The remaining aspects of reliable computing remain outside the scope of this paper.

Unreliable operation is caused by imperfections in the physical implementation of the computer's logic structure. Reliability theory defines the reliability $R(T)$ of a system as the probability of its correct operation up to the time $t=T$, given that the system was operating correctly at the starting time $t=0$. Computers differ from other systems because in their case "correct operation" means the correct execution of a set of programs and protection of data, rather than the continued functioning of a set of physical components of the system. It is the purpose of this section to present those aspects of computer system design that are specifically directed toward the elimination or tolerance of imperfections (called "faults") in the components of the system. It is to be noted that we discuss correct *execution* of a given set of programs and do not include the questions of correctness of the programs, completeness of their specification, and of accuracy of the algorithms, which remain separate fields of study.

The architects and the users originate the sets of programs and data, the definitions of required operations, the time limits for program execution, and the storage requirements. The objective of the designer is to raise the reliability (i.e., the probability of correct execution of these programs) or availability to an acceptably high value, given that *operational faults* may occur during execution. Such faults are caused by three classes of physical events that affect the hardware of the system:

—permanent failures of hardware components;
—intermittent malfunctions of components;
—external interference with computer operation.

As discussed previously, two complementary approaches have been employed to attain satisfactory reliability. Fault-intolerance is the approach that aims to reduce the probability of occurrence of the first fault during a specified time interval to an acceptably low value. In the "pure" fault-intolerance approach the system is designed without redundancy, and every component of the system must function correctly in order to assure correct program execution. The procedures which lead to the attainment of reliable "fault-intolerant" systems are:

—the most reliable components are acquired within the existing cost and performance constraints;
—proven techniques are employed for the interconnection of components and assembly of subsystems;
—the system is packaged to screen out the expected forms of external interference;
—quantitative prediction of system reliability is made using known or predicted failure rates for the components and interconnections.

In the "purely" fault-intolerant (i.e., non-redundant) design, the probability of fault-free hardware operation is equated to the probability of correct program execution. Such a design is characterized by the decision to invest *all* the reliability resources into procurement of high-reliability components and refinement of assembly and packaging techniques. An alternative to the "purely" fault-intolerant approach is offered by the use of various forms of redundancy to attain fault-tolerance.[3] This approach increases reliability by the use of design techniques that allow faults to occur without disrupting the continued correct execution of the programs. Fault-tolerance does not entirely eliminate the need for reliable components; instead, it offers the option to allocate part of the reliability resources to the inclusion of redundancy. The goal of a fault-tolerant design is either a reliability (or availability) prediction that cannot be attained by the purely fault-intolerant design, or a reliability (or availability) prediction that matches the purely fault-intolerant design at a lower overall cost of implementation.

A fault-tolerant computer system must possess the following attributes:[4]

—Its description includes a set of components (hardware) and a set of programs (software).
—It is either initially free of design faults or it is protected against their disruptive effects during program execution.
—It executes the set of programs correctly in the presence of operational faults.

The first attribute stresses the fact that the ability of a computer to continue operating correctly in the presence of operational faults depends not only on the properties of the hardware, but also on the nature of the software, including both the system programs and the user programs. For example, the ability to recover from the errors caused by transient faults frequently depends on special restart features incorporated in the system software as well as on proper partitioning and state vector storage of user programs.

The second attribute requires that design faults should be eliminated from both hardware and software prior to the initiation of the computing process. As an alternative, protective features for the detection and circumvention of design faults in both hardware and software must be incorporated to make the system fault-tolerant. Design faults are caused by errors made during the translation of the original specifications into operational forms, that is, into assemblies of components and of machine language instructions. They are eliminated by validation of the hardware and software designs prior to their operational use. Since complete *a priori* verification cannot yet be assured, computers need protective provisions to detect and circumvent abnormal conditions encountered during operation which may be symptoms of remaining design faults. A completely fault-tolerant operation is attained either when all design faults are eliminated from the system, or when complete protection against remaining design faults is incorporated.

The third attribute of a fault-tolerant computer postulates correct execution of the entire set of programs in the presence of operational faults. Program errors that are caused by faults in the hardware can be avoided or corrected by means of protective redundancy. Protective redundancy may be introduced in three forms:

—additional hardware (hardware redundancy);
—additional software (software redundancy);
—repetition of operations (time redundancy).

These redundant features would not be needed in a fault-free computer; that is, their deletion does not affect computer performance in the absence of operational faults. Given that the faults will occur in the hardware, the redundant features provide a fault-tolerant computing system which carries out its programs correctly in the presence of operational faults. Partial fault-tolerance (also called "fail-soft operation" or "graceful degradation") occurs when operation continues, but one or more programs are not correctly executed in the specified time.

Research results and design experience lead us to suggest that the introduction of protective redundancy can be accomplished by following a systematic procedure:[4]

(1) Performance requirements are established and system architecture is specified with the initial assumption that operational faults will not occur (the "fault-intolerant" design).
(2) Classes of operational faults that are to be tolerated in the design are identified, and the extent of tolerance is specified for each class of faults.
(3) Cost-effective methods of protective redundancy (time, hardware, software) are chosen to cover every class of faults identified above, and system architecture is modified to incorporate the redundancy.
(4) Analytic or experimental techniques are employed to estimate the extent of fault-tolerance that is provided by the protective redundancy.
(5) Checkout methods are devised to test all redundancy features. Where applicable, fault-tolerance is extended to effect automatic maintenance of peripheral systems that are connected to or controlled by the computer.

Design experience has shown that several iterations of (3) and (4) may be necessary to arrive at a satisfactory fault-tolerant system architecture. The following sections discuss the techniques for the implementation of (2) to (5) and illustrate their use in recent computer systems and in proposed designs.

CLASSES OF OPERATIONAL FAULTS

An operational fault is the deviation of one or more logic variables in the computer hardware from their design-specified values. Faults are caused by failures, which are physical changes in the hardware of the computer. Hardware failures are of three types: "solid" component failures, "intermittent" component malfunctions, and externally caused interference with the operation of the computer. The immediate symptom of any hardware failure is a fault. The fault often causes an error in the program being executed by the computer: either an instruction is not executed correctly, or an incorrect result is computed. Both types of errors may be caused at once by some faults.

A systematic approach to the choice of redundancy techniques in computer design begins with a classification of faults and identification of those classes which are expected to occur in the system being designed. Three useful dimensions for the classification of faults are:[4]

—*duration:* transient (intermittent) vs. permanent (solid);
—*extent:* local (single) vs. distributed (related multiple);
—*value:* determinate ("stuck") vs. indeterminate (variable).

In the design methodology the "permanent vs. transient" classification appears to be most fundamental because the two classes usually need different recovery methods. A program restart is sufficient to correct errors caused by transient faults, while replacement or reconfiguration of hardware is needed to eliminate permanent faults from the system. The classifications according to extent and according to value are applicable to both transient and permanent faults.

The extent of a fault specifies how many logic variables in the hardware are simultaneously affected by the fault which is due to a single failure event. *Local* (single) faults are those that affect only single logic variables, while *distributed* (related multiple) faults are those that affect two or more variables, one module, or an entire system. The physical proximity of logic elements in contemporary MSI and LSI circuitry has made distributed faults much more likely than in the discrete component designs of the past. Distributed faults are also caused by single failures of some critical central elements in a computer system, for example: clocks, power supplies, data buses, switches for computer reconfiguration, etc.

The value of a fault is *determinate* when the logic values affected by the fault assume a constant value ("stuck on 0" or "stuck on 1") during its entire duration. The fault value is *indeterminate* when it varies between "0" and "1", but not in accord with design specifications, during the duration of the fault.

It is important to observe that a precise description of fault extent and fault value can only be made at the source of the fault, that is, at the point at which the hardware failure event has actually taken place. The introduction of one or more faulty logic variables into the computing process will often lead to different or more extensive fault symptoms downstream from the point of failure. For example, a "stuck on 1" local determinate fault on the input to a two-input "Exclusive-Or" gate will cause the output variable of the gate to appear as a local indeterminate fault. Furthermore, if this output is supplied as an input to several other gates, the set of output variables of these gates will appear as a distributed indeterminate fault.

Ambiguity is avoided when the term "fault" is restricted to the change in logic variable(s) at the point of the actual hardware failure. The fault-caused changes of logic variables which are observed (because of faulty inputs) on the outputs of correctly functioning logic elements are symptoms of the fault and will be called errors. This distinction establishes a cause-effect sequence as follows:

(1) The *failure* which is a physical event, causes a *fault,* which is a change of logic variable(s) at the point of failure.

(2) The *fault,* in turn, supplies incorrect input(s) to the computing process and causes an *error* to be produced by subsequent operation of failure-free logic circuits.

The preceding discussion makes it evident that the detectability of a fault depends not only on its type, but also on the distance (in terms of computing operations) from the point at which the fault occurs to the point at which checking (fault-detection) is performed. A local determinate fault may cause an extensive error pattern to appear at a point that is several computing steps (in time, space, or both) removed from the fault itself.

METHODS OF PROTECTIVE REDUNDANCY

The key to successful application of protective redundancy is the systematic and balanced selection of suitable methods of its three forms: *hardware* (additional components), *software* (special programs), and *time* (repetition of operations). This section reviews the basic methods of these forms of redundancy.

Hardware redundancy

Hardware redundancy includes the components that have been introduced into the system in order to provide fault-tolerance. As long as faults do not occur, all these components can be deleted without diminishing the computing power of the system. The techniques of introducing hardware redundancy may be divided (on the basis of terminal activity of modules) into two categories: *static* redundancy and *dynamic* redundancy.[5]

The static redundancy method is also known as "masking" redundancy, since the redundant components are employed to mask the effect of hardware failures within a given hardware module, and the terminal activity of the module remains unaffected as long as the protection is effective. The static technique is applicable against both transient and permanent faults. All redundant copies of an element are permanently connected and receive power. Component failures and logic faults are masked by the presence of other copies of the same element. The fault masking occurs instantaneously and automatically; however, if the fault is not susceptible to masking and causes an error, a delayed recovery is not provided.

The original study of the use of static redundancy at the logic element level is due to John von Neumann.[6] He considered transient malfunctions of individual logic gates and showed that arbitrarily high reliability would be attained with high orders of redundancy. Moore and Shannon[7] applied the static redundancy principle to relay contact networks. In practical applications the order of redundancy has to be as low as possible in order to make the cost acceptable to the user. Two forms of static redundancy have been used in practice: replication of individual electronic components in the Orbiting Astronomical Observatory and triple modular redundancy (TMR) with voting in the SATURN IV and V guidance computers.[8] Several other variants of static redundancy have been studied but were not employed in practice because of excessive cost or the need for practically unrealizable special components. It is essential to note that static redundancy is based on the assumption that failures of the individual copies are independent. When related failures take place, the protection by redundancy is lost. For this reason static redundancy (especially at the component level) is not applicable within integrated circuit packages, in which individual components are in close proximity and failure phenomena frequently affect several adjacent components.

In the dynamic redundancy approach fault-caused errors are allowed to appear at the terminals of a module. Fault-tolerance is implemented by two consecutive actions. First, the presence of a fault is detected, then a recovery action either eliminates the fault, or corrects the error. If human assistance is completely eliminated, dynamic redundancy (usually with software support) results in self-repair of a computer system. Limited, that is human- and software-assisted, use of dynamic redundancy techniques in computer hardware has been very extensive.[1,3,5] The most common example is the use of parity to detect errors in data transmission and storage. Important early examples of extensive dynamic redundancy with software and human support are the ESS systems.[9,10] Probably the first operational computer with full self-repair provisions is the JPL-STAR computer.[11]

The application of dynamic redundancy to a computer architecture requires that a number of decisions should be made in the functional design stage. The design choices include: level of modularization, fault-detection hardware, type of recovery action, "hard-core" protection, forms of intermodule communication, validation of inputs, and interfaces with system software.[2] The use of dynamic redundancy has been somewhat inhibited because of the need for an early commitment to it in the hardware design process. In contrast, static redundancy (and software redundancy, as well) can be applied to an existing non-redundant design.

Software redundancy

Software redundancy includes all additional programs, program segments, instructions, and microinstructions which would not be needed in a fault-free computer.[2] They provide either fault-detection or recovery in fault-tolerant computer systems, very frequently in conjunction with dynamic hardware redundancy. Three major forms of software redundancy are:

- —multiple storage of critical programs and data;
- —test and diagnostic programs at various program and microprogram levels;
- —fault-tolerance features of the executive program which implement program restarts and interface with the dynamic hardware redundancy.

Combinations of all three forms are found in most modern fault-tolerant computers.

Compared to hardware redundancy, an advantage of software is the ability to superimpose fault-tolerance features after the hardware has been designed. This allows the design of fault-tolerant systems using non-fault-tolerant 'off-the-shelf' hardware. Another advantage is the relatively easier modification and refinement of these software features after their introduction into the system. The main disadvantage of software redundancy is the difficulty of assuring that the software features will be able to function correctly after the occurrence of a fault and that they will be invoked sufficiently early, that is, before the fault-caused errors have irrevocably disrupted the programs or mutilated the data base. Other disadvantages include the relatively high cost of generating the required software, the storage requirements, including the need to tolerate failures of memories holding the software, and the difficulty of estimating and proving the completeness or the adequacy of the software redundancy features. It must be stressed that dynamic hardware redundancy and software redundancy are not mutually exclusive in practice.[12] A system with all-out emphasis on self-contained dynamic hardware techniques still needs cooperation from the executive program to complete some recovery actions. Conversely, an all-software controlled fault-tolerant system has high risks of excessive delays in initiating recovery without at least some hardware methods for fault-detection. It also needs redundant storage modules and hardware protection of critical decision-making logic. Combinations of software and hardware redundancy are employed in most fault-tolerant systems, but they differ in the choice of the point in the detection and recovery sequence at which software takes over control.[9,11-14]

Time (execution) redundancy

This form of redundancy consists of repeating or acknowledging machine operations at various levels: micro-operations, single instructions, program segments, or entire programs. It is usually employed together with dynamic hardware and software redundancy techniques. Two distinct goals of time redundancy are:

- —fault detection by means of repeated execution or acknowledgments;
- —recovery by program restarts or operation retries after fault detection or reconfiguration has occurred.

The repeated execution of a program is probably the oldest form of fault detection. While suitable to detect errors due to transient faults, it is limited by the fact that consistent errors will be produced by permanent faults, and comparison will fail to reveal the same error in the results. The use of retransmission and of other forms of acknowledgments ("handshakes") has been extensively used in general purpose systems, especially for error detection in secondary storage, channels, and I/O devices.[13,22]

Another common use of time redundancy is found in the identification and correction of errors caused by transient faults, and in program restarts after a hardware reconfiguration.[2] This is accomplished by the repetition after error-detection or 'rollback' of single instructions, segments of programs, or entire programs. While single-instruction retries are transparent to the programmer, longer rollbacks require programming constraints as well as protected storage for the rollback address and for the state vector, including its double-buffering. "Singular" events in a computer are program-controlled events which should not be repeated as part of a program rollback operation, for example, real-time output commands which initiate irreversible actions in the system under computer control. The potential damage makes it imperative that the provision for handling of singular events should be incorporated in rollback procedures.[11,14]

Checkout and extension of fault-tolerance features

The introduction of redundancy poses the problem of verifying that the redundant parts are ready to be used when faults occur. Implementation of checkout encounters difficulties in systems with static hardware redundancy, especially in component-redundant systems.[7,8] Dynamically redundant systems are inherently better suited for redundancy checkouts, since they possess extensive fault-detection and permit sequential switching-in of spare modules to be tested.[11] One critical requirement of checkout is the systematic verification that all fault-indicating signals are operational. Self-checking logic[15] is suitable for this purpose. In software-controlled fault-tolerance this function is carried out by a special fault-signal-test instruction.[16]

The techniques of fault-tolerance can be systematically extended beyond the boundaries of the fault-tolerant computer to effect automatic maintenance of various peripheral systems which communicate with the computer. The methodology of extending fault-tolerance consists of the development of fault-tolerant interfaces, introduction of fault-detection methods in the systems outside the computer, and programming of recovery sequences to be executed by the computer. A case study of the application of these techniques in a spacecraft system is presented in Reference 17. In commercial general purpose systems, the reverse process has taken place. Because of the relatively high unreliability of peripheral mechanical devices, fault-tolerance began at the peripherals and only later was brought into the CPU and main memory.[28]

FAULT-TOLERANT SYSTEMS

The currently existing and proposed fault-tolerant computer systems may be conveniently classified according to the method used to control the recovery. *Hardware-controlled* systems use dedicated hardware which collects fault indications and initiates recovery. While recovery control may be transferred to software after its operability has been assured, it is completed automatically (without external aid). *Software-controlled* systems depend on special programs to interpret fault indications and to carry out the automatic recovery procedures. *Manually-controlled* systems require the participation of a maintenance operator in the completion of recovery; they are not fault-tolerant in the full sense of the word, although they may employ many fault-tolerance techniques.

Hardware-controlled recovery

This approach depends on special hardware to carry out fault detection and to control the initial recovery procedure. After the procedure has established the existence of an operational software system, the completion of recovery is usually transferred to software control. It is evident that further software systems may be superimposed on the hardware-controlled design, leading to a multilevel recovery procedure. A special case of hardware-controlled recovery is found in statically-redundant systems in which faults are masked by redundant hardware, and are totally invisible to the software. Two examples of such systems are the OAO data processor which used component redundancy and the CPU of the SATURN V guidance computer, which used TMR protection.[8] A separate software-controlled recovery system is needed in statically-redundant systems if they are to continue operating in reconfigured mode after the first fault that escapes the masking effect and affects the software.

Dynamically redundant systems usually depend on a dedicated hardware module that gathers fault signals and initiates recovery. Different uses of duplexing and hardware-controlled switchover techniques are found in the memory, power supply, and peripheral units of SATURN V computer in combination with a TMR-protected serial CPU unit.[8] Separate fault-detection and switchover-control units were used for every functional unit. Probably the first operational computer with fully hardware-controlled dynamic redundancy was the experimental JPL-STAR computer.[11] Intended for self-contained multiyear space missions, this computer employs a special Test-And-Repair-Processor (TARP) module to control recovery and self-repair. Software assistance is invoked only to perform memory copying and to resume standard operation after self-repair.[14] The French MECRA computer is another early experimental design.[18] A few other hardware-controlled system designs that have not reached operation have been described in recent literature.[12,16]

The principal advantage of hardware-controlled recovery systems lies in their independence of the operation of any software immediately after the fault has occurred. The recovery process is transferred to software only after its ability to operate has been assured. The relatively late appearance of such systems may be attributed to the need to introduce the recovery module into the design at its inception, thus requiring an early commitment to the hardware-controlled approach.

Software-controlled recovery

In contrast to the previous class, the software-controlled systems depend on special software to initiate recovery action upon the detection of a fault. Fault signals are obtained by both hardware and software methods, for example: parity checkers, comparators, power level monitors, test programs, reasonableness checks, etc. The main limitation of these systems is the need for the recovery software to remain operational in the presence of faults, since recovery cannot otherwise be initiated.

A significant advantage of this approach is that existing 'off-the-shelf' hardware system modules may be used to assemble fault-tolerant organizations. These modules contain various forms of hardware fault-detection, which usually are supplemented by further software methods. For this reason software-controlled systems have appeared earlier and are currently being used in numerous applications requiring high reliability and availability. While every modern operating system incorporates some recovery features, the present paper will be limited to selected illustrations of historically important and advanced systems.

An important early design of the 1950's with complete duplication and extensive recovery provisions was the SAGE system.[19] The IBM System/360 architecture contains very complete provisions for multi-system operation in order to attain high availability, reconfiguration, and fail-soft operation.[21] An early example of a multi-system which includes further extensions of the System/360 design is the IBM 9020 multiprocessing system for air traffic control applications.[13] Noteworthy are the operational error analysis program and the diagnostic monitor of the 9020. The recent IBM System/370 hardware incorporates automatic retry of CPU operations, error coding to correct single-bit errors in processor and control storage, and I/O retry facilities. The software provides recovery management support routines, I/O and channel error recovery, checkpoint/restart facilities, microdiagnostics and on-line diagnostics of I/O device errors.[22] An interesting illustration of extensive use of backup storage and dynamic reconfiguration in a general-purpose time-shared system is found in the MIT Multics System.[23] Another experimental system for high-availability performance in an interactive time-shared environment is PRIME.[24] The Pluribus is a minicomputer/multiprocessor system with extensive fault-tolerance provisions which serves as a switching node in the ARPA Network.[20]

Another direction of software controlled system development is in aerospace applications. The principal illustrations of this approach are the SIFT design,[25] the RCS system,[26] and the C.S. Draper Laboratory modular system.[27] One more area of application which requires fault-tolerant operation and very high availability for several years of continuous operation is the control of electronic switching systems for telephone exchanges. These systems usually employ manual repair by replacement of a failed part as the last (offline) step of the recovery procedure, while maintaining normal operation by means of the remaining system modules. A well documented illustration is found in the ESS systems of Bell Laboratories.[9,10] ESS systems employ a variety of hardware techniques (duplication, matching, error codes, function monitors) and special software (check routines, diagnostics, audits) as well as software and hardware emergency procedures when normal recovery action does not succeed.

Fault-tolerant memories and processors

Besides the complete systems discussed above, significant efforts have been carried out in providing fault-tolerance for storage subsystems. This is especially true for secondary and mass storage which has been characterized by relatively low reliability in the past. Representative error coding applications include the use of codes for error control in data communications, magnetic tape units, disc files, primary random access storage, and a photo-digital mass store.[28] Single-error correcting codes are used in the control storage of ESS No. 1 and the main and control storage of IBM System/370 computers.[9,22] Error-correcting codes have been shown to provide a very effective method for fault-tolerance in the storage medium, and remaining problems are concentrated in providing fault-tolerance in the memory access and readout circuitry.

Recent studies have considered the problem of fault-tolerance in associative memories and processors.[29] In general, processor fault-tolerance has been provided by duplication and reconfiguration at the system level. Some investigations have been conducted in the use of arithmetic error codes as the means for error-detection for processor faults[30] and an experimental processor has been designed and constructed for the JPL-STAR computer.[11] The increasing availability of microprocessors makes further emphasis on duplication very likely, although error-detecting codes remain a convenient method for the identification of the faulty processor in a disagreeing pair.

RELIABILITY MODELING AND PREDICTION

The initial choice of redundancy techniques requires verification that the redundant system possesses the expected fault-tolerance. Insufficiencies of the original design may be uncovered, and the design can be refined by changes or additions of various forms of redundancy. The process is repeated until a fully satisfactory design is attained. The principal quantitative measures are reliability[31,32] (with respect to permanent faults), survivability[4,37] (with respect to transient faults), and availability.[32] Two approaches to the prediction of fault-tolerance are:

—the *analytic* approach, in which fault-tolerance measures of the system are obtained from a mathematical model of the system, and

—the *experimental* approach, in which faults are inserted either into a simulated model of a system, or into a prototype of the actual hardware, and fault-tolerance measures are estimated from statistical data.

A quantitative reliability prediction for the computer being designed requires numerical failure rates for the components. When technologies which are under development are to be used, the failure rates for currently used components need to be extrapolated to the new choice of component technology. It is important to recognize that different failure rates or distributions may apply to failures causing distributed faults. The principal measure of fault tolerance with respect to permanent faults is the reliability $R(t)$, which is a function of the failure rates and directly predicts only the probability of hardware survival. Fault-tolerance is attained only if correct program execution is maintained by the surviving hardware; for this reason transient faults must also be considered. A very common quantitative measure has been the MTBF (mean time between failures), defined as MTBF$=\int_0^\infty R(t)\,dt$. Given the non-redundant reliability $\mathrm{R}(t)=e^{-\lambda t}$, we have MTBF$=1/\lambda$, and the comparison of the MTBFs directly compares the total failure rates (λ) of the competing systems. When redundancy is introduced, the reliability function $R(t)$ is a polynomial in $e^{-\lambda t}$ and the $R(t)$ curves of systems being compared may have crossover points. Then the area under the $R(t)$ curve does not indicate which system is better at a given time, and the MTBF may become a misleading measure. Given a fixed 'mission time' T, the comparison of two or more systems requires only the values of $R(T)$ in order to select the best system. If a fixed mission time is not available, the time interval during which the reliability remains above a given value serves as a convenient comparison measure.[31]

It is essential to note that reliability modeling remains useful even if definite numerical failure rates and mission times are not available, since it permits the comparison of many alternate designs using normalization with respect to the (failure rate × mission time) product λT.

Reliability models

The class of *static* reliability models is suitable for the reliability prediction of systems with static hardware redundancy. The non-redundant system or its element is usually assumed to have the reliability $R(t) = e^{-\lambda t}$. The redundant elements are assumed to be permanently connected, and to fail statistically independently. They have the same failure rate and are instantaneously available to perform the masking of a failure with unity probability of success. Under these assumptions, the reliability of a redundant system is obtained as the sum of the reliabilities of all distinct configurations (including none or some failed parts) that do not lead to system failure. For example, given the simplex (one system) reliability R, the reliability of a duplicated system is $R(duplex) = R^2 + 2R(1-R)$. In general, reliability models of static redundancy are found in standard handbooks and textbooks of reliability theory and are used for reliability analysis of various physical systems.[32]

Dynamic redundancy requires the consecutive actions of fault detection and recovery in order to utilize redundant parts. The use of static reliability models for the dynamic case is equivalent to assuming unity probability of success of both actions; for this reason, very high reliabilities can be predicted as the number of spares is increased. It was recognized early in the studies of dynamic redundancy that imperfect detection and recovery may leave some spares unused.[33] The effect of such imperfections was formalized in the reliability model through the concept of "coverage", defined as the conditional probability of successful recovery, given that a fault has occurred.[31]

In general, the dynamic model[31,34,35] must represent the complete complexity of the proposed fault-tolerant system, including (1) differing failure rates for powered and unpowered modules; (2) number of spares of each module; (3) imperfect fault detection and recovery; (4) method of "hard core" protection; (5) existing intra-module fault tolerance; (6) extent and value of the faults; (7) duration and distribution of expected transient faults. Recent work has considered repairable systems[36] and models that include transient as well as permanent faults.[37,38] The principal objective of further study remains the development of models that integrate the characteristics of both hardware and software and consider both permanent and transient faults.

Analytic models of dynamically redundant systems are complex because of the number of different parameters that may be varied in the search for a balanced design. A very useful tool for reliability prediction is an interactive computer program which permits a ready variation of the important parameters of the redundant system for on-line design refinement. A pioneering effort in automated reliability modeling was the *REL* program, written in the APL language to predict system reliability for a given mission time when the system parameters have been specified.[31] Recent efforts to arrive at general and computationally efficient models have resulted in further APL programs.[38]

Experimental reliability prediction

Two approaches to experimental prediction of reliability are simulation and experimentation with a hardware prototype. While their use is more costly and time-consuming, the experimental methods are essential when the available analytic models do not adequately represent the complex structure of the system or the nature of the expected faults.

An accurate description of the system and characterization of the faults are the principal prerequisites when simulation is employed to derive the fault-tolerance estimates for the computer.[26] This approach has been extensively employed in reliability prediction for the redundant SATURN V guidance computer.[8,39] The use of hardware prototypes requires a large investment of effort in constructing the prototype, but avoids the inaccuracies which may occur in postulating the fault effects in a simulated model of the system. Two examples of use of hardware prototypes are: the switching system ESS No. 1 for which a catalog of fault symptoms was compiled by using a hardware model,[9] and the experimental fault-tolerant JPL-STAR computer.[11] In the JPL-STAR computer an electronic "black box" was used to inject faults of adjustable duration and extent at selected points in the hardware of the system. Another example of the experimental approach is the OAO processor[8] in which a component-redundant system was completely disassembled to determine the number of failed components after 3000 hours of operation.

A recent simulation and analysis system to analyze the behavior of faulty circuits is the LAMP (Logic Analyzer for Maintenance Planning) system.[40] In addition, LAMP also performs logic design verification, generates fault-detection tests, evaluates diagnostics, and produces trouble-location manuals. LAMP exemplifies the current trend toward multipurpose simulation systems in digital system design.

RELATIONSHIPS WITH THE SOFTWARE RELIABILITY PROBLEM

Discussion of the attributes of a fault-tolerant system included the goal that one of the two conditions should be satisfied with respect to design faults:

—the hardware and software should be free of design faults prior to the start of the computing process; or

—the system should contain complete provisions to detect and to circumvent the effects of hardware and software design faults during the computing process.

This means that the software of a fault-tolerant system must either be perfect (i.e., fault-free) or fault-tolerant in the same sense as the fault-tolerant hardware. The basic difference between the two is that operational faults in hardware occur after the start of the computing process, while design faults in software (and hardware, as well) are present at the start, but become disruptive only at a later time. However, software modifications and corrections of discovered design faults occasionally lead to new design faults and therefore the discoveries of software design faults may be expected throughout the useful life of any large software system, similar to the occurrence of operational hardware faults. This practically verified observation establishes the relationship between the methodologies for dealing with operational faults and design faults: the methods of protective redundancy that have proven successful in hardware fault-tolerance may be transferable to provide fault-tolerance of a software system as well.

An overview of the procedures currently used to attain software reliability shows that the "fault-intolerance" approach of perfecting the software prior to its regular use has been the accepted practice of improving software reliability. Three aspects of relevance of fault-tolerance can be identified:[41]

—the contribution of hardware fault-tolerant systems in assuring reliable computing;

—the common aspects of fault-tolerance that are equally applicable to hardware and software;

—the transfer of fault-tolerance techniques and experience from hardware to software, considering:

 —the applicability to software;

 —the potential advantages of software fault-tolerance;

 —the cost of its use, compared against the traditional fault-intolerance techniques.

The immediate advantage to a software system which results from the existence of a fault-tolerant hardware design is the protection of the software against disruptions caused by operational faults. In the case of a fault, the fault-tolerant features execute the corrective action in the hardware and restart the software, usually at a programmer-specified restart point,[14] although in some cases there is a single-instruction restart procedure which is transparent to the programmer.[27] The cost of utilizing the fault-tolerance features to achieve software protection consists of the programming constraints that must be observed to make automatic hardware initiated restarts of the programs possible. The advantages, in addition to the protection itself, also include the ability to distinguish, with a very high probability of success, whether a system crash was hardware-caused or not. Furthermore, a direct extension of the fault-tolerance techniques may be utilized to provide hardware-controlled protection of software and the data base against deliberate attempts to disrupt its operation and to access privileged information.

An area in which a common ground exists for hardware and software reliability efforts is the analytic modeling and quantitative prediction of system reliability.[31] The recent work on software reliability models[42,43] indicates the possibility of mutual reinforcement of research that would lead to the development of analytical models for the total system reliability, including both the hardware and software aspects. A second common area is design verification, in which the rapidly evolving techniques of program testing and proving have obvious applications to the problem of verifying hardware designs.

Finally, we consider the transfer to software of those protective redundancy techniques that have been successfully used in hardware system design. In the static approach, the same computation is carried out by two or more independently written programs.[41,44] The dynamic approach uses an analog of standby sparing with fault detection and switching of software modules.[45] While the cost aspect of both statically and dynamically fault-tolerant software remains to be explored, the continued use of 'pure' fault-intolerance for software reliability cannot be justified by tradition alone. It is hoped that the success of fault-tolerant hardware will stimulate further studies of the merits of fault-tolerance and redundancy in computer software.

ABSTRACT

The state-of-art in software validation as well as the continuing growth of the size and complexity of software subsystems, makes extra costs paid for software error tolerance more than justified. A program in which software redundancy is incorporated i.e. a program in which procedures for run-time validation and recovery are explicitly specified, is generally called a failure-tolerant program. One problem in failure-tolerant programming, which could be particularly serious in real-time computing environments, is the program execution time increased due to incorporation of validation and recovery procedures. This paper introduces an approach to the solution, called the failure-tolerant parallel programming. The essence of this approach is to maximally overlap main-stream computation with redundant computation oriented for validation and recovery. Subsequently, a model system architecture tailored for efficient execution of failure-tolerant parallel programs is described. It is of highly general and modular nature and contains a novel memory subsystem named the duplex memory. Directions of further researches on program structuring and expansion of the model architecture are also indicated.

INTRODUCTION

Computing system reliability is a function of both *hardware reliability* and *software reliability*. Hardware failures occur due to physical component *faults* (i.e., material characteristics) or *design errors*. The former source has been dominating the latter in significance. Recent advances in hardware component technology have substantially reduced the occurrences of hardware faults, thus greatly improving hardware reliability. On the other hand, all software failures are due to design errors. As the size and complexity of software subsystems grows steadily, software reliability has become a very serious problem and an increasingly important factor determining the overall system reliability.

Complete validation, which assures the absolute correctness of a program through verification of its complete behavioral characteristics, still remains to be infeasible with sizable programs.[2,12] On the other hand, more popular and pragmatic approaches aiming at *partial validation* with high cost-effectiveness via testing cannot, by their nature, insure the absence of errors in the program.[10,13,16,20,21] The apparent consequence is the current practice in which errors remain to exist in large programs put into operation. It is also this practice that makes *software error tolerance* an important objective besides complete removal of software errors at the design stage.

The concept of *failure-tolerant computing* i.e., reliable computing despite the presence of system component failures, was born in the very early days of electronic computing.[18,26] Since then, *hardware fault tolerance* has been a main subject of extensive investigation.[1,3,7,25] *Redundancy* is a fundamental vehicle in realizing failure-tolerant computing. A majority of previous studies have been centered around the use of hardware redundancy and in contrast, very little studies were made on the use of software redundancy. A restricted amount of software redundancy has been exploited in the form of *rollback and recovery* defined as follows. Let *state vector* refer to a snapshot of the contents of all the variables of the program in execution. Rollback and recovery is a technique of depositing state vectors at several stages in the middle of program execution and in case of a system failure, resetting the system state by using an old state vector and restarting the execution from that stage. However, the way failure detection, state vector saving and recovery operations are designed and specified has been mostly ad hoc and heuristic. It was only in recent years that studies were made on systematic and cost-effective implementation of a rollback and recovery scheme.[1,5,6,15,19,22,24]

In case of hardware faults, rollback (possibly combined with system reconfiguration using redundant hardware components) and re-execution with the same program will suffice to get over the situation. However, such an approach does not help in case of software failures. From the very nature of software errors, software error tolerance requires more extensive exploitation of redundancy, particularly software redundancy which is essentially a design redundancy. The method of structuring programs in which software redundancy is explicitly incorporated, is generally called *failure-tolerant programming.* It was in recent years that software error tolerance became a subject of serious studies and research was initiated toward the development of structured failure-tolerant programming techniques.[8,11,14,17,22,27]

In the next section, a brief overview of those recent significant contributions is given. Then some desirable directions of extending the state-of-art in failure-tolerant programming, which, we believe, are significant in real-time computing environments, are pointed out. The following section introduces a new approach to failure-tolerant programming (termed failure-tolerant parallel programming) devised to be a desirable extension of the state-of-art, and discusses the requirements on the system architecture oriented for efficient execution of failure-tolerant parallel programs. The following section describes an architecture developed to satisfy the requirements discussed in the preceding section. Finally, areas of extension and further research are discussed and then this paper is concluded.

BACKGROUND

Recent research on failure-tolerant programming and software error tolerance made significant contributions in the following aspects:

First, the notion of a *failure-tolerant program* was solidified. A failure-tolerant program is essentially a self-checking and recovering program. More specifically, a failure-tolerant program contains specifications of the procedures of validating intermediate results at various stages during execution and recovering when an abnormal condition is detected as a result of the check. Thus it consists of two types of program-segments: (1) *object segments* specifying application-oriented computations, and (2) *validation and recovery* (*VR-*) *segments,* each associated with a certain object segment and specifying the procedures of validating the results produced by the associated object segment and recovering in case of incorrect results. Within a failure-tolerant program, powerful facilities for validation and recovery can be incorporated in a systematic manner to any desirable extent. Here "recovery" implies not just the repetition of the execution with the same object segment (which may have failed the validation-test due to the hardware faults or the errors contained in it) but rather the provision of a set of "alternate" object segments and trials with one after another until a certain alternate object segment passes the validation test. If all the alternatives fail, then either the program cannot be successfully completed or a more global recovery action is incurred, provided the failed object segments are nested in another object segment and the latter is associated with a VR-segment.

Importance of good structure in failure-tolerant programs is evident, since structuring a failure-tolerant program by introducing VR-segments into a conventional program containing only object segments is accompanied by an increase in program size and complexity. Recognizing this importance, Randell's group at the University of Newcastle upon Tyne, England developed an experimental scheme called *recovery block structuring* by which validation and recovery functions can be embedded, in a well-structured form, inside each block in programs written in block-structured languages like ALGOL.[14,22] To give some flavor to this structuring scheme, the structure of the *recovery block* (i.e., the failure-tolerant block) is depicted in Figure 1.

In the diagram, double vertical lines define the bodies (i.e. scopes) of recovery blocks, while single vertical lines define the bodies of primary or alternate object blocks. The *primary object block* corresponds exactly to the block of the equivalent conventional

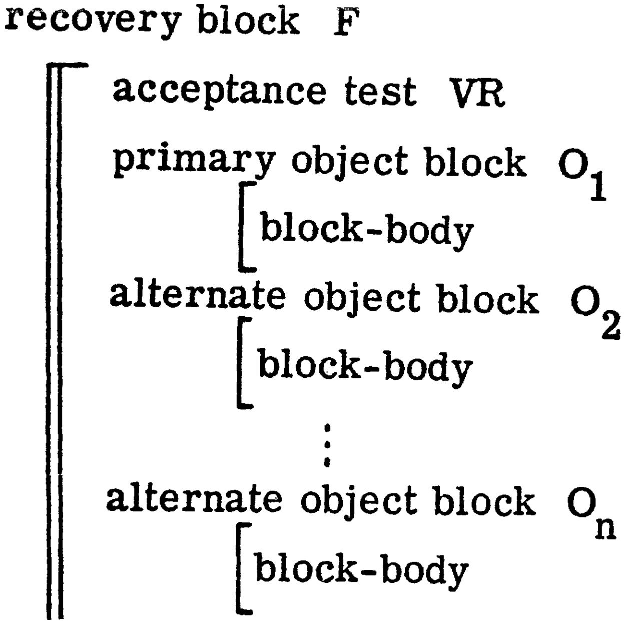

Figure 1—A structural model of the recovery block developed in References 14 and 22

(ALGOL-like) program and is a kind of an object segment. The *acceptance test* is executed on exit from an object block to confirm that the object block has performed acceptably. If confirmed, the control exits from the recovery block. Thus the acceptance test is a kind of a VR-segment. If the result produced by an object block is determined to be unacceptable, the next *alternate object block* is entered and is required to perform the objective operation in a different way or to perform some alternate action acceptable to the program as a whole. The acceptance test is then repeated.

The following aspects of recovery block structuring are rather fundamental and may be found, possibly in different formats, in any structured approach to the failure-tolerant programming.

(1) The primary or alternate object blocks can contain, nested within themselves, further recovery blocks.
(2) When an alternate object block needs to be entered after the result of the preceding object block fails the acceptance test, the system state must be restored to the one current just before entry to the primary object block.
(3) Execution of the acceptance test upon exit from an object block generally requires the reference to both the original values and the modified values of the variables non-local to the object block.
(4) It is not necessary that every block in a block-structured failure-tolerant program be a recovery block.

Second, a technical basis was established for reducing the overhead involved in saving a state vector on entry to each object segment and resetting the system state by using a saved state vector during recovery. The overhead exists in two forms. One is the processor time spent for those activities and the other is the store space occupied by saved state vectors. A useful property which can be advantageously exploited for overhead reduction is that the variables local to the object segment are irrelevant to the recovery and in many cases, only a few of the non-local variables are modified by the object segment.

Based on this, Randell's group developed a scheme for state vector saving and system state resetting, called a *recursive cache mechanism,* to support execution of programs structured by the scheme of recovery block structuring.[14] The essence of this scheme is to save the original value of each non-local variable together with its name (i.e., its logical address) right before the variable is modified for the first time in a new object block. Thus state vectors are saved in compact forms. It is apparently necessary to detect, at run-time, whether an assignment to a non-local variable is the first to have been made to that variable within the current block. This capability is provided by the *flag* attached to each non-local variable. Again, to give some flavor to this mechanism, an example of the recursive cache is shown in Figure 2.

(a)

(b)

Figure 2—(a) A program structured by the recovery block structuring (b) A snapshot of the recursive cache during execution of (a)

Figure 2(a) shows a failure-tolerant program structured by the recovery block structuring scheme. Figure 2(b) shows a snapshot of the recursive cache taken when primary object block O_{B1} is in the middle of its execution. There are two stacks, the *main stack* and the *cache stack*. The cache stack is also divided into regions, one for each nested recovery block in "active" state. The top region of the cache stack in Figure 2(b) contains previous values of non-local variables together with their names i.e., Y2, X1, X2, which have been modified by execution of the current object block O_{B1}. The flags attached to those non-local variables in the main stack are set accordingly. Similarly, the bottom region of the cache stack contains the previous value of non-local variable X1 which had been modified by execution of object block O_{A1} before O_{B1} was entered. If the result produced by execution of O_{B1} fails the acceptance test (LOGICAL EXPRESSION 2), then the top region of the cache stack can be used to reset the content of the main stack to the one current before entry to recovery block B. If it passes the test, the top region is merged into the bottom region of the cache stack so that the result will contain previous values of those variables which are non-local to object block O_{A1} and have been modified since O_{A1} was entered. Thus the result will be a single region containing (9, X1) and (2, X2). Flags in the main stack are also adjusted such that only flags of X1 and X2 be set. Therefore, the combination of the main and cache stacks contain information on the basis of which several old state vectors can be reconstructed.

This is perhaps an oversimplified account of recent developments. Yet it is intended to provide all the essential backgrounds for clarifying main departures of our works presented in the rest of this paper. For more information on the schemes described in this section, readers are of course referred to their original reports.[14,22]

DESIRABLE EXTENSIONS OF THE STATE-OF-ART IN FAILURE-TOLERANT PROGRAMMING

On the basis of recent works in failure-tolerant programming, particularly those introduced in the preceding section, various extensions can be clearly envisioned. Among many desirable extensions, the following ones are considered to be of great significance.

First, one problem in failure-tolerant programming, which could be particularly serious in real-time computing environments, is the program execution time increase due to incorporation of VR-segments. In most of the previous approaches including the recovery block structuring and recursive cache schemes introduced in the preceding section, validation and saving of state vectors fully contribute to the increase of the program execution time. Consequently, when any nontrivial validation is employed or large numbers of non-local variables are modified during execution of object segments, the program execution time, even in the case of normal failure-free operation, could very well exceed the tolerable limit in real-time applications. It is indeed expected that the VR-segment will be frequently a quite complex program-segment. Even in the recovery block structuring scheme in which only a restricted form of a VR-segment i.e. a logical expression is allowed for the sake of reducing errorproneness of the VR-segment, a provision has been made to allow procedure calls within acceptance tests (i.e., logical expressions).[14]

Second, the rationale underlying the restriction of the acceptance test to a logical expression is considered a perfectly legitimate one. Yet the logical expression is considered an excessively restrictive form of a VR-segment in many environments. For instance, it may be desirable to explicitly specify in the VR-segment which alternate object segment, among multiple alternates, is to be tried next in each case of recovery, rather than always letting the system select the next alternate object segment randomly or in the order alternates are located in the program text. It may also be desirable to immediately revert to a global recovery if a certain erroneous condition is detected by execution of a VR-segment, instead of retrying with an alternate. That is, allowance of more flexible structures in failure-tolerant programs may be desirable. Furthermore, our approach toward the first desirable extension mentioned above i.e., execution of VR-segments with minimal increase in the overall program execution time, favors more flexibility in structuring failure-tolerant programs. This will become evident in the next section.

CONCEPT OF FAILURE-TOLERANT PARALLEL PROGRAMMING AND REQUIREMENTS ON THE SUPPORTING SYSTEM ARCHITECTURE

Our main concern in this paper is with the first desirable extension mentioned in the preceding section, that is, incorporation of VR-segments with minimal increase of program execution time.

The fundamental approach we have adopted is to maximally overlap execution of object segments with execution of VR-segments. Since the VR-segment specifies manipulation on the results produced by its associated object segment, dependency of the former for its initiation on the completion of the latter is inherent. However, it is possible to execute the VR-segment associated with an object segment concurrently with the successor object segment(s). Figure 3 illustrates this concept. There VR-segment VR_2 can be initiated only after completion of the correspondent object segment O_2 and VR-segment VR_1, but it may be executed concurrently with object segments O_3, O_4, etc. In an ideal situation where execution of VR-segments is fully overlapped with execution of object segments, the amount of increase in program execution time will be the time required for execution of the last VR-segment (e.g., VR_n in Figure 3) since it is the only VR-segment which cannot be executed in overlap with object segments.

A failure-tolerant program in which computational parallelism, especially parallelism between application-oriented computations and redundant computations for validation and recovery, is explicitly indicated, is called a *failure-tolerant parallel program*. That is, the main type of parallelism which characterizes a failure-tolerant parallel program is the one existent between object segments and VR-segments.

This approach requires a new method of structuring a failure-tolerant program. The major departure of a newly required structuring method from the previously developed ones is in specification of the control structure among program-segments. In addition to inherent dependency of VR-segments on their correspondent object segments, dependency of object segments on VR-segments may also be specified in a failure-tolerant

Figure 3—A simple example of a failure-tolerant parallel program

parallel program. An example of such a situation is when a certain object segment specifies a critical operation such as ordering an emergency action, erasing a secret file, etc. In such a case it is desirable to suspend the execution of the object segment until all the VR-segments corresponding to its predecessor object segments have been verified. Thus critical operations can be controlled to occur reliably. This clearly favors, if not requires, the second desirable extension discussed in the preceding section i.e., more flexibility in structuring VR-segments and overall failure-tolerant programs. Yet such flexibility can be obtained without sacrificing most desirable structuring principles (or strategies) underlying the developed structuring schemes, including the recovery block structuring scheme. This aspect will be discussed later.

On the other hand, the failure-tolerant parallel programming imposes the following requirements on the supporting system architecture i.e., the architecture of a system capable of efficient execution of failure-tolerant parallel programs.

First and the most obvious of all, the system must contain at least two processors, one for execution of object segments, called the *object processor* and the other for execution of VR-segments, called the *VR-processor*.

Second, the state vector at the completion of an object segment is an input data not only to the successor object segment but also to the associated VR-segment. In the rest of this paper, a state vector refers to a snapshot of all the variables appearing in object segments, not including local variables defined in VR-segments, taken at one moment. Furthermore, the VR-segment requires the input state vector undestroyed until it no longer needs to examine it, while the successor object segment, by nature, continuously changes it into the up-to-date one. It is thus necessary to create a "copy" of the state vector current at the end of the execution of an object segment for exclusive use by the VR-processor executing the associated VR-segment. Here the process of creating a copy must cause no or little delay in executing object segments. The store space containing copies of state vectors must also be minimized. If either execution time or store space exceeds the tolerable limit, the objective of failure-tolerant parallel programming is defeated. This requires a new store management scheme substantially different from the previously developed ones. This point will become clearer when we propose one suitable scheme in the next section.

Third, if execution of VR-segments lags much behind execution of object segments, there will be accumulated a large number of unprocessed copies of state vectors. Thus when all the available store space runs out, the object processor must be suspended until the VR-processor catches up. In order to avoid this undesirable situation, execution of VR-segments must be speedy.

A MODEL ARCHITECTURE SUPPORTING FAILURE-TOLERANT PARALLEL PROGRAMMING

In this section we describe a system architecture oriented for efficient execution of failure-tolerant parallel programs. We call it a model architecture since it is of highly general nature and thus is specified at an abstract level. Yet it is expected that elaboration of the architecture into a specific working system will encounter no new logical problems of fundamental nature.

The store management scheme

Potential power of failure-tolerant parallel programs cannot be realized without accompanying the additional cost of the supporting system architecture. The additional cost is paid in the forms of both processor redundancy and store redundancy. Since the object processor runs concurrently with the VR-processor, memory conflicts must be carefully avoided. This rules out the feasibility of having a single state vector or its portion shared by both processors. Thus each processor owns a region of the store during execution of a failure-tolerant parallel program.

The region of the store used by the object processor is called the *main working store*, while the region of the store used by the VR-processor is called the *VR-store.* The VR-store contains copies of state vectors including the up-to-date one plus possibly more than one old one. This, of course, does not mean that the VR-store contains complete duplicates of several state vectors. Let S_i, S_{i+1}, ------, S_{i+j} denote a (chronological) sequence of state vectors that can be reconstructed from the content of the VR-store. Then the VR-store actually contains one complete copy of S_i (i.e., the oldest reconstructable one) and only the differences between pairs of adjacent state vectors in the sequence i.e. $S_{i+1}-S_i$, $S_{i+2}-S_{i+1}$, -------, $S_{i+j}-S_{i+j-1}$.

More specifically, as the object processor executes each object segment, it produces the *execution image* which consists of the values of variables assigned during execution of that object segment. If a variable is assigned several times during execution of the object segment, only the latest assigned value is contained in the execution image. The execution image produced on completion of an object segment represents the difference between the state vector current right before entry to the object segment and the up-to-date state vector (i.e. the one current on completion of the object segment). Each execution image is stored in a segment of the VR-store called a *VR-store-segment.* Each execution image is examined by the VR-processor to determine the acceptability of the result produced by execution of the object segment.

The execution image of an object segment consists of values of both local variables and non-local variables. Thus each VR-store-segment consists of two sections, one for local variables and the other for non-local variables. On entry to each object segment, memory space is allocated for the segment of the main working store containing the set of local variables defined within the object segment. At that time, the same size of memory space is also allocated for the section of the VR-store-segment containing (a copy of) the set of local variables. However, store space for non-local variables is not entirely duplicated. Instead, the section of the execution image containing non-local variables is written in the form of a table in which each entry consists of the logical address and the new value of a non-local variable. The idea is to take advantage of the useful property that in many cases, only a few of the non-local variables are modified by an object segment, while the total number of non-local variables defined may be very large. Thus the table representation leads to a highly compact form of the non-local variable section of the execution image.

As a simple example, consider a block-structured program augmented with VR-segments in Figure 4(a). Figure 4(b) shows snapshots of the main working store i.e. the stack used during execution of object segments in the program. In Figure 4(c) VR-store-segment 1 (or 2, 3, 4, 5) is used to contain the execution image of object segment O_1 (or O_2, O_3, O_4, O_5). Each VR-store-segment except VR-store-segment 1 consists of two sections, one for local variables and the other for a table holding newly assigned values of non-local variables and their logical addresses. Each VR-store-segment is created on entry of the object processor to the correspondent object segment.

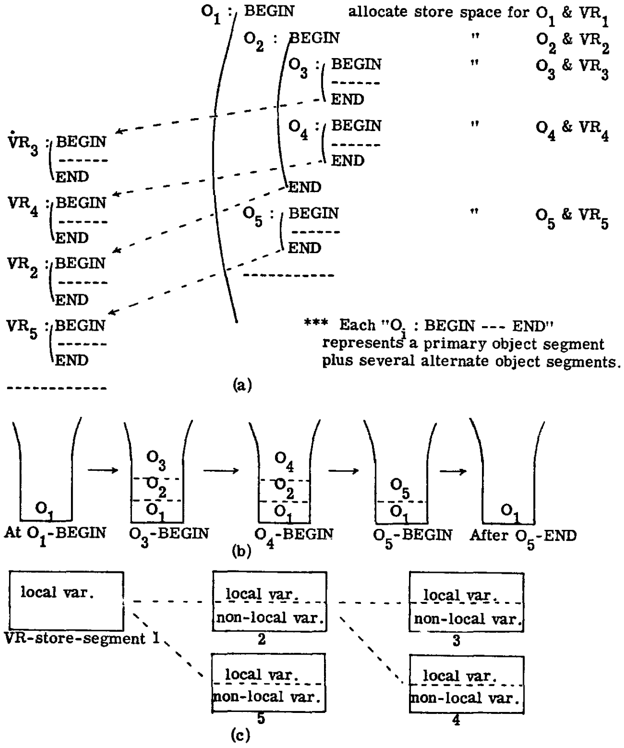

Figure 4—(a) A failure-tolerant parallel program (b) Snapshots of the mail working store during execution (c) A snapshot of the VR-store during execution

At the beginning of VR-segment VR_3, VR-store-segment 3 contains the execution image of object segment O_3 and the object processor has probably entered into O_4. The execution image in VR-store-segment 3 is examined by execution of VR_3. When it has been verified or judged to be acceptable, the local variable section is discarded and the non-local variable section is merged into VR-store-segment 2. If two different values of the same variable were contained in both VR-store-segments 3 and 2, the value in VR-store-segment 2 is the older one and replaced by the value in VR-store-segment 3. At the beginning of VR_4, VR-store-segment 3 does not exist. Then it is no longer possible to reconstruct the state vector which was current right before entry to O_3. There will be no need to reconstruct that state vector since VR_3 has been successfully completed.

Similarly, upon successful completion of VR_2, the values of non-local variables in VR-store-segment 2 are absorbed into VR-store-segment 1. At the beginning of VR_5, VR-store-segments 2, 3 and 4 do not exist. Then the state vector which was current at the initiation of O_2 can no longer be reconstructed.

Here one subtle problem is noteworthy. Consider a simple program in Figure 5(a). Since there are two object segments (thus two VR-segments), there are two VR-store-segments (1 and 3). The body of object segment 1 consists of the upper section, O_3 and the lower section. During execution of the upper section, the execution image will be stored in VR-store-segment 1. At the completion of O_3, VR-store-segment 3 contains the execution image and the VR-processor may start examining it. Then the object processor executes the lower section of O_1 and it stores the execution image into VR-store-segment 1 which already contains the execution image of the upper section. Some values in VR-store-segment 1 are now the ones assigned by execution of the upper section, while others are the ones assigned by execution of the lower section. When the VR-processor has successfully completed VR_3 and needs to merge the verified execution image into VR-store-segment 1, it is not possible to tell for each variable whether the value in VR-store-segment 1 is the older one than the one in VR-store-segment 3.

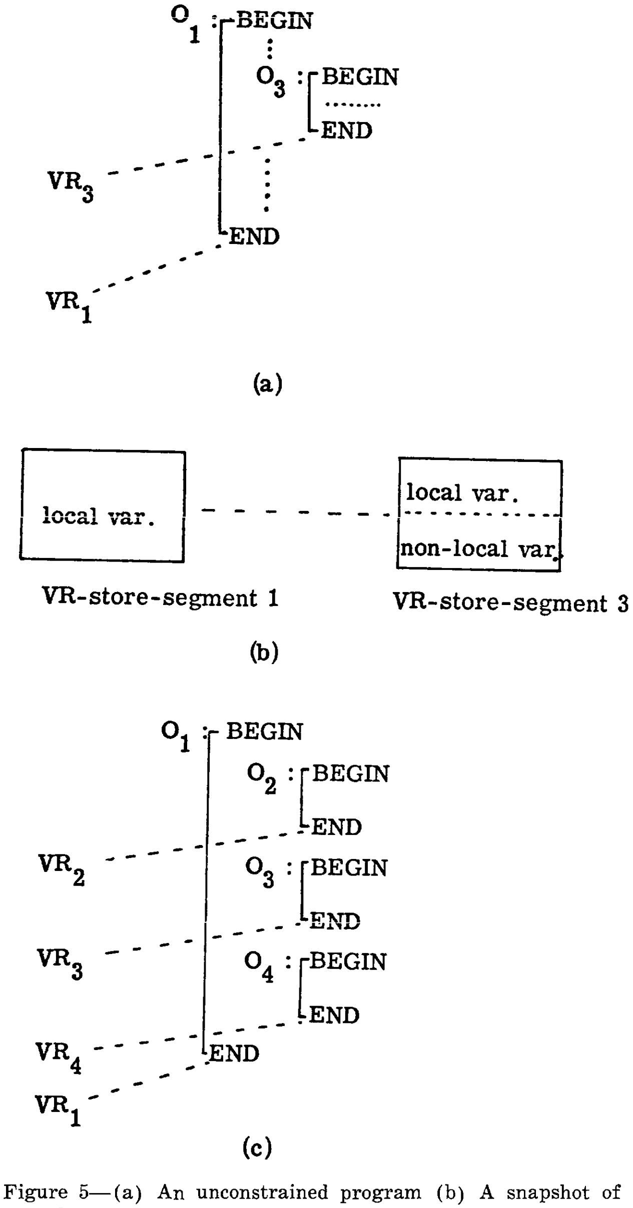

Figure 5—(a) An unconstrained program (b) A snapshot of the VR-store (c) An equivalent program satisfying the constraint

This problem can be resolved by imposing an additional constraint on program structuring. That is, the upper section and the lower section of O_1 in Figure 5(a) must be changed into O_2 and O_4, respectively, nested within O_1. This results in Figure 5(c). Then there will be additional VR-store-segments (2 and 4) created during execution, and the above problem disappears. Therefore, the constraint is that either each object segment contains no other object segments nested in it or its entire body must be composed of other object segments nested in it. This constraint is incorporated only for secure allocation of the VR-store. Thus the programmer is not required to prepare new VR-segments VR_2 and VR_4.

If there are no explicit VR-segments associated with some object segments, the system will insert dummy VR-segments. Or a variation of the above solution is to make the system responsible for restructuring unconstrained programs (e.g., Figure 5(a)) into the ones satisfying the constraint (e.g., Figure 5(c)), rather than imposing the constraint on the programmer. In any case, the solution does not appear to be a costly one.

The model system structure

The store management scheme described above will work (almost) perfectly if execution images can be created in the VR-store without causing any delay in execution of object segments. As far as the local variable section of the VR-store is concerned, this condition can be met without employing unconventional hardware components. Since the same size of the store-segment for local variables is allocated in both the main working store and the VR-store, the only requirement is to set proper base addresses for both store-segments and, for each assignment, write the same value in two locations of the same relative address, one in the main working store and the other in the VR-store.

However, the situation is different in creating the non-local variable section of the execution image. As described before, the non-local variable section is written in the form of a table. Thus whenever a non-local variable is assigned a new value during execution of an object segment, the value is written into the correspondent location in the main working store and at the same time, the value together with the logical address is written into an entry of a table in the VR-store.

If the assignment to a non-local variable is the first to have been made to that variable within the current object segment, then the new value and the logical address of that variable are written into the next available (empty) entry of the table in the VR-store. If it is not the first, there are two choices. One is to write in the same manner as above i.e. write into a new entry of the table. The other is to locate the entry of the table containing the previous value and the logical address of the non-local variable and then replace the previous value with the newly assigned one. After all, only the latest assigned values of variables need to be contained in the execution image. The former approach leads to the larger table-size than the one resulting from the latter approach. In addition, when or before the VR-processor executes the VR-segment to validate the table, it must discard the entry (of the table) containing the older value of each variable for which there is another entry containing the later assigned value. The latter approach leads to the compact table but it requires a special hardware support in order not to degrade the performance of the object processor. The special hardware requirement can be met by incorporation of the *content-addressable* (*i.e., associative*) *memory module* whose access time closely matches the one of the location-addressed memory module used in the system. In addition, incorporation of such a memory module significantly enhances the performance of the VR-processor in executing VR-segments. In view of the decreasing trend of the hardware cost and the performance advantage, the latter approach is considered favorable.

It is also necessary to attach a tag to the logical address of each variable which indicates whether the variable is a local one or a non-local one.

The structure of the model system in which all the above decisions are reflected, is depicted in Figure 6. The model system contains multiple central processors (CP's) and the memory subsystem named the *duplex memory*.

Each CP may function as an object processor, a VR-processor, a supervisory processor or a spare at one time. Employment of general purpose CP's is motivated mainly by the consideration of the flexibility in system reconfiguration. Yet this is not an absolute necessity and can be compromised for employment of processors fixed for a specific function if other factors such as cost and performance dictate so.

The duplex memory contains two types of memory modules, location-addressed memory modules and content-addressable memory modules. Location-addressed memory modules are further divided into two sets. One set of modules provides the main working store for the object processor. The other set, together with the set of content-addressable memory modules, provides the VR-store. Thus the local variable section of each execution image is contained in location-addressed memory modules, while the non-local variable section is contained in content-addressable memory modules. That is, whenever the object processor issues a "write" command, the value is written into two locations simultaneously, one in the main working store and the other in the VR-store. The latter location is in a location-addressed memory module if the tag attached to its logical address indicates "local" or in a content-addressable memory module if the tag indicates "non-local."

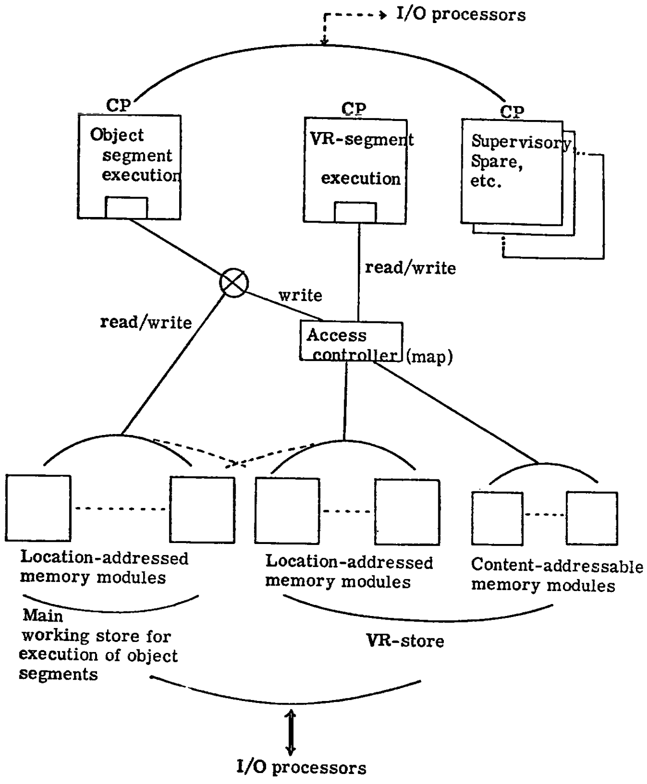

Figure 6—A system architecture based on multiple CP's and the duplex memory

The VR-processor never accesses the main working store except during recovery. The object processor never reads from the VR-store. It is a natural property of this duplex memory that the partition of location-addressed memory modules consisting of two disjoint sets, (one providing the main working store and the other providing the local variable section of the VR-store) may change dynamically.

There is another important reason for employing content-addressable memory modules. Execution of a VR-segment generally involves not only examination of the correspondent execution image but also references to other *ancestor* VR-store-segments i.e., ones created prior to the VR-store-segment containing the correspondent execution image. For instance, when the VR-processor executes VR-segment VR_4, in Figure 4, it examines the content of the correspondent VR-store-segment 4 and it may access ancestor VR-store-segments 1 and 2. References to ancestor VR-store-segments are for obtaining the previous values of non-local variables (i.e., variables non-local to the object segment associated with the VR-segment currently in execution).

It is frequently required for each non-local variable to obtain the latest assigned value among all of its values contained in ancestor VR-store-segments. The desired value may exist in the local variable section of an ancestor VR-store-segment. In this case, the variable is defined within the object segment which created the ancestor VR-store-segment. The desired location (which is in a location-addressed memory module) is exactly the one to which the logical address of the variable is mapped, and thus it can be directly accessed.

On the other hand, the desired value may exist in the non-local variable section of an ancestor VR-store-segment. For instance, assume in Figure 4 that variable Z is defined in object segment O_1, initialized with "100," assigned "200" by execution of O_3 and assigned "300" by execution of O_4. Let us also assume that the VR-processor is currently executing VR_4 and it needs to obtain the value of Z assigned the latest before the object processor entered into O_4. The desired value is "200" and it is contained in the non-local variable section of VR-store-segment 2 since VR_3 has already been successfully completed. The non-local variable section of VR-store-segment 2 needs to be searched in order to get the desired value "200." The problem here is a little complex since if Z has not been assigned a value during execution of O_3, the desired value is "100" contained in the local variable section of VR-store-segment 1. It is not known in advance which VR-store-segment, between 1 and 2, contains the desired value. It is thus necessary to check VR-store-segment 2 first and if its non-local variable section does not contain Z, then the desired value is read from the location, in the local variable section of VR-store-segment 1, to which the logical address of Z is mapped.

In general, it is necessary to search ancestor VR-store-segments in the increasing order of their ages, until either an ancestor containing the variable in its non-local variable section is found or the ancestor addressed by a portion of the logical addresses of the variable is reached. Here employment of content-addressable memory modules for non-local variable sections of execution images is the key to the high speed of search. It enables simultaneous examination of non-local variable sections of all the "ancestor VR-store-segments" which are "descendants" of the one containing the variable in its local variable section. When the VR-processor issues a command for fetching the latest assigned value of a non-local variable among its values contained in ancestor VR-store-segments, one location-addressed memory module and possibly several content-addressable memory modules are simultaneously accessed. The location-addressed memory module is the one addressed by a portion of the logical address of the variable. The content-addressable memory modules are the ones containing the non-local variable sections of those ancestor VR-store-segments which are descendants of the one whose local variable section is mapped to the above location-addressed memory module. Selection of the latest assigned value among all the values of the variable retrieved from those memory modules is also a function of the duplex memory. With this duplex memory, the VR-processor can read or update any value contained in the VR-store with the amount of time close to one content-addressable memory cycle.

Resetting the system state when an execution image is evaluated to be unacceptable, is also speedy with this duplex memory. It is because the resetting process involves basically fetching the previous value of each non-local variable which has been assigned another value since the object processor entered into the object segment whose execution image turned out to be unacceptable, and then storing it into the location of the variable in the main working store. Each non-local variable which needs to be restored in the main working store to its previous value is identified by examining the non-local variable sections of the execution images produced since the object processor entered into the object segment whose execution image was rejected.

Local variable sections of VR-store-segments are mapped to location-addressed memory modules in the same manner as the main working store is mapped to location-addressed memory modules. For some VR-segments, each of their non-local variable sections may be mapped to an independent content-addressable memory module. For others, their non-local variable sections may co-exist inside the common content-addressable memory module, provided some form of an identification code is assigned to each section. The high speed requirement limits the size of each content-addressable memory module to a small one. It may sometimes be necessary to use more than one content-addressable memory module to hold the non-local variable section of a VR-store-segment.

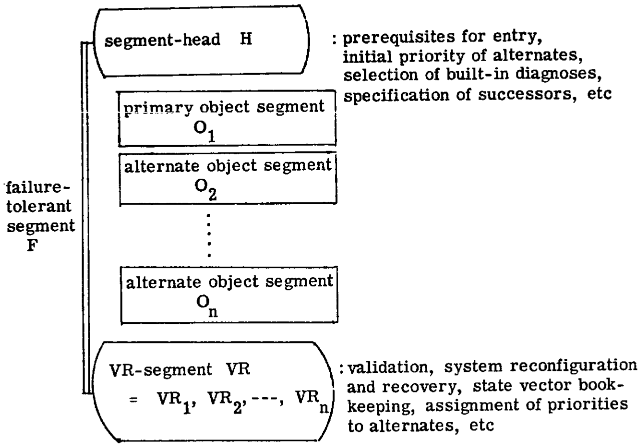
It is believed that this architecture satisfactorily meets all the requirements mentioned before. Creating a copy of a state vector in this system does not incur any delay in processing object segments. The memory interference between the CP's executing object segments and VR-segments is absent or negligible. Employment of multiple content-addressable memory modules is believed to be an effective means of achieving the goals of low average access time and high store utilization. However, successful implementation of a system requires careful selection of design parameters concerning memory management.

AREAS OF EXTENSION AND FURTHER RESEARCH

The preceding sections dealt with the concept of failure-tolerant parallel programming and effective solutions to most fundamental problems involved in realizing its potential power. The model architecture devised for efficient execution of failure-tolerant parallel programs was specified at a highly abstract level in order to preserve simplicity and generality. It incorporated a minimal amount of facility. Naturally, the model architecture can be expanded in many directions to possess additional capabilities by incorporating various proven concepts and schemes. In addition, in order to put failure-tolerant parallel programming in general use, various program design and engineering tools need to be developed. Among numerous desirable extensions and research problems, only a few of the representative ones are listed below.

First, development of a language supporting failure-tolerant parallel programming is an immediate requirement. Such a language should contain more facilities for control structuring and data specification than the ones in conventional programming languages. No useful principles employed in other failure-tolerant program structuring schemes such as recovery block structuring,[14] need to be rejected in structuring failure-tolerant parallel programs. In view of the strong relationship between each object segment and the associated VR-segment, it is almost an indispensable requirement to put each pair of segments in a compartment in the program text. Such a compartment is called a *failure-tolerant segment.* More specifically, each VR-segment is directly dependent upon only one object segment in a failure-tolerant parallel program. Furthermore, the dependency structure among VR-segments is always the same as the dependency structure among object segments. The latter dictates the former. Thus the dependency among VR-segments as well as the dependency of a VR-segment on the associated object segment, need not be explicitly specified and should become a part of the definition of the failure-tolerant segment.

On the other hand, each object segment may be dependent on zero or more VR-segments which belong to other failure-tolerant segments. This type of dependency needs to be explicitly specified. This and other considerations mentioned in the previous section on desirable extensions of the state-of-art in failure-tolerant programming, led to the formulation of the model of the failure-tolerant segment depicted in Figure 7.



segment-head H
: prerequisites for entry, initial priority of alternates, selection of built-in diagnoses, specification of successors, etc
primary object segment O_1
alternate object segment O_2
failure-tolerant segment F
alternate object segment O_n
VR-segment VR $= VR_1, VR_2, ---, VR_n$
: validation, system reconfiguration and recovery, state vector book-keeping, assignment of priorities to alternates, etc

Figure 7—A structural model of a failure-tolerant segment

The model is a generalization of the model of the recovery block depicted in Figure 1. It consists of the *segment-head,* the primary object segment, several alternate object segments and the VR-segment. The segment-head specifies the prerequisite condition for entry into the (failure-tolerant) segment e.g., dependency on the completion of VR-segments belonging to other failure-tolerant segments. It specifies the *successor* failure-tolerant segments i.e. the ones whose initiation is dependent upon successful completion of the VR-segment. It also contains the declaration of the initial "execution priorities" of alternate object segments. It may also specify the types of abnormal conditions which may be recognized by the system during execution of object segments and the actions to be taken on occurrence of each condition e.g., "enter into the VR-segment," "record the occurrence and continue," etc. The VR-segment specifies the procedures of validation, VR-store management, and recovery including system reconfiguration and assignment of execution priorities to alternate object segments. The primary or alternate object segments can contain, nested within themselves, further failure-tolerant segments. However, the structuring rule illustrated in Figure 5 should become a part of the definition of the failure-tolerant segment.

Therefore, programming of the segment-head requires some special language primitives including JOIN-like primitive[9] used for specifying the prerequisite condition for entry, FORK-like primitive[9] for specifying the successors, ones for specifying types of abnormal conditions and appropriate treatments, etc. Programming of the VR-segment also requires some special language primitives such as ones for referring to the old values of variables, ones for system reconfiguration, etc. Development of a language containing all the facilities mentioned above is urgent.

Second, if parallelism among object segments is to be exploited, the model architecture and the program structuring scheme described so far needs to be generalized accordingly. Such a generalization is expected to be a gigantic task requiring a great deal of research.

Third, it is often necessary to periodically save verified state vectors into the file store either as the spontaneous action of the system or as controlled by the failure-tolerant program. Incorporation of an efficient filing capability into the model architecture is an essential requirement.

Fourth, in view of the high cost of a sizable content-addressable memory, it seems both necessary and desirable to use location-addressed modules as back-up memory when a certain program requires more space than that provided by available content-addressable modules. That is, additional content-addressable store space can be simulated on the basis of location-addressed modules and store structuring techniques such as hash-coding. Incorporation of the virtual memory into the model architecture will also be an interesting research subject.

CONCLUSION

The concept of failure-tolerant parallel programming was originated with the objective of utilizing extensive validation and recovery facilities at run-time without disturbing main-stream computation. The model architecture presented is believed to be a satisfactory solution to the efficient execution of failure-tolerant parallel programs. As further researches on the subjects mentioned in the preceding section progress, more insights will hopefully be gained into the potential power of failure-tolerant parallel programming and the cost-effective implementation of systems based on the model architecture.

Strategic planning for MIS—A conceptual framework

by EPHRAIM R. McLEAN
University of California
Los Angeles, California

and

JOHN V. SODEN
McKinsey & Company, Inc.
Los Angeles, California

ABSTRACT

Increasingly, Management Information Services (MIS) divisions within organizations are becoming more centrally involved in the mainstream of corporate activities. MIS projects are becoming more complex and expensive; are affecting more aspects of the business; and are taking longer to design, develop, and install. For these reasons, effective planning for the MIS function is felt to be of paramount importance.

In recognition of this, a conference was held on Planning for MIS in 1974, jointly sponsored by McKinsey & Company, Inc., and the Graduate School of Management at the University of California, Los Angeles (UCLA). Attending were MIS executives and practitioners from both the public and private sectors. During the two days of discussions, a number of conclusions were reached which are detailed in this paper.

Building upon this conference, and on other work of the authors, the balance of the paper is devoted to presenting a framework for strategic planning for MIS. Definitions of key terms are included, as well as a discussion of some common planning pitfalls. Finally, a list of questions is given, designed to aid the MIS executive in carrying out his own organization's planning effort.

INTRODUCTION

Mark Twain's remark about the weather might well be applied to MIS planning: "Everyone talks about it, but nobody does anything about it." The importance of planning for improved managerial effectiveness is widely endorsed by practitioners and academics alike. In fact, given the accelerating pace of change in almost every aspect of the economy, planning is frequently touted as the key to success—if not to survival. But as with the weather, the gap between interest and achievement in the planning area is great. Faced with the pressing problems of day-to-day operations, many MIS executives have neither the time nor the inclination to invest in planning for the longer term. However, there are a number of major organizations here in the United States that *are* doing something about planning; in particular, planning for Management Information Systems (MIS). This paper is about such efforts.

The term, "MIS," standing for either management information *systems* or management information *services,* is being used increasingly throughout the world to refer to that cluster of activities which surround the computer and its supporting personnel. However, it is more than just the data processing department; for it includes the planning, analysis, and design activities—as well as the operational functions—which are necessary for effective computer-based information systems. For this reason, many MIS groups go under the broader title of "Management Services," incorporating not only the computer department but also operations research and management science staff specialists. In this paper, we will use "MIS" to reflect this broader set of activities—computer systems, management services, and indeed the organization itself which provides the foregoing.

In addressing the topic of planning for this group of activities, it is important to establish a proper perspective. As will be discussed later, planning can be looked at from both its time horizon and its focus. The former refers to whether it is short term (one to two years), medium term (two to five years), or long term (five years or more); and the latter, to whether it is focusing on strategic, managerial, or operational concerns. It is our intention here to concentrate on the strategic planning issues.

The reason for this choice is simple. As the MIS function assumes a more central role within organizations, it becomes vital that this role be properly planned for, so that it will be congruent with that of the overall organization. No longer is it feasible—if it ever were—to have systems for their own sake. This is a luxury no organization can afford. And if MIS is to be made responsive to larger corporate objectives, strategic long-range planning is essential.

THE McKINSEY-UCLA CONFERENCE

In recognition of the importance of this issue, an invitational conference was held in 1974 at the University of California, Los Angeles (UCLA), sponsored by McKinsey & Company, Inc., the management consulting firm, and the UCLA Graduate School of Management. This working conference was chaired by the authors of this paper with the assistance of Professor George A. Steiner of UCLA. Some two dozen MIS executives from major private and public sector organizations participated in the two-day conference. A survey was administered to them, focusing on the objectives, development process, and end products of their individual long-range planning efforts.[1] Also, these executives participated in extensive discussions regarding various aspects of their own planning experience as well as preparing summaries of the long-range planning activities of their own organizations.*

The theme of the conference was focused on those aspects of planning that had to do with the central issues of the information services organization itself, as opposed to the planning for individual information systems projects. The reasons for this focus were twofold. First, we wanted the conference to have a broad managerial orientation rather than a technical one. In this way, we believed that the results would be of interest not only to MIS managers and practitioners but also to general corporate executives as well.

The second reason for our choice was the relatively virgin nature of the MIS planning field. Had we chosen to look at the planning problems associated with the design and installation of specific information systems, we would have been addressing an area in which much work has already been done, with articles and books on project and systems management in abundance. However, the literature on strategic and long-range planning for information services is fairly sparse.**

In order to obtain a good cross section of various approaches to planning, the conference participants were chosen to represent a wide variety of private companies, as well as government and education enterprises at the local, state, and federal levels. The average participant represented an organization that had annual revenues or total budget expenses greater than $1 billion, had an annual MIS budget of over $15 million, and had been carrying out a formal MIS long-range planning effort for more than three years. These participants, therefore, represented relatively large, mature MIS organizations, experienced in planning for the information systems effort.

The following are the major points which emerged from the conference discussions.

1. There is a growing need for more formal long-range information systems planning as systems become more complex, require longer to develop, involve multiple functions or departments, cost more money, and have greater competitive impact.
2. The benefits from long-range planning—improved short-term decision making, enhanced communication with both top management and user groups, and a firmer grasp on resource commitments—generally outweigh the costs of the undertaking.
3. Formal planning approaches range from the "controlled reaction" tactics of formally evaluating and ranking known project ideas, to the strategic "top-down" scanning for high-potential application opportunities within the context of the overall organization's strategic plan.
4. The selection of a particular planning approach requires a careful balancing of factors such as the role and charter of the MIS organization, its degree of maturity, and the sophistication of the overall company and individual "user" executives.
5. Success in planning for information systems hinges on three factors:
    a. The previous credibility of the MIS group in managing new project development and ongoing computer operations.
    b. The maturity of the overall organization's management processes, particularly with regards to conducting business planning and in making capital allocation decisions.
    c. The choice of a particular MIS planning approach which suits the needs and constraints of the particular organization at that point in time.
6. In those organizations most advanced in their planning, the MIS executives have become an integral part of the management team of their organization; and, in these companies, MIS strategies have a major impact on, and a corresponding interrelationship with, the long-range business plans of the enterprise. In other words, MIS planning is "interactive," not "reactive."
7. If an MIS organization is relatively underdeveloped in terms of standards, computer operations effectiveness, individual project management capability, and the like, it would be well advised to concentrate on the short term, severely limiting concern for the long term until the near-term situation has been substantially improved.
8. Good formal planning must complement, but can-

* These papers, together with other chapters on MIS planning, are to be published shortly.[2]

** For a few noteworthy exceptions, see References 3 through 12.

not replace, the political sensitivity, entrepreneurship, conceptual contribution, and basic business leadership required of the successful MIS executive.

STRATEGIC AND LONG-RANGE PLANNING

In addition to the preceding findings, another item came to light which is worthy of mention. Because of the multi-year planning horizon of most computer-related projects, it is easy to equate long-range planning with any planning effort which has a horizon greater than one year. And thus, fundamental questions such as "Where is the information services organization going?" and "How is it contributing to the overall success of the enterprise?" become confused with "What project should be started next?" and "How can the continued development of existing projects be more effectively coordinated?"

Unfortunately, the term "Long-Range Planning"—which was the title of the conference—does little to sharpen this distinction. For some conference participants it meant focusing on the former questions; for others, on the latter ones. This dual interpretation became evident from both the conference discussions and the papers which the participants prepared. It can be argued, of course, that both uses of the term are equally valid and equally important for the success of the information services organization. Certainly, if the ongoing operations and project development is not effectively planned and managed, it does little good to speculate on where the organization will be five to seven years in the future. More than likely, it will be an organization with a new cast of characters!

However, as discussed earlier, we wanted the conference to focus on the central issues of setting organizational objectives and deciding upon appropriate strategies and policies. Thus, it seems in retrospect that "Strategic Planning" would have been a more appropriate title than "Long-Range Planning."

A STRATEGIC PLANNING FRAMEWORK

Based upon the discussions of the conference, as well as on other research and on the industrial and governmental experience of the authors, an MIS strategic planning framework has been devised (see Figure 1). The left half of the diagram portrays the tasks needed to arrive at the MIS objectives, strategies, and policies. The right half notes the tasks necessary to accomplish

Figure 1—MIS strategic planning framework

the more detailed planning efforts within the long-range, medium-range, and short-range time frames. First, however, it is necessary that we define what we mean by "strategic planning."

Strategic MIS planning, like Robert Anthony's definition of corporate strategic planning,[13] is the process of deciding on objectives for the MIS organization; on changes in these objectives; on the resources used to obtain these objectives; and on the policies that are to govern the acquisition, use, and disposition of these resources. Strategic MIS planning typically occurs at infrequent intervals and is often triggered by the need for an enterprise to resolve a particularly substantive issue or issues that involves the MIS entity.

Strategic planning tasks

Set the MIS mission

The first task in strategic planning, as shown in Figure 1, is to set the MIS mission; that is, to define the charter of the information services organization. This broad definition of organizational role must naturally be done within the mission and purpose of the overall organization of which MIS is a part. Sometimes the MIS organization receives this mission as given; other times it is arrived at through mutual discussion with top management.

Assess the MIS environment

Once this mission is set, the next task is to assess the MIS environment—to consider the opportunities and risks which are present now and might be present in the future. This would include consideration of such things as:

1. The objectives, strategies, policies, and plans of the host organization.
2. The competitive position of the overall organization.
3. The user groups within the organization—their needs, their current use of MIS resources, and their perceptions of the capability of the MIS organization.
4. The present and emerging technology for information processing.
5. The ability of the MIS organization to effect change.

Set the MIS objectives and develop the strategies

With the MIS mission established and a thorough appraisal made of the environment, it next becomes necessary to set the MIS objectives. There are the desired results that are to be achieved by the MIS organization. Closely linked with the statement of objectives is the development of the strategies or broad courses of action that will be needed in order to achieve these objectives. Thus, objectives and strategies are intimately interwoven; consideration of one invariably involves consideration of the other. These objectives, and their accompanying strategies, typically deal with the following types of items:

1. The fit of the MIS objectives within the overall organizational objectives.
2. The growth, continuity, and level of contribution of the MIS function within the organization.
3. The classes and types of systems and services to be offered.
4. The role of users in systems development efforts.
5. The types of technology to be employed.
6. The type of management and staff to be developed.
7. The posture of the MIS organization vis-à-vis the user, the host organization, the competitive environment, and the professional milieu.

Define the MIS policies

The determination of policies is a critical aspect of strategic planning. Policies are the guidelines to be used in carrying out the strategy. They are specific statements that cover such things as the internal organizational structure of the MIS division; the criteria to be used in deciding upon overall funding levels and resource allocations; the use of steering committees; the procedures to be used in selecting vendors, buying outside services, and/or selling services to outside users; the employment of a data base management scheme; and so forth.

Setting the policy for how the company is going to decide how much to spend for MIS is seldom directly addressed, and it is an area of particular frustration for many companies. Sometimes a mixture of techniques is decided upon as a means of arriving at the MIS budget. These include, for example, a fixed percent of sales or assets; comparable expenditures of similar companies, adjusted for size and profitability; whatever the major company profit centers will agree to pay for; base amounts, plus discretionary increases for high-potential projects; and/or the amount spent last year plus adjustments for inflation. All too often, a lack of policy in this area leads the MIS group to concentrate its attention on justifying the acquisition of major new computer equipment without giving much concern as to underlying reasons for such equipment.

Policies with regard to the allocation of scarce MIS resources are particularly critical since they provide the guidelines by which the portfolio of current and future projects will be selected, funded, and managed. Unfortunately, in many companies where these resource allocation policies have not been well established, MIS management has little incentive to perform disciplined economic evaluations of new project proposals, and general corporate policies are often not precise enough to be useful in evaluating these proposed projects. Thus, in many instances, the implicit resource allocation policy frequently becomes one of allowing the MIS division the self-indulgence of selecting projects primarily based on its interest in utilizing the latest in information processing technology.

Although such policy setting activity is admittedly difficult, it is essential that it be done in order that subsequent, more detailed planning efforts may have a better chance of success.

Planning to implement MIS strategies

As shown in Figure 2, the plans which are needed to implement MIS strategies can be of several types, each of which has the goal of translating the MIS objectives and strategies into increasingly more detailed and specific plans.

Long-range MIS planning deals with meeting the *future* MIS needs of the host organization. It is largely conceptual in character and can have a horizon of from five to seven years or longer. It does not deal with specific projects or even groups of projects, but with emerging types of user needs and approaches that might be useful in addressing these needs. It must also plan for the organizational philosophy to guide the MIS organization of the future and for the skills and capabilities that will be needed in developing and managing future systems. An example of this type of plan is the information systems design architectures that are being developed within a number of organizations.

Figure 2—Implementing MIS strategies

Medium-range MIS planning is what many organizations call their long-range plan. It is the planning that is necessary to meet the host organization's *present* MIS needs, projected two or five years into the future. It is a portfolio of projects, ranked by importance, coupled with projections for their implementation. It also involves the planning for hardware and software acquisitions and conversions, and for the staffing of multi-year projects and development activities.

Short-range MIS planning is generally equivalent to the MIS annual plan. It involves detailed budget preparation, manpower scheduling, and the creation of timetables for individual projects. It also often includes quantitative statements regarding performance targets for the MIS group. It is relatively operational in character.

The choice of a particular approach or set of approaches to MIS planning, assuming that the strategic planning has been properly done, is particularly important. Many organizations falter in that they attempt to carry out all three types of MIS planning simultaneously, before mastering the intricacies of the short-term plans necessary for the effective management of present activities.

Ideally, the MIS strategy should be translated into current-day decisions by sequentially developing first the long-range conceptual plan, then the medium-range managerial plan, and finally, the short-range operational plan. However, those companies that have very short-term MIS strategic objectives, such as to build credibility with users or to "get away from the crocodiles," should focus first on simple operational plans that include very specific quantitative performance measures for effectiveness and efficiency. Then, once the MIS organization has mastered its short-term challenges, it can extend its planning horizon.

We believe that a majority of companies would find a major investment in long-range conceptual planning for MIS to be of little value, for it appears that most enterprises have not yet mastered medium- and short-range planning. However, since short-range operational planning is relatively straightforward, we will focus our remaining discussion on medium-range planning. The development of medium-range MIS plans generally involves the following activities.

1. *Identify potential projects.* Fill a "hopper of opportunity" with ideas for projects relating to new computer system development efforts, enhancements to existing computer services, up-

grading of ongoing MIS activities, and strengthening of the MIS organization and personnel.

2. *Evaluate and rank projects by priority.* Filter the contents of this hopper of opportunity by using the resource allocation policies and overall MIS objectives previously established, so as both to select those projects that will be undertaken next and to identify the types of projects that might be undertaken in future years.
3. *Translate projects into time-phased profiles of activities, resource requirements, and action steps.* Define the means, requirements, and plans of action for implementing the selected MIS projects.

Identifying potential projects

The first step in the development of an information systems plan is to identify those information system projects that have high potential for the organization. There is a wide variety of approaches that can be used to scan for these new opportunities for system development. The following are some of the most common.

1. *The isolated approach,* where the MIS organization reacts to environmental factors by modifying existing systems to meet new legal requirements; proposes retrofits to existing computer systems to enhance their cost and/or operating characteristics; operates on the basis of its own "intuition" regarding new opportunities; and/or synthesizes a list of requests for changes to existing systems already submitted by user managers.
2. *The emulative approach,* where the MIS organization picks up ideas for new projects from the successful computer systems of other companies, similar in size or industry group.
3. *The bottom-up approach,* in which MIS systems analysts interview either selected user executives or, in certain company situations, all major user groups so as to identify the major decision areas, possible information gaps, and operating inefficiencies which could be improved through the use of better computer systems.
4. *The reactive approach,* in which the MIS organization simply responds to decisions made by either the chief executive officer or some higher level corporate executive as to which are the most appropriate new computer system projects for the MIS division to undertake.
5. *The derived top-down approach,* used when the host organization has no overall strategy, involves a detailed analysis of the company in order to hypothesize an overall corporate business strategy from which new high-priority computer system ideas can be selectively developed. These ideas are then further refined through interviews and appropriate systems analysis.
6. *The top-down approach,* in which the MIS organization develops new services as an outgrowth of the existing, substantive company business plan.
7. *The interactive approach,* in which the MIS organization interacts with other parts of the business during the normal company planning cycle so that the identification of MIS project ideas, and assessment of their likely business impact, are integrated into the planning activities of management throughout the company.

The important task here for the MIS executive is to select the particular approach or combination of approaches that best fits the company's unique needs at that point in time.

Project selection

Invariably, there comes a point in this planning process when the collected ideas for new projects must be sorted out so that the highest priority applications or services can be undertaken in the near term. A problem of many planning efforts is the failure to perceive, in advance, the need to establish a means for conducting such a screening. Since the MIS effort is—or should be—a service function to the entire enterprise, this sorting out of priorities is difficult, even when well-chosen resource allocation policies have been established. A simple chart to aid in carrying out this ranking is shown in Figure 3, where the project ideas are listed, and the previously selected resource allocation criteria are applied to each project to the maximum extent possible. The major challenge here is to obtain a summary evaluation of these projects without entering into a detailed project feasibility study, since the primary objective of this effort is to decide just which projects should initially be allocated feasibility study funds.

To make these difficult priority rankings, many corporations have established computer applications steering committees in which judgments regarding these alternate investments in new systems are made on an ongoing basis by selected members of top management. In this way, a continuing consensus regarding the need for new system development activities is obtained; and, in cases where trade-offs and compromises must be made, the affected individuals and user organizations have an active voice in the decisions. Unfortunately, many of these committees have not been as successful in carrying out their prescribed role as they might have been. The overriding problem with ineffectual applications steering committees is that they are unable to resolve the many competing demands for limited MIS resources. The committee either becomes a "rubber stamp" for the recommendations of the MIS director or a "buck passer," deferring any hard choices to a higher level of management. More often than not,

				RESOURCE ALLOCATION CRITERIA							
APPLICATION/ SERVICE IDENTITY	BRIEF DESCRIPTION	OPERATING EXPENSES ESTIMATE	OPERATING BENEFITS ESTIMATE	USER SPONSOR	DEVELOPMENT COST ESTIMATE	DEVELOPMENT TIMESPAN ESTIMATE	ROI ESTIMATE	RISK ASSESSMENT	CORPORATE STRATEGY FIT	MIS ARCHITECTURE FIT	OTHER CONSIDERATIONS
1. 2. 3.				(FUNDED, ALREADY UNDERTAKEN)							
1. 2. 3.				(FUNDED; NOT YET UNDERTAKEN)							
1. 2. 3.				(NOT FUNDED, UNDER CONSIDERATION)							

Figure 3—Sample project portfolio overview

this failure is due to the absence of a clearcut resource allocation policy, one which provides unambiguous guidelines for choosing among projects—guidelines which are firmly rooted in business considerations, not technical ones.

Develop action plans

If an appropriate approach to scanning and ranking information system development projects is taken, the third step in planning—the development of associated resources and activity schedules—is somewhat more mechanical in nature, although vital in reaching such important decisions as computer equipment selection. Generally, these project schedules are quite precise for the near term and somewhat more general for future years. This is as it should be, since the primary purpose of the planning effort is to make near-term decisions that are consistent with a longer term direction, not to decide on specific computer system projects that are to be undertaken three or four years in the future.

FEEDBACK

It is important to recognize that the planning process and resulting decisions are dynamic, not static. As the bottom part of Figures 1 and 2 indicate, there is an important feedback loop, one which measures progress against plans, and ultimately, against the objectives and strategies themselves. For nothing should be felt to be fixed or "cast in concrete." Many an MIS executive has wailed "But this isn't the way we planned things last year" forgetting that a plan is not a forecast *of* the future, but a way of being better prepared *for* the future. Plans and strategies should be flexible and able to be modified and changed as circumstances dictate.

CONCLUSION

Although conceptual frameworks, such as the one that we have presented here in this paper, can be helpful to the MIS executive, it can never replace the common sense and good judgment that an experienced manager must possess. The first step that such a manager must take in reassessing the MIS planning efforts of his own organization is to recognize that the MIS function is not an end in itself but a part—and hopefully a vital part—of the larger objectives and activities of the overall enterprise. Then, in considering how to launch a new and/or revised planning effort, the MIS executive should seek to answer the following questions:

1. Are we reasonably adept at estimating costs, benefits, and risks of proposed new computer projects?
2. In general, do our MIS project postimplementation audits indicate that the MIS organization was able to develop projects within cost and timetable estimates, and that users were able to achieve the benefits they committed to at the outset of the project?
3. Is the MIS function now operating above average from an effectiveness and efficiency standpoint?
4. What approaches are we taking to scan for new computer investment opportunities within the organization?
5. Do we have agreed-upon documented objectives, broad strategies, and policies for the MIS function?
6. Are we making sure that the MIS plan will focus on the company's—rather than the MIS division's—use of the computer?
7. Are the MIS strategy and plans integrated with our overall corporate strategy and plans?

8. What are the respective roles of top management, the MIS division, and the users groups within our organization in the launching and conduct of the planning effort?
9. What will be the end product of this planning effort?
10. Are we monitoring the planning process itself so as to be in a position to improve our efforts the next time around?

The answers to these questions should provide not only a profile of the current status of MIS planning within an organization; but where the responses are negative—or vague—they should point the way to where beneficial progress can best be made.

The economics of software quality assurance

by DAVID S. ALBERTS
The Mitre Corporation
McLean, Virginia

ABSTRACT

This paper presents an examination into the economics of software quality assurance. An analysis of the software life-cycle is performed to determine where in the cycle the application of quality assurance techniques would be most beneficial. The number and types of errors occurring at various phases of the software life-cycle are estimated. A variety of approaches in increasing software quality (including Structured Programming, Top Down Design, Programmer Management Techniques and Automated Tools) are reviewed and their potential impact on quality and costs are examined.

INTRODUCTION

Current realities of large scale computer systems have provided the impetus to undertake this examination into the need for and potential of a quality assurance program. Proponents of quality assurance claim that significant savings in both cost and time can be achieved in addition to improved system performance if a quality assurance program is implemented. The purpose of this paper is to examine these claims by addressing the economics of software quality assurance. Software rather than hardware is the subject of the analysis since the costs of software have far outstripped the costs of hardware and the trend seems to be continuing in this direction (Figure 1).

The stakes involved are high. Estimates of recent Air Force annual expenditures on software are over $1 Billion.[56] WWMCCS alone was estimated to involve $¾ Billion for software (about 10 times its hardware costs),[2] while major software systems also run into hundreds of millions of dollars (IBM OS/360 $200M,[11] SAGE $250M[11] and NASA manned space program $1B[12]). Indirect costs must be added to these huge sums and are by no means trivial in of themselves. For example, software delays often cause delays in reaching the operational phase of a system's life. A 6-month delay (considered almost on-time) translates into a $100M loss of services, based upon a projected 7 year operational life and a $1.4 billion project.

Figure 1—Importance of controlling the cost/effectiveness of S/W

The actions which could be undertaken under the umbrella of a quality assurance plan are quite diverse; so diverse that it is difficult to separate these actions from project management. However, quality assurance is only one aspect of project management. First this analysis addresses the software life cycle and the relative cost on each portion of the cycle. Next productivity is considered insofar as the reduction in errors in each portion of the cycle impacts cost. Finally a variety of methods, techniques and tools which can directly affect the error rate/severity experienced will be examined.

Two questions drive this analysis. First, can QA work? and second, Is it worth it? This paper brings together the experiences and thoughts currently in circulation and forms these into an analysis of the issues involved and presents composite estimates of the potential target of quality assurance (cost of error) and the reported experience of quality assurance programs and methods currently available. Because of the difficulty in separating QA methods from project management and the absence of good cost accounting standards, the costs of a quality assurance program are not explicitly treated in this paper.

PHASES OF THE SOFTWARE LIFE CYCLE

To ensure a complete and systematic review of the potential for a QA plan, each aspect of the software "life cycle" will be examined to determine at what point QA can support substantial improvements. Both direct and indirect costs will be considered.

Direct costs are those associated with the actual performance of the particular phase of the software life cycle under consideration while indirect costs include schedule slippages, system degradation, and errors which contribute or add to the cost of subsequent stages in the process. The software life cycle can be broken down into four phases: Conceptual, Requirement, Development and Operations. While other authors have broken this cycle down somewhat differently, either by separating *Development* into two or more separate phases or by extending *Requirements* to include part of the development phase, the categorization shown here more closely corresponds to distinct levels of effort or expenditures.

After a brief qualitative discussion of the potential role of QA in each of the four phases of the software life cycle, the amount of time and relative costs incurred in the performance of each of these phases will be reviewed. Available data on contributions of errors to cost and delay is examined later.

The conceptual phase

This phase begins with the recognition of a need for the system. The feasibility and general worthiness of a proposed system is addressed. Usually a management decision is required to move into the next phase which involves more detailed specifications of performance characteristics. This phase is typified by numerous briefings designed to establish a recognized need for and cost/effectiveness of the system vis-a-vis organizational missions and functions. Order of magnitude cost figures are the typical modus operandi.

This phase has a relatively low contribution to total cost and may last several years. The question of *software* quality assurance is essentially moot throughout this phase of the life cycle. However, the role of software as it may interface with hardware, and gross estimates of costs and schedules should be reviewed as part of a larger quality assurance effort.

Failure to adequately address these issues could result in having to incorporate into the software development functions or design features which could have been accomplished better in other ways and which restrict flexibility or increase the complexity of the software.

The requirements phase

This phase of the software life cycle refines the conceptual system, further delineating the functions and interplay between hardware, software and the user. In general, data inputs and system outputs are specified and overall load and performance characteristics are determined. In many cases, specific determinations of system hardware and user-oriented languages are made. A properly designed Request for Proposal (RFP), even if the system is to be done inhouse (this step in the design process is skipped only at considerable risk), treads a thin line between overspecification and insufficient detail. The former is often caused by past contractor failures while the latter is a reflection of the fact that the user simply does not know what he really wants or needs.

To a large extent, the "die is cast" with the issuance of an RFP (or corresponding internal document). The constraints placed on system performance, hardware and software at this early stage of the life cycle can have enormous repercussions on the flexibility, reliability, maintainability and cost of the system. Implicit trade-offs between system throughput and ease and cost of use, enhancement and maintenance are often made.

Realistically one cannot expect a prospective vendor to do the necessary work required to examine and weigh each of the possible solutions to the design problem. Even with the most competent of vendors, their objective function differs from the clients. Specifically, a vendor's staff may have certain backgrounds and expertise, or his equipment characteristics more adaptable to one family of solutions than another. To save time or money a vendor may modify an already developed product or assemble a patch work of available system modules rather than seek an "optimal" solution.

Thus, quality assurance cannot begin any later than this phase without considerable risk. The phases which follow are characterized by much higher expenditures than these first two phases, with the obvious result that errors carried forward from this point are very costly.

The development phase

This phase is a transitional one bridging the gap between a well defined concept and an implementable system. The big black box between inputs and outputs has to be broken down into programmable units, logic determined and finally coded. The testing and validation tasks require the generation of test data and test parameters and the development of test tools. Documentation provides the vital link to connect the test activities to the designers, programmers and coders.

It is during this stage that a QA activity reaches its peak, for with increasing detail and concreteness comes the need for constant monitoring to assure that the system in reality is the system in concept. Quality assurance in this phase is simultaneously concerned with the correctness of (1) functional requirements, (2) detailed design, (3) program logic, and (4) code. In addition, the specificity and clarity of the documentation is also a proper subject of a QA plan. The testing and validation of the system or the "quality control" function is the most viable aspect of a quality assurance plan. For many developers, all too often, it *is* the QA plan. This tendency is to become lost in code is at the risk of deviations from intended system functions. Correctness of code is not a guarantee that the code is doing what the user required, but rather that is doing what it was designed to do; quite a different matter. Errors in design are far more perfidious than errors in logic.

The operations phase

This phase bridges the gap between the developers and the users. If QA proponents are correct, some payoff attributed to QA should be noticed during the implementation part of this phase, but its greatest contribution will appear during the productive part of the life cycle which is oddly called "maintenance." This terminology may be an indication of the general lack of quality assurance which exists.

More often than expected, the implementation period becomes a "field test" with the essential aspects of the development phase extending far into the operations phase. Design or even worse functional errors are frequently uncovered which may require extensive reprogramming. The start of implementation is often merely an artificial contrivance to cover a scheduled deadline rather than at the completion of the development phase.

THE SHAPE OF THE SOFTWARE LIFE CYCLE

To place the various aspects of the quality assurance function into perspective, it is necessary to look at the relative costs and time requirements of each of the phases described in the previous section. Figure 2 represents the idealized shape of the software life cycle.[28,13,38,39,40,45] While actual project experience is difficult to come by, a search of the literature for real-world cost and time data has been sufficiently productive to enable the construction of a composite software life cycle. This composite was developed from bits and pieces of available information on different phases and parts of phases of large systems. The degree of consistency found among projects gives rise to a fair degree of confidence that this composite is a useful tool in obtaining estimates of the potential benefits of a QA plan. Using the composite life cycle concept, this section relates the time required for accomplishing each portion of the cycle to software costs expended.

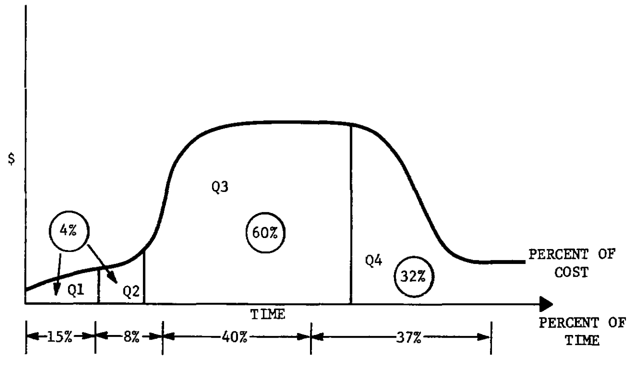

Figure 2—Idealized software life-cycle

The time axis

The percentages of time thought to be denoted to each phase of the software life cycle as implied by the shape of the idealized curve are as follows: Conceptual 15%, Requirements 8%, Development 40%, and Operations 37%. This differed from the reported experience of several large DoD projects.[33] In actual practice the conceptual phase accounted for 30% rather than 15%, while development took only 12% (compared to 40%). The requirement phase accounted for the same percentage of time in actual practice as was expected, while the operations phase (implementation and maintenance) lasted longer in actual practice (50%) than is implied by the curve (37%).

In absolute terms, these projects spanned 16 years from inception to termination. The percentages translate into a conceptual phase of 4½-5 years; a requirements phase of about 1.5 years (these two were actually performed simultaneously for about 6 months); 2 years for development and 8 years for operations. The requirements phase consists of the preparation of specifications, drafting an RFP and the evaluation and selection of a vendor. About half (3½% of Total Life Cycle Time) the time was devoted to specifications. The RFP's took slightly less (2½% TLCT) with about 4-5 months (2%) devoted to review, evaluation and selection. The components of the development phase (2 years) are more difficult to characterize by time, since the steps within are either overlapping (requirements analysis and design) or simultaneous (code, test, document).

Relative cost of software life cycle phases

The relative costs of each of the four phases of the software life cycle can also be inferred from the shape of curve presented in Figure 2. To verify these inferences, data from several studies are pieced together and a composite software life cycle (Figure 4) is constructed and presented in a following section. The shape is compared to the idealized versions found in the literature. It should be remembered that the purpose in developing this composite is to obtain estimates of the relative costs of each phase to use in the determination of the potential effects of instituting various forms of quality assurance. Therefore, the cost balance between development and maintenance as well as among steps in the development phase were of greatest concern.

Operations vs. development

The balance between development and operation depends primarily upon the length of the maintenance period used in the calculations. To standardize these calculations for comparison purposes a maintenance time period equal to 50% of the total life cycle (or 8 yrs) will be used. A study[9] which monitored costs fairly closely from requirements through *one year* of maintenance reported expenditures (in terms of man years) for Requirements, Development and Operations.

These figures were weighted (3 for management; 2 for programmer and 1 for staff support) to determine costs incurred. Assuming a negligible cost for the conceptual phase, say 1% and an operational life of 8 years, the percentage of total costs incurred by each of the four phases of the life cycle were calculated as follows: Requirements 1.5%, Development 51.3% and Operations 46.2%. The ratio of Development to Operations (Implementation and Maintenance) in this case would be 1 to 1.1.

Implementation is difficult to separate from development and maintenance since it in reality is a transitional period between the two. For this reason data about implementation is hard to find and interpret. This being the case the remainder of this paper treats operations as essentially equivalent to maintenance.

A look at cost data available for development vs. maintenance costs for OS releases 18, 19, and 20.0[13] are even more heavily weighted toward maintenance with ratios of 3 to 1 for OS 18 with only two years of maintenance included and 1.25 to 1 for all three releases with only one year of maintenance included. The experiences reported on in this section with respect to the balance between development and maintenance costs show that the costs of maintenance consistently exceed costs of development. Since QA would be expected to have the greatest impact upon costs in the operations phase, a conservative cost equation (conceptual cost+requirements cost+development cost=operations cost) will be used to *minimize* the estimated potential for QA.

Relative costs within the development phase

The activities undertaken during the development phase can be grouped into (1) analysis and design, (2) coding and debugging and (3) testing or validation.

The ratio of the cost of these activities to one another is often thought to be a function of the complexity of the system to be developed. That is, a non-linear (exponential) relationship is said to exist between complexity and the cost of testing. Testing costs are highly related to the number and severity of errors to be discovered and fixed, the number of which is related to system complexity. Proponents of QA will argue that this exponential relationship need not be the case if proper management (including a good QA plan) is exercised. Since the success of QA is directly related to error rates and error rates are the underlying causes of the cost relationships among the activities undertaken during development, this section will concentrate on the ratio of testing (or validation) to the total of development costs.

	Analysis and Design	*Coding and Debugging*	*Validation*
SAGE	39%	14%	47%
NTDS	30%	20%	50%
GEMINI	36%	17%	47%
SATURN V	32%	24%	44%
OS/360	33%	17%	50%
AVERAGE	34%	18%	48%

SOURCE: 14

Figure 3—Breakdown of development costs for selected systems

A study[8] which looked at the relative costs of design, coding and debugging in relationship to validation reported that the ratio of validation (testing) costs to the total development effort ran between $1/3$ to $1/2$.

Figure 3 gives a breakdown of the development phases of five large projects. The results[14] are very consistent from project to project and in the range of the results of the first study referenced. The range $1/3$-$1/2$ also includes the experience from ALPHA-6[9] reported on earlier in this chapter.

A composite software life cycle, based upon a 16 year length (50% operational life) and the relative costs for the four phases given in Figure 3, is presented in Figure 4. The shape is far more leptokurtic than the

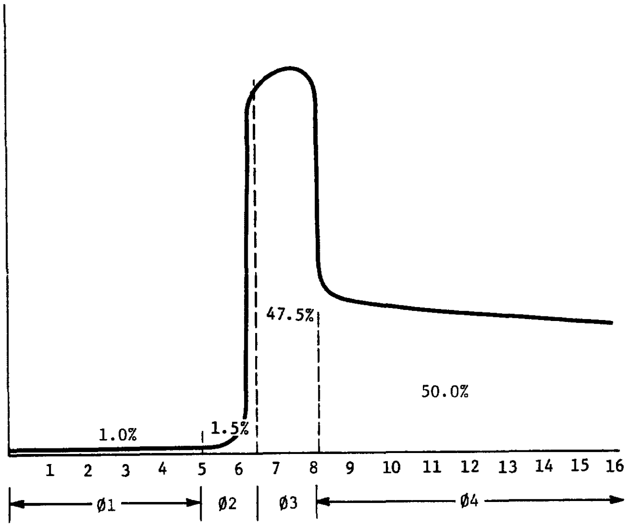

Figure 4—Composite software life-cycle

"idealized" curves found in the literature with the length of the maintenance tail spreading its significant costs over many years. This is due in larger part to a contraction of the development phase. The visual impact of the meager resources applied to the Requirement phase also represents a departure from the idealized shape.

THE COST OF ERROR

A measure of system quality is the number of errors which occur. Hence, ratios of one kind of error to another have been proposed[22] as indicators of quality software. It is taken on faith that well designed systems can be put together with little resultant error, and for those errors which occur, the mean age of the errors becomes a vital statistic with which to judge software.

This section is devoted to estimating the source, kind, type and severity of errors generated during development. It would be of interest to examine the requirements stage to place a value on the "errors" which originate there and trace their impact throughout the rest of the life cycle; but aside from intuitive feelings about their impact no real data appears to be available.

Frequency and severity of errors

No two researchers group errors in quite the same way. As a result, the available information on software errors had to be interpreted and classified based upon the explanations provided in individual studies. Errors are classified in this paper as either design, logic or syntax. These categories are sufficient for the purpose at hand. Design errors are those which require changes in the specifications used by the programmers. Usually they represent a lack of understanding (or proper communication) of a computation or process, which results in the wrong "problem" being solved. Logic errors occur when the system design is translated into programmable form (detailed flow charts). Syntax errors are self-explanatory. Few of the studies of software errors present actual data pertaining to frequency and severity. Taken together[1,4,6,8,47] those that present some data all report design error as occurring most frequently. Ranging from a high of 64%[1] to 46%.[6] Syntax errors were reported to be about 15% of the known errors. Logic errors ranged from 21% to 38%. The significant point to note is the large percentage of design errors.

Available data on cost of detection and correction reveals that design errors cost the most to diagnose and fix. Syntax errors are reported to be more of a nuisance than a significant cost particularly with the use of automated precompiler processing.

Origin and detection of errors

Where errors originate as well as when and how they are discovered are important inputs to the design of an effective QA plan. Syntax errors originate, surface and are resolved within a brief period of time and for all intents and purposes can be considered totally encompassed within the process of coding. Such is not the case with design and logic errors. Design errors can be caught during a design review (if there is one), during preparation of detailed flow charts or occasionally during coding. Simple logic errors (process before read) can be caught at compilation time or during program testing. Because of the numerous paths in any program which can be tested many logic errors are not observed until the validation, implementation or maintenance stages. A study of a large software development effort[1] found that 54% of the errors were not caught until acceptance testing or presumably until after development was complete. To make matters worse, the overwhelming proportion of these were design errors. Reported figures indicated that 70% of the design errors were not caught at earlier stages while by contrast 80% of the programming or logic errors were caught during development. If the mean age of error were calculated for this case it would be quite high due to the high percentage of design errors involved.

Estimation of the costs of errors

Using the three categories of error (design, logic and syntax) it appears that design errors account for at least 80% of the *total cost of error*. This percentage is arrived at by noting that about ⅔ of all errors caught are design errors; with logic and syntax errors making up about equal proportions of the remaining ⅓. Compared to the cost of tracking down and correcting coding errors, the cost of syntax mishaps is small. However, the cost of design errors is more than double (2½ times) that of coding error. The calculation of the contribution of design error to the total cost of error consists of taking the weighted (expected) cost of an error [% design errors × 2½ + % coding + syntax errors × 1] and dividing it into the contribution of design [% design × 2½] using the percentage given above 83⅓% of the total cost of error can be attributed to design errors. This relatively large contribution to total error cost should play an important role in the design of a QA plan and will be used as an input in the calculation of the potential effectiveness of quality assurance.

The next calculation which is required for the assessment of the potential of quality assurance is the percentage of total life cycle cost which can be attributed to error. Once this percentage is obtained, an estimate of the benefits of a QA plan can be developed based on a "tool by tool" analysis of the kind of error it addresses (design, logic or syntax) and the percent error reduction claimed or experienced. These calculated benefits can then be compared to the cost associated with these components of a QA plan for a final assessment of the economics of quality assurance.

To estimate the cost of error the following method was used. For a slightly conservative estimate, it was assumed that (i) all costs in design (ii) coding and (iii) documentation to be non-error related. All checkout and validation costs (recognizing that only some of these costs can be reduced by reducing the number of errors, since some costs are fixed) were attributed to error. From the ALPHA-6 data then 47% of development cost (assuming the code, test, and document costs were equal) could be traced to errors. Further data on developments costs for several large systems (given in Figure 3) averaged almost exactly the same percentage (48%).

Maintenance costs can be attributed to correcting errors and to enhancements, but "enhancements" often result from initial design errors. For the sake of discussion assume that half can be directly related to error. This amounts to the conservative estimate of almost half of the total life cycle costs (47.6%) being directly tied to error (see Figure 5). On the cost basis of a large system, the total cost of error is in the hundreds of millions. If quality assurance methods can reduce error by even small amounts, they would appear to be worthy of serious consideration. For example, a 10% reduction in error (⅔ Design, ⅓ logic and syntax) as they have been reported in the studies reviewed would represent a saving of almost $25 million based upon a relatively large effort (cost= $½ billion over the 16 year cycle). A five percentage error reduction (only ½ design) would result in a savings of over $10 million.

THE EFFECTIVENESS OF THE TECHNIQUES AND TOOLS OF QUALITY ASSURANCE

The assurance of quality can be brought about by any number of different approaches which have been suggested. These range from essentially project management techniques to methodologies of design to syntax checking tools. Many of the methods which will be discussed in this section can be expected to have a much broader impact on design, development and implementation than is pertinent to a discussion of quality assurance. This section will address the impact these methods have on error rate and error-related productivity.

Error Type	*% Total Errors*	*Relative Severity*	*% Total Cost of Error*
Design	2/3	2.5	83+%
Logic	1/6	1.0	8+%
Syntax	1/6	1.0	8+%
	Development Phase	*Operations Phase*	*Both*
% Total Life Cycle Cost	47.5%	50%	97.5%
% Cost Due to Error	48%	50%	—
% Total Life Cycle Cost Attributed to Error	22.6%	25%	47.6%

Figure 5—Error and software life cycle costs

In some cases, their contribution to quality is rather straightforward, particularly for error detection tools. However, for those which promise the most sweeping reforms, essentially those dealing with management or design effectiveness, measurement is difficult and little concrete information is available.

It is the purpose of this section to analyze based upon available data the potential of quality assurance in terms of the cost of error, development productivity and the cost of quality assurance. In the following paragraphs, some of the most widely discussed techniques and tools will be reviewed.

Structured programming

The advantages touted for Structured Programs range from improved program design to improved documentation. Improved design is linked to fewer design errors and fewer logic/programming errors. Fewer statement types are linked to fewer syntax errors and an almost self-documenting program. Fewer errors imply greater productivity during development and reduced operations costs. Further, the streamlined design is claimed to be easier to upgrade and enhance. Finally, the planning and conceptualization required by Structured Programming is said to enhance the performance of project management.

Reported increases in error free productivity ranged from 50%[25] to 125%[47] with the introduction of Structured Programming while error reductions of between 30%-90% were reported by another study.[17] Quantitative results of ease of enhancements were not found, however, a study of the development cycle[56] estimated 25% reduction in the elapsed time from requirements to implementation, from 6 years to 4.5 years.

Top-down development

The essence of Top-Down Development is simultaneous systems integration and development which results in a viable, executable, if rather skeletal system at an early state. This development approach amounts to an ordering of the sequence of system decomposition decisions beginning with a simple description of the entire system or process and continuing with successive refinements until a programmable design is reached. Top-Down Development is a natural companion of Structured Programming, so much so that the two concepts are often confused. The claimed advantages of this approach include the increased ease of implementing a QA plan with a resultant reduction in design error and productivity improvements associated with the systems integration and testing efforts during the development phase.

Perhaps the most significant advantage claimed from a QA perspective, is the early existence of a complete system's design replete with the design specification of system components and interfaces. Not only does such a document enhance the changes of a coherent and consistent design, but it also serves as a vehicle for establishing a correspondence with "user" oriented functional specs. The system components are placed into perspective for all to see and comment upon. Misunderstandings that often were not surfaced until acceptance testing can be resolved at this time. Design problems often not found until systems integration may be corrected reducing the high cost currently associated with these problems.

The incorporation of the testing function throughout development, made possible by the continual existence of a testable system, offers QA with an opportunity to be more of a pro-active force in development.

There are recognized pitfalls as well. Care must be taken to ensure design feasibility in terms of existing software and hardware, since actual coding is significantly delayed.

Holistic design is difficult to achieve and false starts are likely. However, when weighted against the known shortcomings of bottom-up design there is little question that a Top Down approach when combined with some common sense offers substantial advantages to both developer and user.

Hard estimates of the reduction in error and increases in productivity from the use of this approach alone are not readily available. However, when used in conjunction with Structural Programming and a Development Support Library,[25] a productivity improvement of over 300% (when compared to a system using a Development Support Library alone) was experienced. With Structural Programming alone, productivity gains of 50%-100% were experienced; thus, the addition of a Top Down Design approach seems to further enhance performance significantly.

For the purposes of this analysis, the expected performance of this approach will be conservatively bounded from above. In terms of development productivity, a very conservative range which includes gains made by reduced systems integration and testing, and by better manpower and computer time scheduling would be between a 5-10% improvement in productivity. This improvement could be reasonably expected from the savings in the integration step alone.

As far as design errors are concerned, the increased attention to overall design could be expected to reduce configuration and architecture errors significantly and virtually eliminate errors in the specification of offered system functions. One study[6] showed that machine configuration and architecture errors accounted for just over 20% of all design errors while errors in the functions offered accounted for about 25% of the design erorrs. Both are susceptible to being caught early. An examination of specs by others not involved in their formulation resulted in the detection of between 30%-40% of these errors. An increase from this to a 50% rate of error detection might realistically be achieved by the use of Top Down Design.

Other recent innovations

In addition to Structured Programming and Top Down Development, a number of other approaches to improving software quality and productivity have been advanced. Among these are the techniques of the Chief Programmer Teams, Egoless Programming, and automatic or semi-automatic tools ranging from Design Assertion Consistency Checkers to Automated Test Case Generators.

The management oriented techniques are aimed at achieving increased communications and coordination while the automated tools seek to provide complete, systematic and low cost verification. This section will briefly explain some of these innovations concentrating on the contribution or impact likely on the performance of the QA functions.

Programming organizations

In this section, the effects of the Chief Programmer Team, Egoless Programming and Democratic Team Organization on the performance of the QA function will be addressed. Egoless Programming and Democratic Teams are essentially loosely structured programming environments in direct contrast to the Chief Programmer approach which is highly structured. It is interesting that the changes from current practice being advanced to improve software quality are in opposite directions. Both approaches, however, take aim at the individualist who becomes ego-involved with code to the extent that error detection is thwarted. The loosely structured approaches attack this problem directly by eliminating "ownership" of code to reduce defensiveness. The Chief Programmer Team approach is meant to be employed in conjunction with Structured Programming and Top Down Design which systematically eliminates tricks and gimmicks in programming and imposes ridged forms. Users of both types of approaches claim better communication leading to reduced misunderstandings and error rates. On the one hand, the Chief Programmer Team approach is criticized for being too authoritarian while the other approaches are said to tend to alleviate the individualist and require more sophisticated management techniques. Experience indicates that managing bright

	Methods of Detection			
Error Type	*Manual Inspection*	*Formal Methods (Simulation, etc.)*	*Tests Runs*	
Design	45%	20%	35%	100%
Logic/ Coding	24%	22%	54%	100%

Figure 6—Error detection for design and logic/coding error types

creative staff is no mean task regardless of the techniques employed. The key seems to be in the actions taken to increase the understanding and clarity of assignments not in what abstract management philosophy is employed.

Automated tools for quality asssurance

The literature contains countless tools developed to check out design, flow charts, code and even documentation systematically and quickly. Their performance can more easily be measured than the techniques previously discussed, but their contribution to the potential of an overall QA plan is limited. Their very nature (highly specified and deterministic) limits their effectiveness in dealing with other than highly structured situations. Thus, these tools are most applicable to the detection of errors in code and simple sorts of logic errors rather than major flaws in program logic or design approach. Nevertheless, they can significantly contribute to increased productivity, earlier detection and hence some reduction of the "ripple" effect (19% of the errors introduced as a result of error correction[55]). An analysis of error types and means of detection[6] showed that (See Figure 6) manual inspection uncovered only 24% of logic and coding errors compared to 45% of design errors indicating the potential for the use of automated tools. Such tools could have an impact in reducing the percentage of logic and coding errors (54%) not caught until testing. One study gave evidence to support this feeling[21]. The use of automated instruction and path checkers (ASSIST and NODAL) reportedly catch between 67%-100% of the errors and at between 2-5 months earlier than they would have otherwise been detected. Automated error checking is currently at the state of development where it is either language or application specific and it would probably be of marginal value to develop such a tool for a specific project.

Figure 7 summarizes the results with respect to the reported effectiveness of quality assurance methods and shows the dollar impact that improvements in development productivity can have based upon a project whose total life cycle costs equal $.5 billion.

SUMMARY AND CONCLUSIONS

This section places the relevant estimates developed during this report in perspective and highlights important aspects in the assessment of the economics of Software Quality Assurance. This paper first addressed the software life cycle to identify the areas which could be improved by a QA plan. Second, an examination of the frequency of software error, its sources or origins, methods of detection and associated costs was presented. This was followed by an examination of some of the methods and techniques suggested for quality assurance. Highlights of these examinations and analyses follow.

Summary of findings

The examination of the software life cycle revealed that costs were concentrated in the Development and Operations phases. The typical Development Phase accounted for just under 50% of the total costs while lasting about 2 years (12% of a 16 yr. cycle). About half of the development costs were spent on check-out and testing activities in contrast to about $1/3$ for analysis and design and $1/6$ for actual coding. The Operations phase while consuming just under 50% of the total life cycle costs was spread over an eight year period.

Errors were classified into three types (design, programming/logic, syntax). The last accounting for some 15% of all errors. Design errors outpaced program/logic errors by a little less than 2 to 1 accounting for a little more than half of all errors. Program/logic errors ran about one-third of the total.

The severity of errors, as measured by the cost of detection and correction, was found to be higher for

Technique	*Error Reduction*	*Productivity*		*\$ Impact of 1% Improvement In Development*	*Potential Impact*
		Range	*Mid-Point*		
Structured Programming	30-90%	50%-100+%	75%		$175 Million
Top-Down Design	Substantial	10%-200%	100%		$250 Million
Management Organization	—	—	—	$2,375,000	—
Automated Tools	Caught earlier	Up to 25%	10%		$ 25 Million

Figure 7—Performance of quality assurance techniques

design errors than program/logic or syntax errors (least costly). Weighted by costs it was calculated that design errors accounted for just over 80% of the total cost of error. In terms of the total software life cycle then, with 47.5% of its costs in development and 50% in maintenance, the cost of error could easily run over 50% of the total software life cycle cost.

To combat error and improve software quality a variety of methods have been suggested. Preliminary reports have been encouraging in both the areas of productivity improvement and error reduction.

Conclusions

While the data drawn upon comes from a large variety of sources (different systems, different environments and from studies using different definitions and analysis methodologies), the experiences reported were so compatible that, while more detailed data is necessary for the actual development of a QA plan specific to a given set of system and organizational circumstances, the conclusion that QA can be cost effective is inescapable.

From the analysis presented in this paper, the development of a QA plan should concentrate on techniques and methods for the early detection and elimination of design errors. The researchers reporting on the development of ALPHA-6[9] indicated that if more resources were applied during design, it would have resulted in substantial savings in the costs of testing and maintenance. An extrapolation of the data they presented gives a multiplicative factor of 5; that is, a dollar more spent in design would have saved 5 dollars spent on testing and maintenance. While this example may be unusual, it, together with the fact that a significant portion of total system cost can be attributed to error point to the cost impact that a QA function can provide.

A parameterization of the impact that error and productivity improvements have on total software system costs based upon a $½ billion total life cycle cost (about $250 million for S/W Development) has been made. For each 1% of error reduction (½ coding + ½ design) a savings of just over $1½ million could be expected. For each 1% improvement in Development productivity a saving of $2,375,000 could be expected. It should be noted that Design errors have more than double the impact than do coding errors.

Thus the leverage of QA in large programs is significantly high to warrant serious consideration. The costs of developing and implementing a QA plan are difficult to specify for a given organization, especially in light of their management considerations. However, even with the additional expense QA still promises to be cost-effective. For example, if management overhead for software development is approximately 5% of development costs and a QA plan increased this overhead by ¼, then a reduction of error by approximately 1% (coding) alone could offset these additional costs.

Implementation of quality control in software development

by FRANK TSUI and LEW PRIVEN
IBM
Gaithersburg, Maryland

ABSTRACT

In recent years, many tools have been developed in the areas of programming techniques, design methodology, development processes, and test strategies. All of these are aimed at producing a quality product with a minimum cost. Together with emergence of these tools, there is a recognition of the problem of how to effectively implement them into a total systems development environment. One of the factors to a successful development is the ability to exercise proper control over the various development processes.

We will first establish the objectives for software quality control. Then, descriptions of the terminologies defining the various development processes will be presented in order to provide a common background. A basic philosophy of the entire development procedure and the notion of *Continuous Integration* will be presented. The introduction of quality control into this procedure will be discussed. Finally, some justification for such an approach will be shown.

INTRODUCTION

A large amount of effort has been spent on developing programming and design techniques. The various tools and methodologies[1,2,4,5,12,15] are aimed at different steps in the development processes. Basically, these tools may be classified into the following categories in terms of their intended applications:

(i) Design, Code and Documentation
(ii) Test and Verification
(iii) Control of the Development Processes

In order to attain a good quality product, it is essential to understand how and where these tools apply in the development activities. The subject of this paper comes under the third category, Control of the Development Processes.

In this paper we will present a unifying paradigm of the entire development procedure. Within this global system, several development cycles for different functions may be in progress simultaneously. The development cycle is similar for each function. That is, the activities within each development cycle are fairly standard and flow in a fixed sequence much like an assembly line. For example, if we examine how a programmer does his job, normally the following activities take place:

(i) Design/Document
(ii) Code
(iii) Test
(iv) Integrate
(v) Performance Measure
(vi) Release

This is a "natural" process; id est, if left alone, most programmers would follow this sequence in implementing a program, except, possibly for the documentation part. Since programming lends itself to a natural flow, the process or the development cycle should keep this intact.

In lieu of the yet experimental and basically primitive automatic program correctness verifiers,[11] quality control is obtained via the introduction of inspections and reviews[7,8] into the development cycle. Then two additional steps called Error Prone Analysis and Post Functional Test Analysis will be introduced to monitor the development cycle and the entire development procedure.

GOAL OF QUALITY CONTROL

Today's environment demands that programming products be of "high" quality. From the users' point of view this means: functionally complete, easily usable and installable, and low error rates. Additionally, to the developer it means that the schedule must be met at the lowest cost. This is certainly a tall order based on the past performance of the programming community, but it can be achieved with the proper management and quality control techniques.

The main objective here is to ensure that only a minimal number of software problems exist. This may not be as obvious as it appears at first glance, for it is not sufficient that just the final product contains a small amount of problems. It has been the experience[4,7] that correcting a problem in the final product will require much more effort than correcting that same problem in the early phase of the development. Thus it is essential that errors be detected and corrected as early as possible and only a minimal amount of problems be allowed to slip from one phase of the development to the next.

The secondary objective, although it may be just as important as the main objective, is to increase the ease of usage and future maintenance of a product. As the cost of producing a completely new system increases, the property of being able to enhance and build upon the existing system becomes significant.

TERMINOLOGIES AND DEFINITIONS

In this section some basic notions of Design, Code and Test will be explicitly defined in order to facilitate the introduction of the concept of inspection or review.

The Design phase of the development cycle is composed of two levels: High-Level Design and Detailed Design. The High-Level Design contains the following information.

(A) An over-all functional specification describing *what* is to be performed.

(i) For each major function, the modules' names should be specified; and within each module, the description is carried to the level where each statement represents approximately 20 lines of executable source code.
(ii) All control blocks with major fields and their purposes identified.
(iii) For each function, all the macros that need to be designed should be listed and described to the depth where each statement represents approximately 20 lines of executable code.
(iv) For each module, all data files and tables should be presented along with a brief description of their purpose and method of access.

(B) The dependencies for each major function are presented by modules, identifying both internal and external cases.

(i) Internal dependencies specify those macros and control blocks which are shared by several modules.
(ii) External dependencies indicate all the modules, control blocks, and macros needed but were not included in the overall functional specifications described above.

(C) The linkages between functions (by modules) are specified.

(i) Parameter list is identified.
(ii) All system Generation/Initialization requirements must be described.
(iii) All locks and authorization into data files are described.

(D) For each function, a control flow (in some flowchart form—preferrably with a predetermined Structured flow chart) describing the logic should be given by modules.

The Detailed Design is a refinement of the High-Level Design. Thus the information described above for High-Level Design serves as the input to the Detailed Design phase. The information contained in the Detailed Design is used as the input to coding. It contains the following:

(A) A complete "Structured" logic flow (by modules) should be given.

(i) Each box in the flowchart should represent approximately 20 lines of executable source
(ii) Reference to control blocks and data files should be by field names.
(iii) Macro invocations should specify all required parameters (by values).
(iv) Each predicate in the flowchart should have a corresponding "purpose" description.

(B) Data structure should be clearly specified. Each data file and table should be described down to each field identifying the following:

(i) intended usage
(ii) attributes
(iii) access method
(iv) value range (if any)

The coding phase utilizes the Detailed Design as its input. Here the Detailed Design is converted to source code and machine compiled or assembled. Each module should be at least compilation or assembly error free. There should be a module prologue preceding the actual code, stating the following about that module.

(a) major functions
(b) control blocks referenced (if any)
(c) macros used (if any)
(d) Entry-Exit conditions (if non-standard)
(e) linkages (if any)
(f) I/O parameters (if any)
(g) list of logic revisions made since last version (if any)
(h) version number and date
(i) module owner

An important point here is that the code must follow the Detailed Design. Structured flowchart with its corresponding Structured Programming Language would make this process much easier than otherwise.

The Testing phase depends heavily upon the documents generated during High-Level and Detailed Design. Generally, there are three categories of testing:

(a) Functional Test
(b) Component Test
(c) System Test

The functional test refers to the verification of each function utilizing a series of test cases within the intended environment. This may be the most time consuming test, depending on how detailed the test cases are. The component test involves the verification of inter-functional activities. The system test is performed to insure that no part of the system is ill-affected (including performance) and that the system as a whole does not crash even under unusual, non-intended environment. An extensive description of testing processes may be found in Reference 6.

IMPLEMENTATION OF QUALITY CONTROL

Before we can meaningfully discuss Quality Control, there has to be an underlying development philosophy. In this section, we will first present a paradigm of the complete development process. Within that paradigm the development cycle with the built-in controls will be discussed.

In order to insure low error rates, some quality control techniques must be utilized. This implies a defined procedure that can be instrumented to provide a) the necessary points for measurement and b) feedback path to correct defects. As stated earlier, the "natural" sequence of activities of Design, Code, Test, Integrate, Performance Measure, and Release should be kept as part of the process. Together with these activities, some checkpoint must be obtained before an activity is considered complete and another begun. The question is whether there is any one activity that plays an overriding role in defining the interaction between the other activities. Design seems to be the logical choice, but integration will be shown to be the key in defining the sequence of design and development activity.

Similar to building a house, the sequence that programs are put together is very important. In the case of a house, first the foundation, then the outside walls, then the roof, etc. are "put together" in that sequence. The parts may be built independently and simultaneously. Once the "basic" framework of the house is completed, the other components such as kitchen cabinets, toilets, etc. may be added separately. The same concept holds true for programs; there is a main functional path that must be completed first. Then the other functions can be added until the entire product is complete. This technique works best when functions are added individually. The technique is called Continuous Integration; it provides two significant attributes to the programming, development process. This is conceptually similar to Iterative Enhancement.[3] First, by adding functions individually to an already working base, error isolation can generally be narrowed down to the newly added function or interface areas. This is critical as the system becomes more complex. Second, the development of each discrete function entails the same development cycle and can be tracked through the process by a standard set of quality control techniques.

The concept of Continuous Integration can be easily demonstrated as follows:

		Modules			
		A	B	C	D
New Functions	1	X	X	X	X
	2		X		X
	3	X	X	X	

Figure 1

Modules A, B, C and D are already developed, and they form the working base. Now, three new functions need to be added.

Figure 1 shows the relationship between additional, new functions and the impact to the modules. The crosses represent "affected." With Continuous Integration the three functions would be developed independently; although they can be developed simultaneously. As any one function is completed, it is integrated into the working base and a new base is formed.

Consider the alternative. Had we developed them by modules, the delay of any one module would affect the completion of at least two functions. If module B is delayed, nothing will be completed. This can be disastrous. The testing and verification of functions are also difficult with the Modular approach. All affected modules must be completed at the same time before any one function can be tested. Suppose modules A and C were completed first. Functional verification can not be performed until the most "affected" module B is completed with all its new enhancement. If the modules were developed at physically different sites, then the problems are even more complex.

Continuous Integration utilizes a "blueprint" for putting the system together called the system build plan. This plan is used to determine in what sequence code must be developed and, thereby, the design sequence. Figure 2 represents a unifying paradigm within which Continuous Integration is applied.

To have the processes started, assuming that the product has been defined via the commitment process, a system build plan must be produced. As shown in Figure 3, the production of the build plan is an iterative process, requiring trade offs in resource, function, and schedule. Once this has been agreed to for the

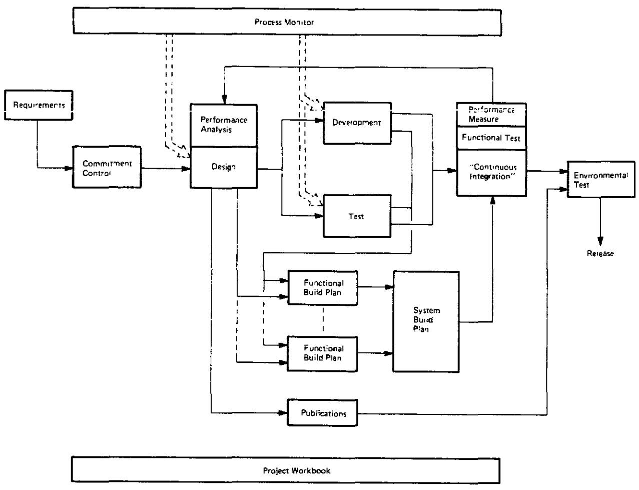

Figure 2—Programming processes paradigm

initial product definition, the processes shown in Figure 2 can be used to control the program production and introduction of changes.

Another area that is significant to the total development and quality control is documentation. A project "workbook" that contains at least the design documentation for each function must be maintained in an up-to-date manner. This documentation is used as:

(1) Source for user publication
(2) Source for test case development
(3) Control Information for Continuous Integration
(4) Source for quality control activities.

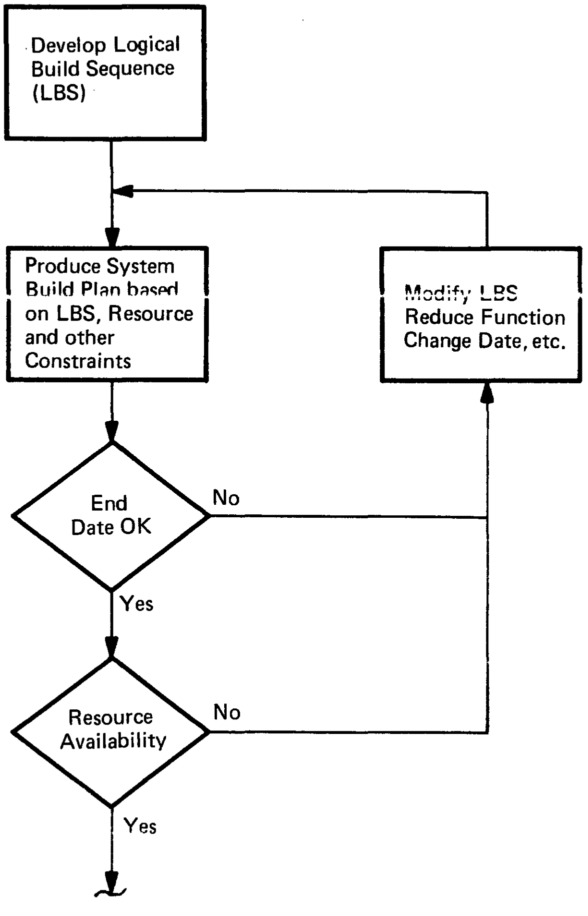
It is important to remember that Figure 2 is not a time sequence chart for the whole system; however, it is for any one function. At any given point in time, some activity will be taking place in each area. The processes outlined have many other facets that will not be discussed in this paper, for they are not relevant to the main topic of quality control. Refer to Reference 14 for further details.

In summary, the main features of the paradigm that are significant to quality control are:

(a) Process definition that provides for discrete turnover points between activities (e.g., design to code).
(b) Control over the input to the system via commitment control.
(c) A blueprint for putting the product together (e.g., system build plan). The system build plan is also the mechanism used to review the status of each function as well as the integrated system. Using this mechanism, inputs from the quality control activities can be used to modify the blueprint and/or reallocate resources to assist areas in need.
(d) Work units (functions to be developed) that move through the processes in trackable units.
(e) Documentation of the design which provides independent source material for quality control checking.

Now, we will show precisely how items (a), (d) and (e) mentioned above can be achieved by inserting quality control checkpoints into the development cycle of any major function. Recall that several functions may be developed simultaneously but they all follow a similar development cycle.

First a set of inspections or reviews[7,8] will be included into the cycle in order to attain the main objective of quality control, which was mentioned earlier. That is, with the inspections in place, the number of errors passed from one phase to the next will be greatly curtailed. Strict Exit Criteria will be imposed at each step such that the ensuing step may not start until the previous step is completed. In addition to the built-in controls of inspections and exit criteria, there should be explicit control steps in the development cycle. Namely, two new steps (a) Error-Prone Analysis and



Develop Logical Build Sequence (LBS)
Produce System Build Plan based on LBS, Resource and other Constraints
Modify LBS Reduce Function Change Date, etc.
End Date OK
No
Yes
Resource Availability
No
Yes

Figure 3—System build planning

(b) Post Functional Test Analysis are included. There will also be a Test Planning process in the development cycle. Finally, we have the complete picture of a Development Cycle in Figure 4. All the terminologies (e.g., High-Level Design) follow the definitions provided in the previous section.

Each inspection involves the following 4 steps:

(a) Preparation
(b) Inspection itself
(c) Rework
(d) Follow-up

In the preparation step, all the appropriate and required outputs for that phase (e.g., Detailed Design) must be distributed to the inspectors. The inspectors are then given enough time to digest the material before the actual inspection. Typically, the inspectors are composed of a moderator, the designer of the function, the coder of the function, a testing representative, and a publications or documentation representative. Refer to Reference 7 for details on inspections. The objective of an inspection is to identify problems as opposed to offering solutions and better alternatives.

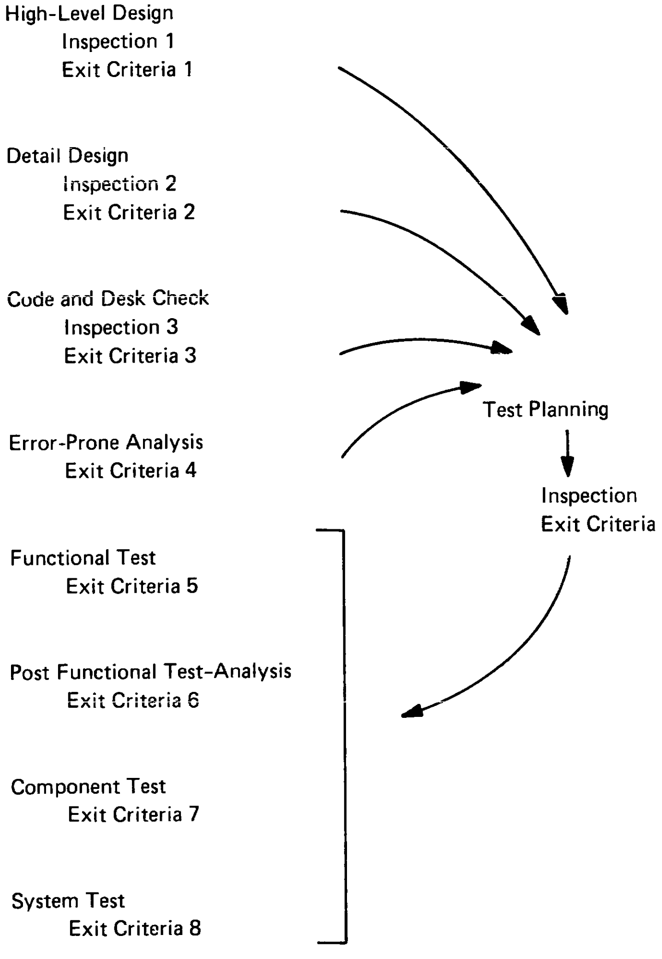


Figure 4—Development cycle of any function

The Error-Prone Analysis step follows the coding phase. The content of the inspection results from High Level Design, Detailed Design, and Code is analyzed. Those areas that required continuous corrections and changes are identified. The reports generated during this step serve two purposes. They will allow the developers to decide whether certain areas should be reworked before entering the Test phase. The decision might require a change to the build plan mentioned earlier. The reports can also be used as additional guideline to the Testing phase in that the error prone areas may require more extensive test effort.

The Post Functional Test Analysis step, as the name suggests, immediately follows the Functional Test. The recorded test results are analyzed. Besides identifying areas which are functionally weak, the data may be used to estimate the number of errors that will occur when the system goes into production. This estimate is measured against a pre-established error tolerance level. Thus the results from Post Functional Test Analysis may be used to determine the quality of the final product.

Due to constraints of available space, we will not discuss each exit criteria. Only the Exit Criteria 1 will be described along with recommended tools for the High-Level Design phase.

The output from the High-Level Design is a design specification in the form of flow-charts and HIPO[9,13] diagrams. The recommended tool here is the structured programming concept in that the flowcharts abide by the rules of structured programming. These will be used for the inspection. The Exit Criteria 1 contains the following:

(1) High-Level Design inspections results logged into an inspection file.
(2) All necessary rework signed-off by managers and logged on the inspection file as complete.
(3) The updated version of the High-Level Design Specification is logged into a project workbook, signed-off by managers, and distributed to (i) project developers, (ii) testers, (iii) documentation and publications groups and (iv) product assurance group (if any).
(4) Each module is assigned an owner.

Note that the required output, High-Level Design Specification, serves, not only as input to the next phase of the development, but also as input for (a) early test planning and (b) documentation.

The Development Cycle (Figure 4) may be viewed as the static component of development environment as every function is produced by going through the same cycle. Its dynamics are shown in the Programming Process Paradigm (Figure 2). Thus the Development Cycle, into which various quality controls are built is the static part of a dynamic Programming Process Paradigm.

SOME JUSTIFICATIONS

In the previous section, we have presented an implementation of quality control in software development. The Inspections, Error-Prone Analysis, and Post Functional Test Analysis are all aimed at attaining the main objective of low error rate. The Exit Criteria which ensures proper control and certain amount of documentation are aimed at achieving the secondary objective of easiness of enhancement and usage.

These objectives of quality control seem to be "user" oriented rather than the developers. We believe that if properly implemented, the developers will benefit just as much. That is schedules will be met, and total development cost will go down. This can be demonstrated by comparing the cost of quality control (in people hours) against the cost of having to correct the errors (in people hours) afterwards.

Figure 5 shows the estimated person hours to inspect code and design. Recall that inspections are conducted with a designer, coder, tester and a representative from publications. One of these may be the moderator. So inspections require four people. Figure 5 shows the cost of quality control in developing different sized products in terms of people-hours based on 10 hr/k for High-Level Design, 15 hr/k for Detailed Design, and 13 hr/k for Code inspections. (k=1,000 lines of executable code)

It is conjectured[10] that on the average a programmer makes 7 errors per 1,000 lines of source code. Assuming that the normal testing eliminates 50 percent of the errors and that with the Inspections and other quality controls the test efficiency goes up to 60 percent, then Figure 6 shows the number of errors left after release. The range of error-elimination efficiency of Inspections is chosen to be 30 percent, 40 percent, 50 percent and 60 percent.

It is estimated that each of these remaining errors costs approximately 70 people hours to fix. This includes identify the problem, make the correction, compile or assemble, test, and check the test. In some cases where redesigning becomes necessary the cost can be much higher. So far, we have assumed unique errors. For each of the unique remaining errors there may be several ill effects, causing one to spend more time in verifying that these are all due to the same unique error. We will, however, use the conservative 70 people hours. The question is whether the cost of correcting these remaining errors to the level that the quality control techniques yield is more than the cost of introducing these techniques into the development. Figure 7 shows the cost of correcting these errors to the levels of different Inspection efficiencies. For example, it costs 105 people hours to bring 3.5 errors down to 2 errors.

	1K	5K	10K	20K	50K
High-Level Design Inspection	40	200	400	800	2000

Code Inspection	52	260	520	1040	2600
Error-Prone Analysis	5	5	8	10	20
Post Functional Test Analysis	8	10	15	20	30
Total	165	775	1543	3070	7650

Figure 5—Cost in person hr.

	1K	5K	10K	20K	50K
Errors Remaining (Normal)	3.5	17.5	35	70	175
Errors Remaining (with Inspection - 30%)	2.0	10.0	20	40	100
Errors Remaining (with Inspection - 40%	1.7	8.5	17	34	85
Errors Remaining (with Inspection - 50%)	1.4	7.0	14	28	70
Errors Remaining (with Inspection - 60%)	1.1	5.5	11	22	55

Figure 6—Errors in released product

A comparison between Figures 5 and 7 shows that not until we can conduct quality control to the point of 60% error elimination before testing does the introduction of these techniques become economically worthwhile. In reality, a lower level of quality control proficiency would probably suffice, for machine time cost was never introduced into the comparison. Note that the quality control techniques here do not require any machine time. Furthermore, we assumed a fixed 70 people hours for error correction. This resulted in a linear relationship between the size of the product and the error correction cost. A more reasonable relationship would show that the cost of fixing an error would be higher the larger the product as in Figure 8.

For small modules, the error correction percentage of quality control would have to be high before it is economically worthwhile.

	1K	5K	10K	20K	50K
To 30% Inspection Efficiencies	105	525	1050	2100	5250
To 40% Inspection Efficiencies	126	630	1260	2520	6300
To 50% Inspection Efficiencies	147	735	1470	2940	7350
To 60% Inspection Efficiencies	168	840	1680	3360	8400

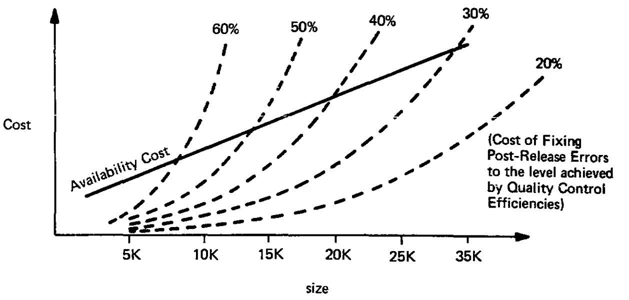

Figure 8

CONCLUSION

In this paper we have introduced a development philosophy called Continuous Integration and a general software devlopment paradigm which can facilitate several Development Cycles. Within any one Development Cycle, a set of quality control techniques may be implemented. With the implementation of quality control, it is shown that the following can be achieved:

(1) lower error rate
(2) ease of maintenance
(3) lower total cost

The economical comparison, although still not precise, does provide a guideline to the management for evaluating quality control techniques.

A computer performance prediction model

by ROBERT W. OTTO and MARK AUERBACH
Office Chief of Staff, Army
Washington, DC

ABSTRACT

This paper presents a model which departs from the classical queuing theory approach and uses probability to predict computer system throughput. The probability a program desires computer resources (CPU or channels) is obtainable from system measurements or can be estimated. Knowing these probabilities, the multiprograming throughput of a system concurrently executing a number of programs is calculable. The multiprograming model presented is easy to use and requires only the probabilities denoted above. The serial model, reviewed briefly in this paper has been previously published.

INTRODUCTION

The Management Information Systems Directorate (MISD), Office of the Chief of Staff, Army, is responsible for planning hardware and software expenditures for the Army. As the number of Standard Army Management Information Systems grew, Data Processing Installations became saturated. The problem was to validate installation requirements for a hardware upgrade.

The validation process was two-phased. The first phase determined, for the present system, Standard Army Management Information Systems runtime predictors. The second phase extrapolated Standard Army Management Information Systems runtimes to other hardware configurations.

The time needed for extensive computer benchmarking was unavailable. A decision was made to formulate a simple analytic model for determining computer system relative throughput. This paper describes a simple analytic model (in a batch environment) for both serial and multiprograming modes. The latter formulation is probabilistic and both formulations can be exercised with the aid of a desk calculator.

As a follow-up action, when time was available, benchmarks were run. A comparison of theoretical and actual results is presented.

SERIAL MODE FORMULATION

A computer system processing a program resides in one of four mutually exclusive states. These states, a function of the Central Processor Unit (CPU) and Input/Output (I/O), are:

1. $\mathrm{CPU}\cdot\overline{\mathrm{I/O}}$ (CPU busy and no I/O)
2. $\mathrm{CPU}\cdot\mathrm{I/O}$ (CPU busy and I/O)
3. $\overline{\mathrm{CPU}}\cdot\mathrm{I/O}$ (CPU idle and I/O)
4. $\overline{\mathrm{CPU}}\cdot\overline{\mathrm{I/O}}$ (CPU idle and no I/O)

A Resource Utilization Factor (RUF) is the proportion of processing time expended in one of the above states. For a given hardware configuration the RUFs are software dependent, and can be obtained by evaluating performance monitor data.

The serial mode formulation evaluates computer subsystem hardware characteristics. For example, the evaluation characteristics of a disk subsystem are seek time, latency time, and transfer rate. The Resource Correction Factor (RCF, which is more fully explained in Appendix A) is the ratio of a baseline machine characteristic to the same characteristic of the target machine. Associated with each RUF is an RCF.

The Machine Conversion Factor for two computer systems operating in the serial mode (MCFS) is the ratio of time it takes the systems to execute the same program. The MCFS expressed mathematically is:

$$\mathrm{MCFS}=\frac{\mathrm{RUF}_1+\mathrm{RUF}_2+\mathrm{RUF}_3+\mathrm{RUF}_4}{\frac{\mathrm{RUF}_1}{\mathrm{RCF}_1}+\frac{\mathrm{RUF}_2}{\mathrm{RCF}_2}+\frac{\mathrm{RUF}_3}{\mathrm{RCF}_3}+\frac{\mathrm{RUF}_4}{\mathrm{RCF}_4}}$$

where

RUF_k = proportion of time spent in kth state by baseline machine.

$(\mathrm{RUF}_k/\mathrm{RCF}_k)$ = proportion of time spent in kth state by target machine.

By definition the sum of the RUFs for the baseline system is unity and the MCFS equation reduces to:

$$\mathrm{MCFS}=\left(\sum_{K=1}^{4}(\mathrm{RUF}_k/\mathrm{RCF}_k)\right)^{-1} \qquad (1)$$

Example 1: Given the following:

RUF_1 $(CPU\cdot\overline{I/O})=.4$
RUF_2 $(CPU\cdot I/O)=.1$
RUF_3 $(\overline{CPU}\cdot I/O)=.3$
RUF_4 $(\overline{CPU}\cdot\overline{I/O})=.2$

compute the MCFS for a CPU four times faster ($RCF_1=4$) than the original CPU. Utilizing the above equation:

$$MCFS=((.4/4)+.1+.3+.2)^{-1}=1.43$$

This implies CPU replacement results in a target system with throughput 1.43 times greater than the baseline system. RUF_3 and RUF_4 are unaffected because the peripheral subsystem is unchanged. The rationale for equating RCF_2 to unity is as follows:

When the CPU and I/O operations are overlapped the effect on RCF_2 is governed by the smaller RCF involved.

Example 2: With the addition of a peripheral subsystem whose transfer rate is twice as fast, compute the MCFS using the information in Example 1.

$$MCFS=((.4/4)+(.1/2)+(.3/2)+.2)^{-1}=2.0$$

In this example the CPU RCF is four and the I/O RCF is two. The smaller of the RCFs governs and RCF_2 is set equal to the I/O RCF.

MULTIPROGRAMING MODE FORMULATION

In the multiprograming mode, core resident programs are contending for computer resources (Central Processor Unit (CPU) and selector CHannels (CHs)). Contention is the need for a program to acquire a computer resource when the resource is unavailable. The following formulation assumes (1) resource contention is a random event and (2) the probability a program requires a resource and the resource is unavailable, is the intersection of the probability of the program desiring the resource and that at least one other program desires the resource. The Degradation Factor (the DF is more fully explained in appendix B) is the proportionate increase in a program's wallclock time attributed to resource contention. (For purposes of this paper wallclock time is the interval of time a program resides in core.) The DF consists of a CPU contention component and CH contention components.

A computer's operating system services I/O requests on a first come, first served basis. Since I/O requests have no priorities, the DF CH contention components for program i are:

$$DF_{i,j}=CH_{i,j}\left(1-\prod_{\substack{k=1\\k\neq i}}^{N}(1-CH_{k,j})\right) \qquad (2)$$

where

$DF_{i,j}$ = program i contention for channel j.
$CH_{i,j}$ = probability program i requires channel j.
$CH_{k,j}$ = probability program k requires channel j.

Both i and k range from 1 to N (number of programs being processed). Once i is set, k then takes on all other values in the range.

The multiprograming model assumes the scheduling algorithm allocates CPU priority equally to all programs. (This model can be modified for a system having CPU prioritized scheduling algorithm). The DF of the CPU contention component for program i is:

$$DF_{i,c}=CPU_i\left(1-\prod_{\substack{k=1\\k\neq i}}^{N}(1-CPU_k)\right) \qquad (3)$$

where

$DF_{i,c}$ = program i contention for CPU. (c is the number of channels plus unity).

CPU_i = probability program i requires the CPU.
CPU_k = probability program k requires the CPU.

(Recall that both i and k range from 1 to N.)

The DF for program i is unity plus the sum of the contention components, which expressed mathematically, is:

$$DF_i=1+\sum_{c}DF_{i,c} \qquad (4)$$

where, as previously defined:

c = number of contention terms which is number of channels plus unity.

The Machine Conversion Factor for a computer system operating in a Multiprograming mode (MCFMP) is the sum of the inverses of the DFs. (See Appendix B for derivation). Expressed mathematically the MCFMP is:

$$MCFMP=\sum_{i=1}^{k}DF_i^{-1} \qquad (5)$$

where

k = number of programs concurrently being processed.

Example 1: Given the following Resource Utilization Factors (RUFs) for a two channel system:

	Program A	Program B	Program C
RUF_1 $(CPU\cdot\overline{I/O})$	.4	.5	.1
RUF_2 $(CPU\cdot I/O)$	.1	.1	.3
RUF_3 $(\overline{CPU}\cdot I/O)$	.3	.3	.1
RUF_4 $(\overline{CPU}\cdot\overline{I/O})$	.2	.1	.5

and with additional information that the ratios of CH1 and CH2 usage for the above programs are 3:1, 1:1, and 1:3, respectively, compute the MCFMP.

Adding $CPU\cdot\overline{I/O}$ and $CPU\cdot I/O$ yields the proportion of CPU usage. Adding $CPU\cdot I/O$ and $\overline{CPU}\cdot I/O$ yields the proportion of total I/O usage. Performing the indicated additions yields the following:

	Program A	Program B	Program C
CPU	.5	.6	.4
I/O (Total)	.4	.4	.4
I/O (CH1)	.3	.2	.1
I/O (CH2)	.1	.2	.3

CH1 contention components are:

$$DF_{1,1}=.3(1-(1-.2)(1-.1))=.08$$
$$DF_{2,1}=.2(1-(1-.3)(1-.1))=.07$$
$$DF_{3,1}=.1(1-(1-.3)(1-.2))=.04$$

CH2 contention components are:

$$DF_{1,2}=.1(1-(1-.2)(1-.3))=.04$$
$$DF_{2,2}=.2(1-(1-.1)(1-.3))=.07$$
$$DF_{3,2}=.3(1-(1-.1)(1-.2))=.08$$

CPU contention components are:

$$DF_{1,3}=.5(1-(1-.6)(1-.4))=.38$$
$$DF_{2,3}=.6(1-(1-.5)(1-.4))=.42$$
$$DF_{3,3}=.4(1-(1-.5)(1-.6))=.32$$

Degradation Factors for each program are:

$$DF_1=1+.08+.04+.38=1.50$$
$$DF_2=1+.07+.07+.42=1.56$$
$$DF_3=1+.04+.08+.32=1.44$$

and the MCFMP is:

$$MCFMP=\frac{1}{1.50}+\frac{1}{1.56}+\frac{1}{1.44}=2.00$$

Thus, the multiprogramed system executing three programs has twice the throughput of the same configuration executing in a serial mode.

Example 2: Given the following RUFs common to all programs processed:

$$RUF_1(CPU\cdot\overline{I/O})=.4$$
$$RUF_2(CPU\cdot I/O)=.3$$
$$RUF_3(\overline{CPU}\cdot I/O)=.1$$
$$RUF_4(\overline{CPU}\cdot\overline{I/O})=.2$$

compute the MCFS and MCFMP if the original is replaced by a CPU twice as fast ($RCF_1=2$).
The MCFS calculation is:

$$MCFS=((.4/2)+.3+.1+.2)^{-1}=1.25$$

The "new RUFs" ($\overline{RUF}$s) for the faster machine are:

$$\overline{RUF}_k=(RUF_k/RCF_k)(MCFS) \qquad (6)$$

where

$\overline{RUF}_k$ = proportion of time spent in kth state by faster machine.

Thus:

$$\overline{RUF}_1(CPU\cdot\overline{I/O})=(.4/2)(1.25)=.250$$
$$\overline{RUF}_2(CPU\cdot I/O)=.3(1.25)=.375$$
$$\overline{RUF}_3(\overline{CPU}\cdot I/O)=.1(1.25)=.125$$
$$\overline{RUF}_4(\overline{CPU}\cdot\overline{I/O})=.2(1.25)=.250$$

From the $\overline{RUF}$s the probability a program requires the CPU is .625, and the probability a program requires a channel is .50. Given a 3 to 1 ratio for CH1 usage to CH2 usage, (CH1 usage is .375 and CH2 is .125), compute the MCFMP for three programs concurrently processed.
The CH and CPU contention components are:

$$DF_{i,1}=.375(1-(1-.375)^2)=.23$$
$$DF_{i,2}=.125(1-(1-.125)^2)=.03$$
$$DF_{i,3}=.625(1-(1-.625)^2)=.54$$

Since all programs have identical RUFs, the DF for each program is:

$$DF=1+.23+.03+.54=1.80$$

The MCFMP for a system where all programs have identical RUFs is:

$$MCFMP=(MCFS)(k/DF) \qquad (7)$$

where

k = number of programs concurrently being processed.

For this example the MCFMP is:

$$MCFMP=1.25(3/1.80)$$
$$MCFMP=2.08$$

This example demonstrates that, given a set of representative system RUFs and approximating the average number of programs concurrently processed, the MCFMP of a system can be determined.

FORMULATION REFINEMENT

If the initial benchmarks are executed in both a serial and multiprogramed mode, equation 4 is written as:

$$\overline{DF}_i=1+(T)\left(\sum_c DF_{i,c}\right) \qquad (4')$$

where

T = a proportionality constant

Replacing DF with $\overline{DF}$ equation 5 becomes:

$$MCFMP=\sum_{i=1}^{k}\overline{DF}^{-1} \qquad (5')$$

Having an empirical value for MCFMP equation 5′ is initially solved for T. The MCFMP for the target systems are computed as demonstrated in the multiprograming mode formulation section with equations 4 and 5 replaced by equations 4′ and 5′.

LIMITATIONS

The multiprograming formulation is valid for concurrent processing of at least two and possibly three programs (expected queue lengths are very short). When concurrently processing four or more programs significant queues will form, and a more complex queuing theory formulation is necessary.

RESULTS

From hardware monitoring, the average Resource Utilization Factors (RUFs) and channel usage for Standard Management Information Systems executing on an IBM 360/30 were obtained. These RUFs are:

$\mathrm{CPU}\cdot\overline{\mathrm{I/O}}=.55$
$\mathrm{CPU}\cdot\mathrm{I/O}=.06$
$\overline{\mathrm{CPU}}\cdot\mathrm{I/O}=.18$
$\overline{\mathrm{CPU}}\cdot\overline{\mathrm{I/O}}=.21$

Channel 1 accounts for 78 percent of I/O activity and channel 2 accounts for 22 percent.

Using an instruction mix it was determined that the average instruction time for an IBM 360/30 is 23.6 microseconds; for an IBM 360/40 13.6 microseconds; and for an IBM 360/50 6.5 microseconds. The following chart compares the calculated Machine Conversion Factor (MCF) using the model, to the actual benchmark MCF.

System	Calculated MCF (T=1)	Calculated MCF (T=1.3)	Benchmark MCF
30	1.0	1.0	1.0
30MP (2 programs)	1.4	1.3	1.3
40	1.3	1.3	1.3
40MP (2 programs)	2.0	1.9	1.7
50	1.7	1.7	1.6
50MP (2 programs)	2.8	2.6	2.6

The calculated MCFs were used to validate hardware requirements at 36 Army Data Processing Installations in order to initiate a procurement for the necessary upgrades.

APPENDIX A

RESOURCE CORRECTION FACTORS

A Resource Correction Factor (RCF) is the ratio of a baseline measurement characteristic to the measurement of the same characteristic of the target computer system. For example, calculation of a computer system's throughput for replacement of a disk subsystem requires two RCFs. One RCF is the ratio of transfer rates and is used when I/O is occurring; the other RCF is the ratio of seek time plus latency time and is used when the device is busy only and no I/O is occurring.

Calculation of a computer system's throughput for replacement of a Central Processor Unit (CPU) requires an analysis of software. Knowing the instruction repertoire of a computer, the incidence of use of the various instructions can be obtained by software monitoring. To obtain a CPU RCF:

(1) Multiply each instruction's frequency of use by the instruction's execution time.
(2) Sum the results of step one.
(3) Take the ratio of step two for the baseline CPU to the target CPU.

Example: Given the following:

		BASELINE CPU		TARGET CPU	
INSTRUCTION	FREQ	TIME	(FREQ) (TIME)	TIME	(FREQ)(TIME)
Load	8	4	32	1	8
Store	4	3	12	2	8
Branch	6	7	42	5	30
Add	2	2	4	2	4
			90		50

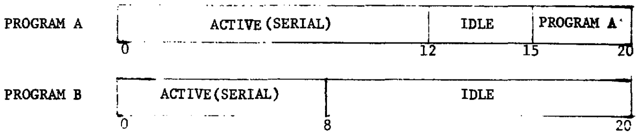
The CPU RCF is 90/50 = 1.8

APPENDIX B

DEGRADATION FACTOR

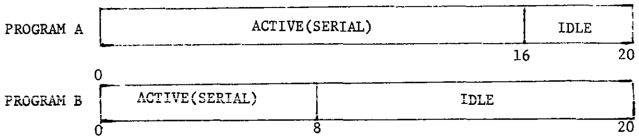
Multiprograming is the concurrent processing of two or more programs and the sharing of computer resources by these programs. Multiprograming increases wallclock time (time a single program resides in core) and increases total computer system throughput. The Degradation Factor (DF) is the ratio of wallclock time for a program processing on a computer operating in a multiprograming mode to a serial mode. The Machine Conversion Factor for the Multiprograming mode (MCFMP) is the increase in system throughput for a system operating in a multiprograming mode opposed to a serial mode. The MCFMP can be calculated by taking the sum of the inverses of the DFs.

Example 1: Given that programs A and B executed with serial wallclock times of 12 units and 8 units respectively, and multiprogramed wallclock times of 15 units and 20 units respectively, compute the DFs and the MCFMP.



The DF for program A is 15/12=1.25 and the DF for program B is 20/8=2.5. The MCFMP is (1/1.25)+(1/2.5)=1.2. The multiprogramed system has 1.2 more throughput than the serial system.

Example 2: Assuming both programs in the previous example required exactly 20 units of wallclock time when multiprogramed and each program retained its ratio of active to idle time, compute the MCFMP.



The total active (serial) processing time of programs A and B, divided by the wallclock time is the MCFMP. The MCFMP is (16+8)/20=1.2, thus verifying the method used in Example 1.

A queueing network model for the effect of data compression on system efficiency*

by ALAN JAY SMITH
University of California at Berkeley
Berkeley, California

ABSTRACT

Data compression is often employed in data base systems to reduce the volume and therefore the cost of large online data bases. The use of data compression is normally assumed to imply a tradeoff—storage space is decreased in return for which the CPU is required to spend time coding and decoding the data, with a consequent decline in system throughput. We employ queueing network models with classes of customers to show that the effect of data compression on system efficiency can be calculated. Our calculations indicate that under some circumstances, data compression may actually increase system throughput by decreasing input/output transfer time and/or increasing the useful processing per data record. We formulate and solve several models to indicate the power of our technique.

INTRODUCTION

Large data base systems exist or are being developed for applications including library information retrieval, such as the Spires system at Stanford University and the Intrex System[1] at M.I.T., for business data management, such as IBM's IMS system[2] and for military applications such as the Navy Fleet Material Support Office.[3] In all data base systems, the cost of the online storage devices, be they disks, drums or more exotic devices such as the photostore, can be expected to be a very large fraction of the hardware cost of the system. In standard computer systems, examination of manufacturers price sheets suggests that the memory hierarchy accounts for about one half of the cost of the hardware; in a data base system the storage devices can be expected to account for even a larger fraction of the system cost.

Because of the high cost of maintaining information online in a computer system, the application of data compression has become increasingly attractive. Normally, the use of data base compression implies a tradeoff; the decrease in storage space and cost is achieved only at a substantial expense in coding and decoding the data base. In this paper we develop a model for the effect of data compression on system efficiency. We show that under certain circumstances, system throughput may actually be increased through the use of data compression.

In the next section of this paper we briefly review some of the more common and effective methods of compression that are applicable to computer files. The third section summarizes the mathematical solution to a very general class of queueing networks. We analyze a simple model of data compression in the fourth section and present numerical results. Other, more sophisticated models that take into account more of the characteristics of real systems are presented in the fifth section and the mathematical formulation for some of these models is given.

REVIEW OF DATA COMPRESSION METHODS

Information theory

In his classic paper in 1948, Claude Shannon created the subject of information theory.[4] He defined entropy as a measure of information and showed how to estimate mathematically the amount of information contained in a message or set of messages. Although his formulation is completely general, the direct application of his results is difficult; most data compression schemes employ simple but effective redundancy removal techniques that are not directly derived from (although they are certainly related to) information theory considerations. Some of these techniques are briefly discussed below.

Null suppression

Many files are largely composed of "nulls," zeros in numeric fields and blanks in character fields. These nulls are inserted either because of empty fields or because the field length is larger than the data item

* Research sponsored by the Joint Services Electronics Program Contract F44260-71-C-0087.

it contains. Simply omitting these nulls (and inserting field separators where necessary) can eliminate a great deal of redundancy and can substantially compress the file.

Run length coding

Run length coding involves coding runs of identical data items (or groups of data items) as a count of the number of occurrences followed by a sample of the item(s). Thus a run of five zeros might be encoded as "50." This technique is most effectively employed to run length encode nulls (zeros or blanks) but may also be useful when other characters are repeated.

Statistical encoding

Statistical encoding techniques are directly derived from information theoretic considerations and take advantage of the varying probabilities of occurrence of characters or groups of characters. Shorter codes are used to represent the most common items and longer codes the less frequent. Huffman devised a simple and optimum method of statistical encoding. Huffman coding is almost always used only on a character by character basis for ease of implementation and thus generally produces only limited data compression.

Pattern substitution

One of the most effective methods of compression is pattern substitution. Character or digit strings of length greater than one are replaced with shorter strings; these shorter strings can be assigned using Huffman's algorithm. Thus coding and decoding dictionaries are created and are used to translate to and from the compressed form.

Front and back compression—differencing

When a field of a set of records is stored in sorted form, only the differences between records need be retained. Thus in the phone book, the whole page of "Smith's" could be shortened by only giving first and middle names. If the loss of information is no problem, as in index structures, only that part of a record that serves to distinguish it from its neighbors need be retained. Thus the trailing part(s) of a record field can often also be deleted.

QUEUEING NETWORKS WITH CLASSES OF CUSTOMERS

In this section we summarize the mathematical solution to a very general class of queueing networks. The material is entirely drawn from Baskett et al.[5] and the reader is referred to that paper for a more complete presentation.

A queueing network is a model of the following type: There are a number of service stations (e.g., computers, toll booths, checkout counters, work stations), each with one or more individual servers. Behind each service station (we use the term server interchangeably with service station except where confusion is likely to result) a queue forms. Customers arrive in the queue behind the service station, are served according to one of the queueing disciplines discussed below, and then each customer, with a certain probability, either joins the queue behind another server or leaves the system. Customers can also arrive at a given rate at certain servers from outside the system.

The generality of the queueing network model can be extended by allowing customers to be of different types (from different "classes") and by allowing each type of customer to have different routing probabilities and different service requirements. Our models will depend heavily on the use of classes of customers.

Servers (service stations) may be of one of four types for the product form solution (of equation (2)) to the queueing network to be valid; we present only those three types of servers that are relevant to our models.

Types of servers

Type 1: There is a single server at a service center, the customers are served in first come, first served order, all customers have the same service time distribution at the service center and this distribution is the negative exponential. The service rate may depend on the number of customers queued and waiting for the server.

Type 2: There is a single server at the service center and the processor is shared among all customers waiting for the processor (i.e., each customer receives service at a rate of 1/n when there are n customers). The service time distribution can vary by customer class and may be arbitrary. Type 2 servers are frequently used to model the CPU in a computer system and represent quite accurately the operation of a processor that is scheduled in a round robin manner with a short quantum.

Type 3: The number of servers in the service center is greater than or equal to the maximum number of customers that can ever be queued at this server. Each class of customer may have a distinct service time distribution of arbitrary form. Users at their teletype terminals are well described as Type 3 servers.

All service distributions for Type 2 and Type 3 servers must have rational Laplace transforms, but this requirement is no barrier since any non-pathological distribution can be approximated arbitrarily closely by one with a rational transform.

Let us define $1/\mu_i(j)$ to be the mean service time at the i^{th} server, which is of Type 1, when there are j customers queued or in service. Let $1/\mu_{ir}$ be the mean service time of a customer of class r at server i for a server of Type 2 or 3. μ is then the "rate" of service, and is equal to the reciprocal of the mean.

$p_{i,r;j,s}$ is defined as the probability that a customer of class r, when it completes service at server i will change to class s and go next to server j. Let n_{ir} be the number of customers of class r at service center i. Let $n_i = \sum_{r=1}^{R} n_{ir}$. Let N be the number of customers, R the number of classes and M the number of service stations.

Our models will have exactly one chain; that is, a customer at server i in class r can in some manner reach server j and be in class s if and only if it is possible for a class s customer to ever be at server j. Thus all possible customer states (i,r) communicate with all others. In this case we can define a set of equations which specify the variables e_{ir} as follows:

$$\sum_{\forall i,r} e_{ir}p_{i,r;j,s} + q_{js} = e_{js} \quad \text{for all j, s} \tag{1}$$

where q_{js} is the rate of customer arrivals of class s to server j from outside the system (exogenous arrivals). If $q_{js}=0$ for all j, s, then the e_{ir} are determined to within a multiplicative constant; otherwise they are specified uniquely. The e_{ir} can be interpreted as the relative (or absolute) arrival rate of class r customers to service center i.

The steady state solution for the queueing network we have described has a very convenient form; the overall steady state solution is the product of terms for each server in the network. Let y_i be the state of the i^{th} server (number of customers, etc., see below). Then

$$P(S=y_1,y_2,\ldots,y_N) = Cd(S)g_1(y_1)g_2(y_2)\ldots g_N(y_N) \tag{2}$$

where C is a normalizing constant, d(S) is a function of the number of customers in the system and g_i is a function depending on the type of server i. If service center i is of Type 1 then

$$g_i(y_i) = n_i!\left[\prod_{r=1}^{R}\frac{1}{n_{ir}!}[e_{ir}]^{n_{ir}}\right]\prod_{j=1}^{n_i}\frac{1}{\mu_i(j)} \cdot \tag{3}$$

If service center i is of Type 2, then

$$g_i(y_i) = n_i!\prod_{r=1}^{R}\frac{1}{n_{ir}!}\left[\frac{e_{ir}}{\mu_{ir}}\right]^{n_{ir}} . \tag{4}$$

If service center i is of Type 3, then

$$g_i(y_i) = \prod_{r=1}^{R}\frac{1}{n_{ir}!}\left[\frac{e_{ir}}{\mu_{ir}}\right]^{n_{ir}} . \tag{5}$$

We note that only the mean service times $(1/\mu)$ appear in the above expressions; thus the steady state distributions are independent of the form of the service time distributions for customers at servers of Types 2 or 3.

We will, for simplicity, consider only models in which the number of customers (N) is fixed. This represents a situation in which the degree of multiprogramming is constant. The extension to open systems (ones with exogenous arrivals and departures) is straightforward, but it adds only additional parameters to our models and provides no new information. For such a closed system, d(S) = 1.

The normalizing constant may be calculated as follows:

$$C = 1/\sum_{\text{all feasible S}}[g_1(y_1)g_2(y_2)\ldots g_N(y_N)]. \tag{6}$$

That is, the sum of all steady state (equilibrium) probabilities must be 1. The sum is taken over all "possible" states S. Possible states are those in which the total number of customers in the system is equal to the proper figure (in this case N) and all class/server and class/number in class combinations are correct. Thus if it is impossible for a class 3 customer to be at server 5, then any state with a class 3 customer at server 5 is not feasible, and the summation must not include such a term.

We note that for open systems, it is possible to get a closed form expression for C, the normalizing constant.

Prior to the development of solutions for queueing networks with classes of customers, queueing networks were limited to one class of customer. It was thus impossible to differentiate among customers when they arrived at a server. By allowing each customer to be of a different class, it is possible to route each customer differently in the network. By allowing customers to change classes, it is possible to route the same customer through the same service center more than once and to have the customer display different behavior, both in service requirements and in departure branching probabilities. In the paper by Baskett et al.,[5] it can be seen that this ability to differentiate among customers yields measurably different steady state probabilities in comparison with the approximations employed previously.

A SIMPLE MODEL FOR DATA BASE SEARCH

With a single, FCFS, storage device

In this section we will describe, solve and present numerical results for what is a simple model for data base operation with compression. We have chosen this particular model for two reasons: It illustrates virtually all of the interesting features of our technique and our ideas and it contains a small number of parameters that can be varied intelligently. Formulation of more sophisticated or complex models is straightforward and two such are presented in the next section.

We will consider a data base system in which the only operation to be modeled is the search operation. The system will be multiprogrammed to a constant factor of N. Each of the N processes (customers) will follow the following sequence of steps repetitively:

1. Computation—The CPU will perform the necessary computations on the record just retrieved, and then will perform the operations necessary to initiate the next read operation (process in class 2).
2. The process will be suspended while a record is read from the secondary storage device and transferred to a buffer area in main memory (process in class 1).
3. The CPU will perform the decompression operations necessary to translate the record into decompressed form (process in class 1). Operation continues again at Step 1.

This sequence of operations is diagrammed in Figure 1 where a number of useful parameters of the model are also shown. We define these parameters below as well.

$1/\mu_1$ The mean time to transfer a record from secondary storage to main storage.

$1/\mu_{21}$ The mean time to decompress a stored record.

$1/\mu_{22}$ The mean time to perform the computations in Step 1 above.

Server 1, the secondary storage device, will be modeled as a Type 1 server. That is, customers will be serviced in first come, first served order and the service time distribution will be the negative exponential. This formulation should be an adequate approximation for any I/O device that services the customers in the order of arrival with no parallel operation (e.g., disk, drum, extended core storage).

Server 2, the CPU, will be modeled as a Type 2 server; the customers will be serviced in processor sharing model. We note that since the model yields the same steady state probabilities independent of the service time distribution, the highly skewed service time distributions often found in computer systems cause us no inconvenience. Such skewed distributions are, in fact, unlikely for the applications that we discuss.

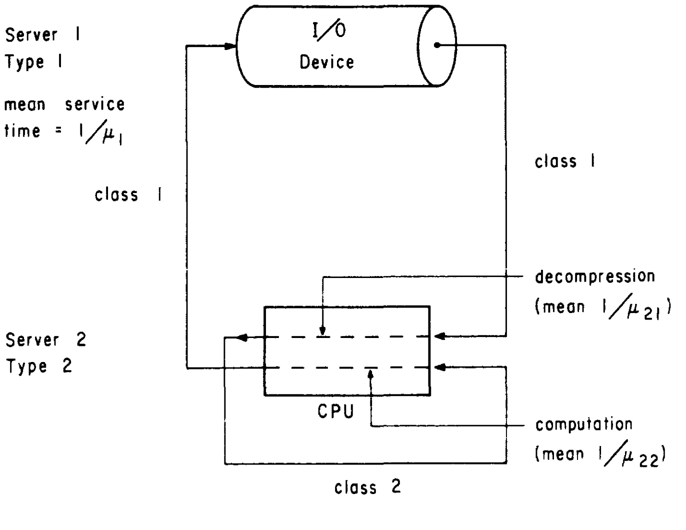


Figure 1—Model 1

From the above descriptions, it is evident that for the transition probabilities we have:

$$\begin{aligned} &p_{1,1;\,2,1}=1\\ &p_{2,1;\,2,2}=1\\ &p_{2,2;\,1,1}=1\\ &p_{i,r;\,j,s}=0 \text{ for all other i, j, r, s.}\end{aligned} \tag{7}$$

From equation (1) for the e's, it is clear that the e's are all equal and may vary (jointly) by a multiplicative constant. For convenience we choose that constant so that

$$e_{i,r}=1 \text{ for all i, r.} \tag{8}$$

For only two servers, the product form solution is of the form

$$P(S)=Cg_1(y_1)g_2(y_2) \tag{9}$$

where

$$\begin{aligned} g_1(y_1)&=n_1!\left[\prod_{r=1}^{2}\frac{1}{n_{1r}!}\right]\left[\prod_{j=1}^{n_1}\frac{1}{\mu_1}\right]\\ &=\frac{1}{\mu_1^{n_1}}\end{aligned} \tag{10}$$

and

$$g_2(y_2)=\frac{n_2!}{n_{21}!n_{22}!\mu_{21}^{n_{21}}\mu_{22}^{n_{22}}}. \tag{11}$$

Thus

$$P(S)=C\frac{n_2!}{\mu_1^{n_1}n_{21}!n_{22}!\mu_{21}^{n_{21}}\mu_{22}^{n_{22}}}. \tag{12}$$

The computation for the normalizing constant is indicated in equation (6).

The parameter of interest in this model will be the fraction of time that the CPU spends processing class 2 customers, since that is the computation that is independent of the amount of compression that is employed. If we assume that this computation (on class 2 customers) represents the "useful" work of the system, then we are actually measuring the throughput of the system. The figure of merit is thus

$$\text{throughput}=\sum_{\substack{\forall\, S \text{ such that}\\ n_2>0 \text{ and } S\\ \text{is feasible}}} P(S)\cdot\frac{n_{22}}{n_2}. \tag{13}$$

Although it is simple to write down a closed form expression for the throughput of the system, the large number of terms prevents any clear or easy interpretation of the resulting formula. Symbolic optimization techniques, which are applicable to the models we describe in this section, are likewise infeasible. Attempts to determine the optimum degree of compression, where the effects of compression are indicated in equation (13), were unsuccessful using the Macsyma[6] symbol manipulation facility. For this reason we present only numerical results, as indicated in Figures 2, 3, 4, 5, 6, 7, 8 and 9.

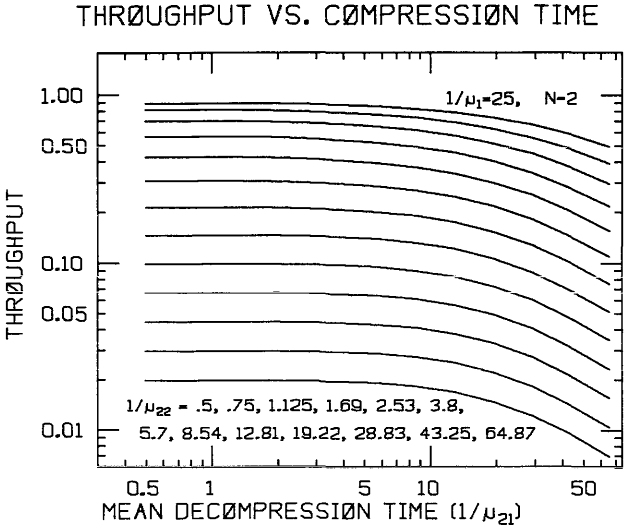

Figure 2

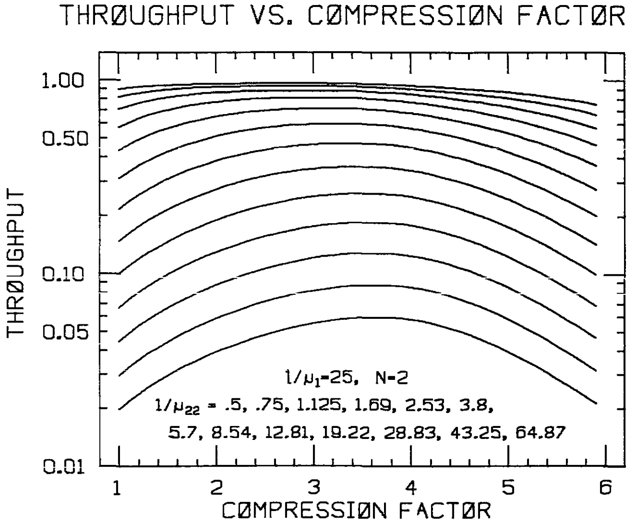

Figure 4

In Figures 2 through 5, the mean service time at server 1 (the secondary storage device) has been taken to be 25 milliseconds. Figures 2 and 4 display computations for a system with a degree of multiprogramming (N) of two; the same data is presented in Figures 3 and 5 for a multiprogramming level of five.

Both Figures 2 and 3 give the system throughput, measured as the useful processor utilization (equation (13)), for a system in which we have varied the mean decompression time ($1/\mu_{21}$) for different values of the mean useful processing time ($1/\mu_{22}$). The values of $1/\mu_{22}$ were varied from .5 to 64.87 milliseconds; each value differs from neighboring values by a factor of 1.5. We note that in the computations presented in Figures 2 and 3, we have allowed ourselves no benefit from the use of compression; compression has neither increased the amount of useful processing per record nor decreased the amount of time to transfer a record. Despite this, it is only when the decompression time exceeds about one-third of the input/output service time (transfer+latency) that the system throughput declines significantly. This decline, and the point at which it begins, is surprisingly independent of the amount of normal processing required per record ($1/\mu_{22}$). This is accounted for by three observations: for small useful processing, the system has substantial excess capacity available for compression and decompression, for large useful processing, the compression

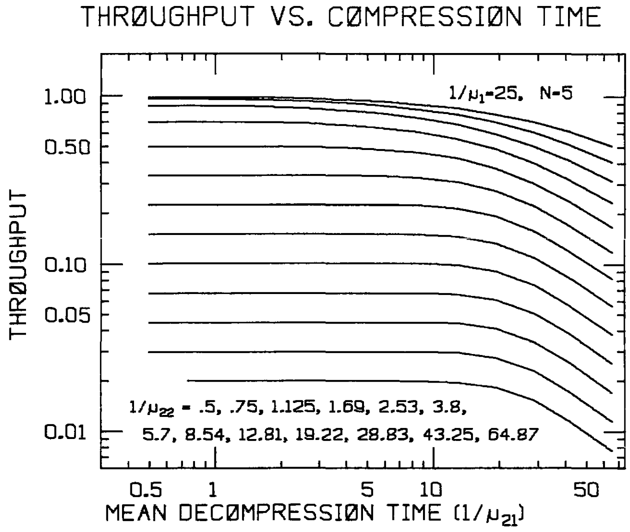

Figure 3

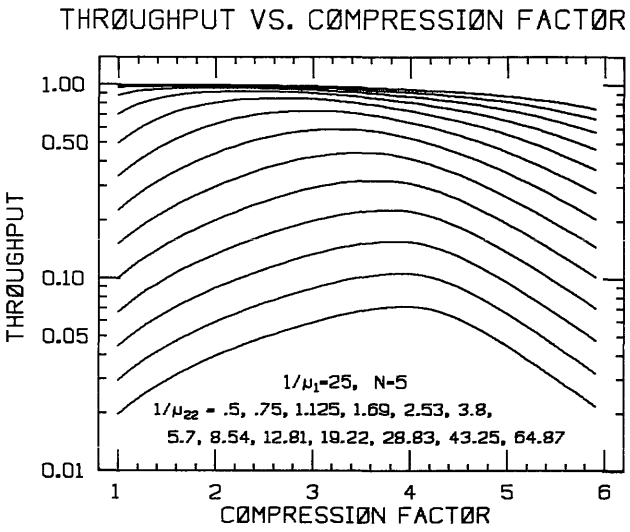

Figure 5

time is a small added increment and is only marginally apparent. In both cases, the effect of the decompression is masked by the input/output service time.

In computing the data displayed in Figures 4 and 5, we have taken a rather more optimistic attitude. We assume here that with the addition of data compression, the size of the record transferred and the consequent input/output service time is unchanged. The information content of the record is therefore increased by a factor equal to the degree of compression D. The usefulness of this latter effect applies to those cases in which we are performing a search; simple lookup operations to a known location within a record result in no increase in useful processing time when the record content is increased. We will let $1/\mu_{22}{}^*=D/\mu_{22}$, where $1/\mu_{22}{}^*$ is the effective mean useful processing time; on the figures we give only the values of $1/\mu_{22}$, which are unadjusted for the compression factor.

The value for the mean decompression time, $1/\mu_{21}$, was computed as follows:

$$1/\mu_{21}=e^{D-1}-.9. \qquad (14)$$

This expression (equation (14)) represents our intuitive idea of the cost of data compression; we have no set of measurements to justify it. We can observe its reasonableness when we consider the experiments by Shannon.[7] Shannon attempted to measure the information content of English. When considered on a letter by letter basis, English requires about 4.14 bits/letter for optimum encoding; for equifrequency coding, it requires 4.7 bits/letter. When coded in groups of two letters (digrams), English needs 3.56 bits/letter. Coding English word by word required about 2 bits/letter. Shannon then conducted experiments with human subjects in which he asked them to predict the next letter of a text, given the preceding letters. This experiment yields a figure of about 1 bit/letter. We observe that each additional reduction of text size required substantially more processing time and larger tables; the final and most effective form of compression involved the long range syntactic structure of English and its semantic content as well. Thus an exponential increase in compression/decompression time with an increase in the degree of compression is reasonable.

It can be seen from both Figures 4 and 5 that the use of compression has resulted in an increase in the system throughput of better than a factor of two for the best value of the degree of compression. The relation of the effect of compression to throughput is most evident in Figure 5 where the peak in each curve moves to the left as the value of $1/\mu_{22}$ increases; compression becomes increasingly less useful as the system utilization climbs until for almost full utilization compression is of no use at all; it simply appears as overhead.

We observe in comparing Figures 2 to 3 and 4 to 5 that the change in the degree of multiprogramming has almost no effect; the shape of the curves is only slightly changed as are the numerical values displayed. This effect can be accounted for by remembering that the bottleneck in the system is the input/output device, which is a first come, first served, server.

A many spindle parallel service system

In our model, which we analyzed earlier, we postulated a single secondary storage device which processed requests for information in a first come, first served manner. Such systems exist; an example is the Ingres System[8] which currently uses a single spindle disk drive to hold all data files. At the other end of the spectrum, one can imagine a system with a very large number of spindles, overlapped seeks, drums with sector queueing and multiple channel controllers to minimize channel interference.[9] We can approximate the operation of such a system with a very simple modification to our model of Figure 1. We let server 1, the secondary storage device, be of Type 3 rather than Type 1. A Type 3 server is one in which the number of individual servers at the service station equals or exceeds the number of customers in the queueing network. For a large number of spindles and a small degree of multiprogramming, this provides an excellent approximation which allows great computational efficiency.

We replace the function $g_1(y_1)$ as defined in equation (10) with the function $g_1(y_1)$ as defined in equation (15), below:

$$g_1(y_1)=\frac{1}{n_1!\mu_1^{n_1}}, \qquad (15)$$

$g_2(y_2)$ is as defined in equation (11); thus the expression for the state probability is

$$P(S)=C\frac{n_2!}{n_1!n_{21}!n_{22}!\mu_1^{n_1}\mu_{21}^{n_{21}}\mu_{22}^{n_{22}}} \qquad (16)$$

where the normalizing constant C is defined as in equation (6).

Figures 6, 7, 8 and 9 correspond to Figures 2, 3, 4 and 5, but employ the model formulation of this section. As before, the mean secondary storage fetch time is 25, the mean useful processing time is varied from .5 to 64.87 and the degree of multiprogramming (N) takes on the values 2 and 5.

Figures 6 and 7 provide an interesting contrast to Figures 2 and 3 in two respects. We see that the throughput drops off almost immediately with the introduction of compression; a dropoff that wasn't apparent until the mean decompression time reached approximately 8 in Figures 2 and 3 is apparent for values as small as 2 in Figures 6 and 7. This effect is expected; the secondary storage device was the bottleneck in the system in our earlier model, but it is much less so here. Compression, therefore, has a far more deleterious effect.

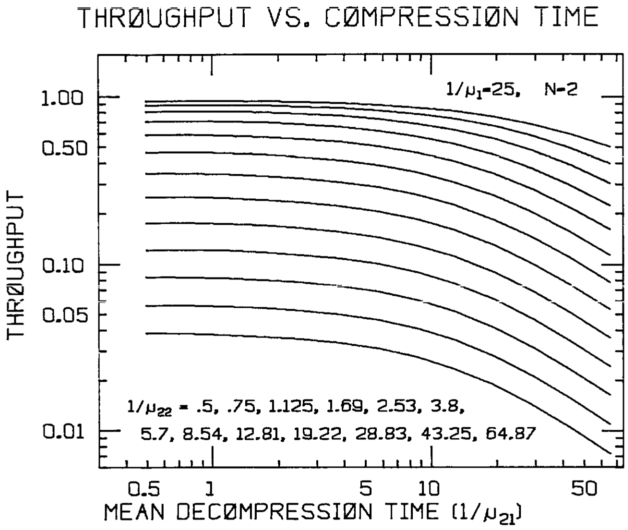

Figure 6

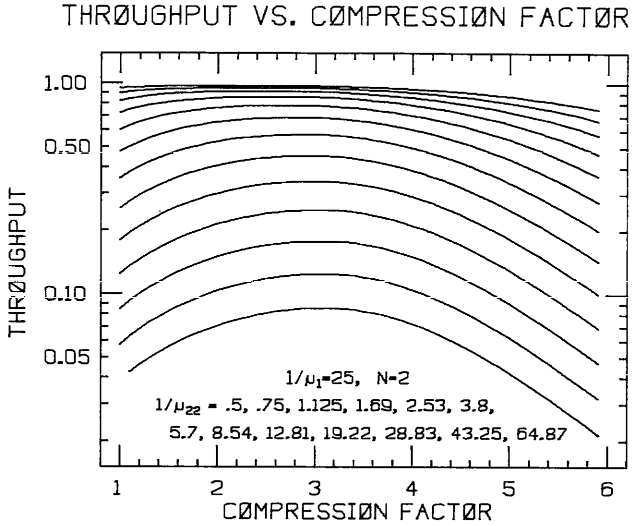

Figure 8

The ability of the storage device to process requests in parallel also introduces a difference between Figures 6 and 7 that wasn't apparent when comparing Figures 2 and 3. The increase in the degree of multiprogramming has resulted in a substantial increase in the system throughput.

The differences between Figures 2 and 3 and Figures 6 and 7 are repeated when one compares Figures 4 and 5 with Figures 8 and 9. The optimum degree of compression has decreased, since the system very much reflects the effect of the processing time required for decompression. This is most pronounced in Figure 9 in which the system can be seen to attain high throughput through multiprogramming to a degree of five. A large increase in throughput is also observed when the degree of multiprogramming increases in going from Figure 8 to Figure 9.

Conclusions

The model described in this section has given us insight into the effect of data compression on system operation. It can be seen that when the processing time required for data compression is sufficiently small, system performance will only deteriorate slightly. When one takes into account the possible increase in processing time per record fetched when compression is introduced, system throughput may increase very substantially. By substituting into our model the

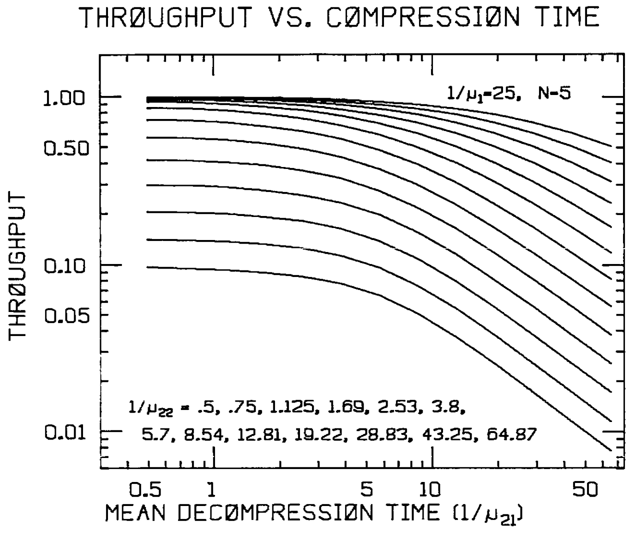

Figure 7

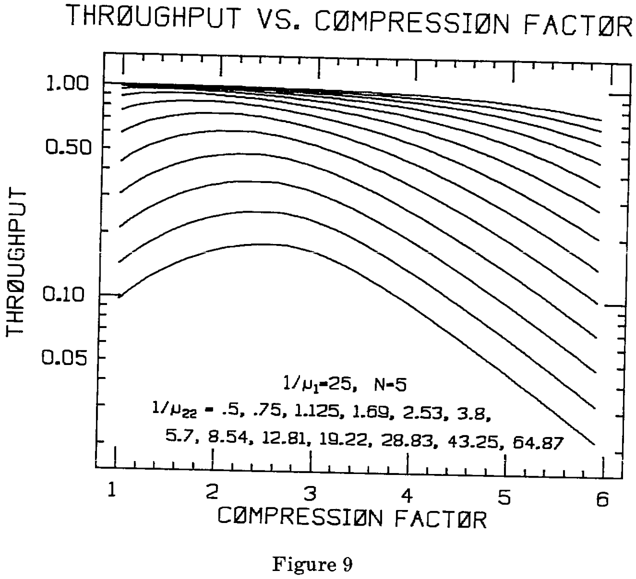

Figure 9

measured values for μ_1, μ_{21}, μ_{22} and N, one can obtain a good estimate of the exact effect of data compression.

In addition to giving us useful results, our analysis has provided a very simple example of a general and powerful technique; that of system modeling with queueing networks with classes of customers. In the next section we indicate some of the power of our techniques with further models.

OTHER MODELS

In the last section we presented a model and its solution for the operation of a data base system using data compression. In this section we describe two more models, of increasing complexity, which capture features often found in data base systems. Our purpose is to indicate the generality that the queueing network formulation for the efficiency problem permits and to demonstrate the ease with which a system of substantial complexity can be modeled.

Both of the models of this section will be primarily concerned with update operations. The first will assume, as did the model of the previous section, that the file records can be located in one operation; the second model of this section will consider the use of a tree structured index.

Model 2

Every process will repetitively follow the following sequence of steps:

1. Perform whatever computation is necessary to choose a record to read (process in class 1).
2. Read a record from the I/O device (class 1).
3. Decompress the record just read (class 2).
4. Perform any desired computations and update to this record (class 3).
5. Recompress the record after computation and updating is complete (class 4).
6. Write the record back into the I/O device (class 2).

A possible extension to this model which may be straightforwardly modeled is one in which, with a certain probability p, the update of the record caused it to expand in size by an amount sufficient to require that an overflow record be written.

In Figure 10 we diagram Model 2 as we have described it.

The solution to this model is simple. The e's (of equation (1)) are again equal to 1, since all of the $p_{i,r;j,s}$'s are equal to one.
Then

$$g_1(y_1) = \frac{n_1!}{n_{11}!n_{12}!\mu_1^{n_1}} \tag{17}$$

and

$$g_2(y_2) = \frac{n_2!}{n_{21}!n_{22}!n_{23}!n_{24}!\mu_{21}^{n_{21}}\mu_{22}^{n_{22}}\mu_{23}^{n_{23}}\mu_{24}^{n_{24}}} \tag{18}$$

The same computations as were used in the previous section suffice to determine the normalization constant C. The figure of merit becomes the fraction of time the CPU spends servicing customers in classes 1 and 3. Therefore, we determine

$$\sum_{\substack{\forall S \text{ feasible} \\ n_2>0}} \frac{n_{21}+n_{23}}{n_2} P(S) \tag{19}$$

which may be calculated quickly on a computer.

It is possible to take into account additional complexities in the operation of the system and we indicate one such possible model in Model 3. This model represents a system with three secondary storage devices, each of which may have a different service rate. The records are stored using a tree structured index, as is used by IBM in its ISAM access method.[2] The index in the case of this model is two levels deep; thus three read operations are needed to find a record, given the primary key. We assume that records, once updated, are rewritten to their original location without the need to access the index structure. The probabilities of finding an index or data record on a given device are specifiable at will in the model. We assume that the placement of index records is independent of the placement of data records; by the addition of a large number of additional classes, this restriction can be removed. The degree of multiprogramming can be specified as preferred or the system can be made into an open one as indicated earlier.

The behavior of a process is as follows:

1. Perform the necessary computations in order to choose a record to read (class 1).

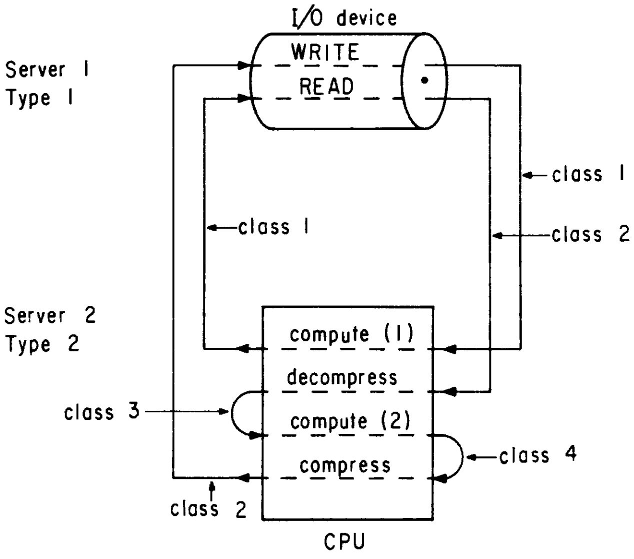

Figure 10—Model 2

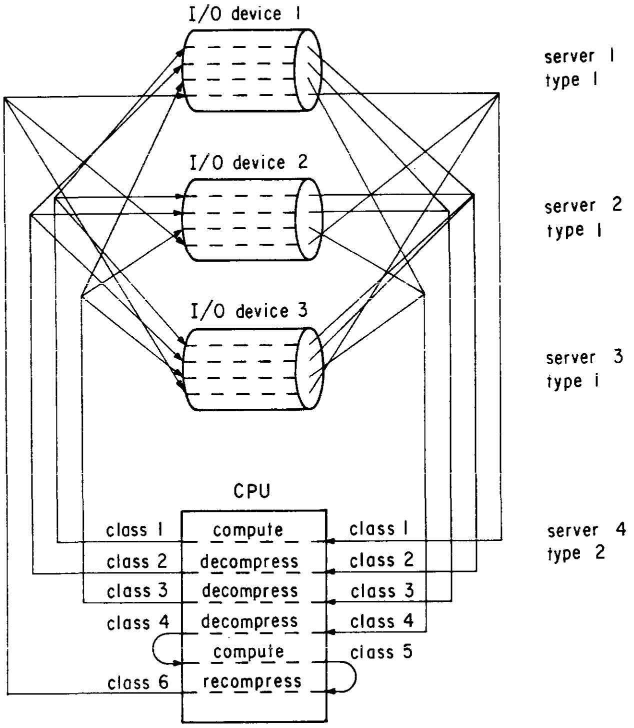

Figure 11—Model 3

2. Read an index record, level 1 (class 1).
3. Decompress the index record (class 2).
4. Read an index record, level 2 (class 2).
5. Decompress the index record (class 3).
6. Read the data record (class 3).
7. Decompress the data record (class 4).
8. Perform whatever update operations and computations on the recently retrieved record that are desired (class 5).
9. Recompress the data record (class 6).
10. Write the data record back on the secondary storage device (class 4).

More complex storage structures and system configurations can easily be dealt with by increasing the number of devices and when necessary, the number of customer classes in order to differentiate between customers and between different operations on the same customer at the same server.

We should mention briefly that as the number of servers and the number of classes of customers increases, the number of system states grows very quickly and it may be computationally infeasible to analyze some systems. Some efficient methods for computing these state probabilities in queueing networks with classes of customers are described by Muntz and Wong.[10]

CONCLUSION

In this paper we have demonstrated the use of queueing networks with classes of customers for modeling the effect of data compression on system efficiency. The simple models developed in section IV indicate that even when compression results in no increase in useful processing time per record or reduction in record retrieval time, it may not significantly impair system performance. When the increase in useful processing per record is considered, compression can be seen to substantially increase system throughput. Earlier, we formulated two more sophisticated models that indicate the generality possible with our modeling technique. We expect that the methods demonstrated in this paper will be of great use to system designers considering the use of data compression for computer file systems.

The Federal Communications Commission and major policy matters affecting computer communication

by FRANK J. MARTIN, JR.
Sutherland, Asbill & Brennan
Washington, D.C.

ABSTRACT

This is a time of great change in FCC regulatory policies affecting computer communication. Over the next several months, the FCC will be called upon to consider and decide many issues which may well shape the nation's data communications for years to come.

This paper briefly reviews the important FCC cases which set the stage for today's policy issues. These include the *Specialized Common Carrier Decision,* the *Domestic Satellite Decision,* the *Interconnect Docket,* and the *Computer Inquiry.*

Then, the paper analyzes the recent FCC decisions and pending cases which are of special significance to the computer community. The AT&T DDS and HI-LO cases are discussed, as are the Satellite Business Systems proposal, the *Telenet v. Tymshare* complaint, and the AT&T DATASPEED 40 decision. The paper closes with a prediction that a new Computer Inquiry seems likely.

INTRODUCTION

This is an era of great upheaval in communications policy. In the *Specialized Common Carrier Decision,*[1] the Federal Communications Commission (FCC) made a deliberate decision to expand the domestic private line common carrier market beyond the two traditional carriers by authorizing new regulated carriers to enter the market and provide a range of specialized land-based data and other services in limited geographical areas. This was followed by the *Domestic Satellite Decision*[2] in which the FCC adopted a similar policy of multiple entry in the vitally important domestic satellite field. This new emphasis on competition in regulated long haul signal carriage has almost certainly increased the pace of innovation and the flexibility available to data communication users and to private line users generally. However, since AT&T dominates the entire communications field, and operates the enormously profitable monopoly interstate switched telephone services, in order to keep competition working the FCC has been forced to tackle the formidable, perhaps impossible, task of trying to assure that AT&T will not cross-subsidize its competitive services by use of monopoly profits, or otherwise use its monopoly control over necessary facilities to drive out competitors. Moreover, recent FCC actions having the effect of permitting IBM, the giant of the data processing industry, to enter the domestic satellite field as part owner of Satellite Business System,[3] means that the FCC has also taken on the task of assuring that IBM will not use its dominance in the closely related data processing field to gain competitive advantages in the communications field.

In the late sixties the FCC began to question and to strike down tariff restrictions designed to perpetuate carrier dominance in the incidental communications service and equipment fields. Thus, in the so-called *Interconnect Docket* (Docket 19528),[4] the FCC has recently striken most of the former tariff restrictions against use of customer-provided data and ancillary terminals. The FCC also eliminated the rest of these restrictions still in effect as to certain voice terminals and equipment.[5].

Although in its *Computer Inquiry*[6] and in subsequent authorizations of suppliers of so-called value-added networks as regulated common carriers,[7] the FCC seemed committed to full support of the traditional carrier restrictions against non-common carrier customer resale of communications circuits obtained from carriers, there are now some indications that in its decision in the *Resale and Shared Use* Proceeding,[8] expected sometime in early 1976, the FCC may relax or eliminate these restrictions altogether so as to permit resale and sharing on an unregulated basis. This could involve free entry of new communications middlemen, and actual detariffing of now regulated value added carriers and others, with resulting freer operation of competitive forces on pricing and the available range of customer choices.

There are also certain pending matters which focus on possible inadequacies of the FCC's Computer Rules and which will in all likelihood require some changes in those rules. In its *Computer Inquiry,* the FCC relied heavily on a distinction between message switching and data processing to distinguish communications services, which regulated carriers will be permitted to provide, from data processing services, which carriers are prohibited from providing except through separately incorporated subsidiaries. In other words, in the *Computer Inquiry,* the focus was on services and not on equipment and terminals. But now the carriers are offering PBX's (Private Branch Exchanges) which incorporate some of the systems architecture and perform some functions of computers. In addition, AT&T in particular is seeking to offer intelligent terminals pursuant to its tariffs. Are such items communications or data processing devices? Is the offering of such devices by carriers the equivalent of offering data processing services? (The FCC ruling on AT&T's DATA-SPEED 40 terminal will be discussed below.) Because of the inherent danger of cross-subsidy and interconnection restrictions by carriers, these are important questions which may affect competition in the terminal and equipment markets. In addition, the FCC is now focusing more precisely on some definitional questions raised in the *Computer Inquiry* as to what constitutes integral and incidental data processing or communications functions in a hybrid offering.

THE NEW SPECIALIZED AND DOMESTIC SATELLITE COMMON CARRIERS

Background: specialized carriers

In 1969 the FCC authorized Microwave Communications, Inc. ("MCI"), to provide point-to-point voice and data communications as a common carrier over microwave facilities between Chicago and St. Louis.[9] AT&T at first refused to provide local loops or local distribution facilities to MCI, claiming that such interconnection would harm AT&T's own communications network. However, the Commission held that AT&T did not prove that harm would result and AT&T was ordered to provide local distribution facilities for its new competitor.[10]

The MCI grant prompted an influx of applications by others seeking to provide specialized communications services in competition with the established common carriers. Instead of deciding each case individually the FCC initiated a rulemaking proceeding in Docket 18920.[11] Comments on all issues were received, including the need for more diverse and specialized data communications services, the impact of competition on the services and rates of established carriers, and the problem of local distribution, etc. Finally, in May of 1971 in its First Report and Order in Docket 18920, the FCC adopted a general policy favoring multiple entry of new specialized carriers. It stood by this decision on reconsideration, and its policy was sustained on appeal by the Ninth Circuit Court of Appeals.

In the *Specialized Common Carrier Decision,* and related new authorizations, the FCC thus established a policy that suppliers of domestic private line services should be expanded beyond the (then) existing nationwide carriers to include new carriers operating in limited geographical areas and offering a range of new specialized services including facilities for higher speed and more reliable data transmission at lower costs. In so doing the FCC stipulated that it would not provide a protective umbrella for the new carriers but that competition would rule the day. Existing carriers were to be allowed to depart from nationwide rate averaging where justified by costs or competitive necessity, and to take full advantage of any real economies of scale resulting from their overall operations, however, existing carriers were not to be permitted, through exercise of monopoly power, to withhold local distribution or other essential facilities from their new competitors, nor were they to be permitted to subsidize their competitive offerings by use of profits from monopoly services to drive their new competitors from the market.

Quality and reliability inquiry

The *Specialized Common Carrier* case, Docket 18920, is still in progress for determination of the measure of protection subscribers and users should be given respecting the quality and reliability of data communications services. The FCC tentatively decided against prescribing minimum standards of technical performance, but has proposed and sought comments on requiring carriers to specify, in standard terminology, the known quality and reliability supposedly available in particular offerings, and to make refunds where these standards are not met. Also, the FCC has suggested that carriers might be urged to publish periodic reports as to quality and reliability achieved, complaints received and refunds made.

In May of 1975, at the instance of one of the new specialized carriers, Data Transmissions, Inc. "Datran"), the FCC clarified the scope of Docket 18920 to include a definition of the scope of specialized services contemplated by the specialized common carrier authorizations.[12] The enormous importance of this is obvious, since it involves the scope of direct carrier competition to be allowed.

Satellite carriers

In the *Domestic Satellite Decision,*[13] the FCC similarly determined that the benefits of satellite technology could best be realized domestically by allowing multiple entry and competition, and by imposing on AT&T, the dominant domestic carrier, and Communications Satellite Corporation ("Comsat"), the international satellite carrier, certain requirements designed to assure that their other important services would not be burdened, and that their dominance in other communications fields would not be used for unfair competitive leverage. Last year, the FCC in essence approved entry in the domestic satellite field by IBM and Comsat General (a subsidiary of Comsat), who have recently announced that they, together with Aetna Life & Casualty Co. will seek FCC authority to establish a $250 million single satellite network for voice, data and image communications, to begin operations in 1979. Customers will access the new satellite network, which will be known as Satellite Business Systems, through 16 to 23 foot dish antennas mounted on their rooftops or elsewhere near their terminal sites, thus eliminating the need for interconnection with other carriers for local distribution or local loops.[14] Thus, the FCC has now taken on the task of supervising fair competition in data communications by the giant of the data processing industry, in addition to the formidable task of policing fair competition by the giant of the communications industry, AT&T.

The major issues.

The task of policing newly authorized competition has to date involved the two major problem areas anticipated by the FCC in the *Specialized Common Carrier Decision,* namely, (1) the problem of local distribution for the new competitors who as a practical matter cannot economically duplicate existing local distribution facilities controlled by AT&T and other telephone companies, and (2) the enormously complex problem of distinguishing between improper cross-subsidy by AT&T of its competitive services with monopoly profits, which was to be prohibited, and merely allowing AT&T to take full and fair advantage of real cost economies of scale, which the FCC promised it would allow.

Local facilities.

The matter of possible anticompetitive withholding of local distribution facilities arose in the Summer of 1973, when MCI advised the FCC that AT&T had refused to interconnect with MCI to provide local distribution through local telephone exchanges, even though AT&T did provide such exchange service in connection with its own competing private line services. The Chief, FCC Common Carrier Bureau advised by letter that under *MCI* and the *Specialized Common Carrier* decisions AT&T was obligated to provide local distribution through its affiliated company telephone exchanges. AT&T answered that it had no intention of participating in a "through service" with MCI or any other private line carrier, and that it would connect to the local exchanges only if state regulatory commissions authorized such interconnection. In a letter order, dated October 4, 1973, the Commission Chairman confirmed the earlier advice of the Common Carrier Bureau Chief, and stated that AT&T should submit its tariffs to the FCC only, and not to state regulatory commissions, since the latter had no jurisdiction of the matter. MCI then requested further clarification because despite the above, some AT&T affiliated companies declined to provide local interconnection for foreign exchange service (FX) or common control switching arrangements (CCSA) offered by the specialized carriers. The Common Carrier Bureau Chief again wrote to AT&T stating that FX, CCSA, and related services were covered by the Commission's October 4 letter order. Court contests were begun,[15] and in December of 1973 the FCC initiated Docket 19896,[16] ordering AT&T to show cause why it was not providing local distribution to the new specialized carriers. In April 1974, the Commission issued its decision in Docket 19896,[17] confirming that interconnection for local distribution had to be provided on a nondiscriminatory basis by AT&T, and this decision was sustained on review by the Third Circuit.[18] In consequence of this, and further tariff proceedings in Docket 20099 which followed, the parties eventually reached agreement on interconnection tariff provisions which the FCC accepted in May, 1975.[19]

The scope of state authority.

The question of the FCC's exclusive authority, as against state regulatory authorities, which was raised by AT&T in the course of its fight to withhold local distribution service from its new competitors, may not be entirely settled, however. The question is now pending review by the U. S. Court of Appeals for the District of Columbia in an appeal from an FCC order.[20] In that case, a petition for declaratory judgment was filed with the FCC by Southern Pacific Communications Company ("SPCC"), one of the new specialized carriers. SPCC claimed that the FCC's decision in Docket 19896, discussed above, entitled it to an order directing Pacific Telephone and Telegraph Co. and Southwestern Bell Telephone Co. to provide local distribution for certain of SPCC's FX and CCSA services, even though SPCC's facilities in question were located wholly within one state. In October 1975, the FCC ruled that it had exclusive jurisdiction to order interconnection since SPCC's facilities, though located entirely within one state, are nevertheless used though in a majority of instances as links in interstate communications. The FCC rejected the telephone companies' contention that interconnection to the local telephone exchanges was within the control of state utility commissions.[21]

Cross-subsidization

The vexatious problem of cross-subsidy has been under study by the FCC for at least 15 years. Recent developments have only resulted in greater urgency for a solution to an old problem. In *Nader v. FCC,* the United States Court of Appeals for the D.C. Circuit severely criticized the FCC's obvious inability to decide cross-subsidy and other important regulatory questions within a reasonable time.[22] In response to the court's order, the FCC was compelled to submit a schedule for decision of the cross subsidy issue in the *Private Line Case* (Docket 18128), and Phase II of Docket 19129 (AT&T Rate Case).

In compliance with that schedule, the Chief of the Common Carrier Bureau on January 19, 1976, issued a recommended decision which, if adopted by the Commission, will perhaps be the greatest setback ever experienced by AT&T before the FCC. In effect, the Bureau Chief held that AT&T has in fact been improperly subsidizing its competitive services with profits from its monopoly MTS and WTS services. For example, in August 1974 AT&T's rate of return on MTS and WATS were found to be 8.9%, and 12.3% respectively, whereas its rate of return in private line telephone and telegraph services were found to be 5.5% and −0.3%, respectively. AT&T's overall interstate rate of return was found to be 8.7%. Thus, in summary, AT&T's competitive service earnings were found to be significantly below its system-wide rate of return of 8.7%, while its monopoly service earnings were found to be significantly in excess of that system-wide rate of return.

The Bureau Chief rejected Bell's contention that fully distributed costs (FDC), the traditional cost allocation method used in rate making, should not be used. He refused to adopt AT&T's proposed "long run incremental cost" method (LRIC), as a substitute for fully distributed costs. Under LRIC, as advocated by AT&T, rates for competitive services would be based on management forecasts of future demand, technological developments, incremental investments and expenses, and competitive developments, while rates for monopoly services would be set at a high enough level to cover all costs, including historical costs, that were not easily identifiable or attributable to specific service offerings. The Bureau Chief did not reject altogether the concept of marginal cost pricing, i.e., pricing based on marginal, as opposed to full historical costs of providing a service, and suggested that Bell should look into further use of this concept in such things as peak/off-peak pricing of monopoly services.

The Bureau Chief recommended that AT&T be ordered to conduct a new comprehensive fully-distributed cost study for a recent one year test period, and to file tariffs which assure the minimum allowable overall rate of return in all categories of services. In early February of this year, in Docket 20376, AT&T's allowed rate of return was again increased from the 8.5% level established in 1972 in Phase I of Docket 19129, to 9.5%.[23]

Exceptions to the recommendations of the Chief of the Common Carrier Bureau were due March 19. Replies are due April 19. Following that the Commission has promised the Court of Appeals to issue its final decision in the *Private Line Case* by August 2, 1976.

In Phase II of Docket 19129, the Commission staff early this year filed proposed findings recommending that AT&T be required to divest Western Electric, and that many reductions be required in its claimed rate base. An initial decision by the Administrative Law Judge is, in response to the Court of Appeals requirement, scheduled for September 15, 1976, and final FCC action is scheduled for April, 1977.

Rate design issues.

But AT&T's reaction to the new competitors has not been limited to the struggle over interconnection to its own facilities, or defending itself against charges of cross-subsidy in preexisting competitive services. In November 1973, AT&T filed its so-called Hi-Lo tariff for its voice grade private line services (Series 2000/3000). By this filing AT&T sought to depart from its tradition of nationwide rate averaging and, in order to compete more effectively with the new specialized carriers, reduced rates on high-density routes, and established separate higher rates for short haul services of 25 miles or less. After an exchange of pleadings challenging and defending the Hi-Lo concept, the FCC designated the case for hearing[24] as to whether the Hi-Lo rates were based on cost savings or on competitive necessity or some other lawful consideration. The rates went into effect, subject to an accounting order and possible refund, on June 13, 1974.

In an Interim Decision issued September 18, 1975,[25] the FCC found that the Hi-Lo concept was reasonable, but that AT&T had not carried its burden of proof as to the reasonableness of the new rates, by showing that the criteria used for designating high-density, low-density and short-haul routes actually reflected network operations and actual costs. It accordingly remanded the case for further hearings on these matters.

But in January, 1976, in a surprising volteface, the FCC ruled that the Hi-Lo rates were illegal.[26] It noted that several parties, including MCI, had complained that AT&T's failure to carry the burden of proving claimed cost justification was grounds for outright rejection of the Hi-Lo tariff, and that in view of AT&T's persistent refusal to produce cost data, etc. in response to interrogatories, it would be a denial of due process to give AT&T a second chance at a further hearing. The FCC said on reconsideration that it did appear that AT&T did not have, and could not develop from records it had maintained, the cost and other data that would be necessary for possible justification of the Hi-Lo tariff. It accordingly decided to strike the tariffs as unlawful rather than allow them to remain in effect while AT&T developed extensive new studies and data in a further effort to justify them. AT&T was given 90 days from publication of the FCC's January decision in the Federal Register to file new tariffs, and 60 additional days to complete the cost justification data specified in the September Interim Decision. The FCC did not order any refund under the accounting order because it concluded that it did not have enough data to prescribe appropriate rates, and because the Hi-Lo tariff had lowered some rates while raising others with the result that most customers did not suffer significant net increase.

AT&T has also responded to the challenge of the new data oriented services of the specialized carriers by its ambitious Dataphone Digital Service (DDS) offering. In early 1973, it sought authority to supplement its existing microwave facilities between New York, Philadelphia, Chicago, Boston and Washington, D. C. to permit transmission of a digital bit stream, ultimately at 1.544 megabits per second, in an unused portion of the baseband on 4 to 6 GHz microwave radio channels. It was recognized that further approval would have to be obtained to before commercial service began under DDS, but even this first foot-in-the-door was vigorously opposed by Datran, MCI, SPCC, and other specialized carriers. The White House, through its Office of Telecommunications Policy (OTP), urged that any approval of DDS should be conditioned on strict requirements prohibiting cross-subsidy or other anticompetitive practices.

The FCC did not want to slow down provision of a needed service, and decided that the issues relating to competitive impact could be better addressed when commercial operating authority was sought. The FCC believed that by that time it would have concluded other important rate-making policy cases such as the *Private Line Case* (Docket 18128) involving cross-subsidy. In March 1974, AT&T filed its tariff to begin DDS commercial service, and offered such service initially between the five cities mentioned above, with expansion expected to 19 additional cities by late 1974. The service offered was two-way simultaneous digital transmission at 2.4, 4.8, 9.6 and 5.6 kilobits per second. The tariff rates were considerably below Datran's rates, and Datran and others argued that AT&T was obviously using its monopoly telephone service profits to subsidize its competitive digital data services. In December 1974, the FCC allowed the tariff to become effective on an experimental basis,[27] but ruled that the low rates would be applicable only in the five cities pending the outcome of an investigation into the lawfulness of those rates which it initiated as Docket 20288. The rates applicable in the additional 19 cities were to be the same as the higher private line rates for 12 months or until the investigation was concluded, whichever occurred earlier. The investigation was to include the cross-subsidy issue and also whether DDS was a class of service separate and distinct from AT&T's higher priced private line services.

The proceedings in Docket 20288 have been characterized by continuing disputes as to the nature and amount of cost data that AT&T should supply in response to the FCC hearing order and interrogatories filed by Datran and the separated trial staff. Proposed Findings were due to be filed in the case on March 15, 1976, and an Initial Decision is expected sometime later this year.

Recently AT&T filed tariff revisions to extend the low DDS rates to the 19 cities as to which higher rates applied for one year under the FCC's December 1974 designation order. The Independent Data Communications Manufacturers Association (IDCMA) and Datran opposed this, asserting that the experimental period had shown an adverse effect on competition and possible predatory pricing by AT&T. The Commission, however, refused to suspend or reject the effectiveness of the low rates in the 19 additional cities.[28] Then the FCC staff asked for reconsideration of this ruling on the ground that AT&T had admitted at a conference that it had not kept and could not produce cost data on DDS to show that the low DDS rates were cost justified. The staff contended that this showed that the tariff filing was unlawful. The Chief of the Common Carrier Bureau declined to reject the filing, but intimated that AT&T's failure to produce cost figures might well cause the DDS rates to be ultimately held illegal.[29] In view of the FCC's action this year in the Hi-Lo case, this does indeed seem quite possible.

CUSTOMER-PROVIDED TERMINAL EQUIPMENT

In June of 1972 the FCC began the so-called *Interconnect Proceeding,* Docket 19528. To assist it in making its determinations, the FCC established a federal/state Joint Advisory Board pursuant to § 410 of the Communications Act.[30]

After comments and reports on specific questions were received,[31] the Joint Board recommended, as an alternative to carrier-supplied connecting arrangements at customer expense, a type acceptance certification program to be administered by the FCC. The Joint Board recommended that the certification program apply to data and "ancillary" devices, including extension telephones, but not to other voice terminal equipment such as private branch exchanges (PBX's), key telephone systems, and main station and coin-operated telephones. FCC certification would, under the Joint Board's recommendation, be based on the applicant's submission of required test data. Also, each device would have affixed to it installation, maintenance and operating instructions. Standard plugs and jacks and other simple connecting devices were to be provided for in carrier tariffs.

In the fall of 1975, the FCC adopted a certification program similar to that recommended by the Joint Board.[32] In so doing, it noted that it had been seven years since *Carterphone* and that the carriers had never come forward with any justification either for the original tariff restrictions, or for the carrier supplied connecting arrangements subsequently provided for in the temporary tariffs.

The FCC ruled that its new certification program would adequately protect the telephone network from harm, i.e., from electrical hazards to personnel and equipment, and from degradation of service to persons other than the user of a particular device. Instead of requiring type approval of entire terminal devices, however, applicants will be permitted to register only connecting circuitry within any particular device. This will avoid problems of proprietory information disclosure raised by IBM and others. The new certification program, which applies to carrier-provided, as well as to customer-provided, data and "ancillary" equipment, including extension telephones, but not PBX's, key telephone systems and main station and coin operated telephones, was to go into effect April 1 of this year. However, the FCC has recently postponed this to May 1, 1976. In its recent ruling on reconsideration of the November decision,[33] the FCC also declined to exempt carrier-supplied terminal equipment from the new program and in general confirmed its original ruling.

The FCC followed the Joint Board's lead in leaving voice telephone equipment (other than extension telephones) subject to current tariff requirements for carrier-supplied connecting arrangements because, it said, the parties may not have addressed themselves specifically to this aspect. It did indicate strongly, however, that it saw no technical harm problems and proposed in the near future to issue further rule changes to include PBX's, key telephone systems, main station telephones, and coin telephones in the new certification program. Such action was, in fact, taken on March 18, 1976.[34]

AT&T and other carriers as well as the National Association of Regulatory Utilities Commissioners (NARUC), in petitions for reconsideration and stay of the new program, objected strongly that AT&T's "protective module" plan should have been adopted and argued that the FCC's plan is so deficient technically and otherwise that it cannot possibly work. They also argued that it was inappropriate and prejudicial for the FCC to allow unlimited interconnection of customer-supplied equipment prior to a determination, in the Economic Impact Inquiry, Docket No. 20003,[35] of the effect such interconnection will have on monopoly telephone services and rates. The Joint Board itself has recently voted to recommend this same course.[36]

In Docket 20003, the Commission is also considering the economic impact on the switched telephone network, and local telephone companies as well, of its recent authorizations of the new specialized and domestic satellite carriers, and the extent to which cross-subsidy of competitive offerings by monopoly carriers might be prevented by requiring them to make such offerings through subsidiary companies keeping separate books, etc.

There is perhaps an outside chance that the interconnect battle could be decided in a case now pending in the United States Court of Appeals for the Fourth Circuit.[37] The *Telerent Leasing* case, which was argued before the Fourth Circuit in September of last year, and at this writing has not been decided, involves an appeal from an FCC ruling in early 1974[38] that it alone has jurisdiction over the interconnection of customer-provided terminal equipment, even though such connection is to local telephone exchanges regulated by state utilities commissions. The effect of the Commission's ruling was to cancel a North Carolina Utilities Commission regulation prohibiting interconnection of "foreign attachments" of any kind. Opponents of the registration program contend that the FCC's rulings intrude unlawfully on local exchange jurisdiction given to state utility commissions by Section 221(b) by the Communications Act. However, the FCC ruled in *Telerent Leasing,* and contends before the Fourth Circuit Court of Appeals, that the interstate telephone service, over which it clearly has jurisdiction, is not and cannot possibly be provided except over local exchange facilities, and that it is evident that its exclusive jurisdiction over interstate communications must therefore extend to interconnection of terminal equipment to such facilities.

PROBLEMS RELATING TO THE DISTINCTION BETWEEN DATA PROCESSING AND COMMUNICATIONS

Background

In its *Computer Inquiry*[39] the FCC first explored the increasingly blurred relationship between communications and computers. It decided that whether or not computers were engaged in communications depended upon the use to which the computers were put. It recognized that computers perform communications functions—namely, message and circuit switching—and concluded that when doing so they are subject to regulation as a communications service. But the FCC seemed to say that everything else computers do including, inter alia, storing, retrieving, sorting, merging, and calculating according to programmed instructions is essentially data processing, which should not be regulated by the FCC. Because of the intermingling of communications with data processing in many remote access data processing offerings, and because such intermingling could lead to unfair competition in the data processing field by carriers who might resort to cross-subsidy of their data processing offerings, or restrictive interconnection practices as to data processing offerings of others, it was decided that the FCC would not permit regulated carriers to offer essentially data processing services, except through separate subsidiary corporations keeping separate books. Where data processing and communications (including computer controlled message or circuit switching) are both involved in a service (i.e., where there is a "hybrid" service), then whether the service is deemed hybrid *communications,* such as may be provided by a common carrier, or require regulation if provided by others, is a question of the primary purpose of the offering. If the primary purpose is found to be to serve signal carriage and/or message-switching requirements of a customer, and data processing is an integral but incidental part of a package offering, the offering is deemed a hybrid *communications* offering and may be offered by carriers and is subject to regulation if offered by others. On the other hand, if the primary purpose is to provide data processing services, and computerized message or circuit switching (i.e., communications) is an integral but incidental part of a package offering, the offering is deemed to be hybrid *data processing* service and may not be offered by carriers and is not subject to regulation.

To enforce its computer rules, the FCC decided to rely basically on the regulated carriers from whom the communications component of any hybrid offering to be made by a non-carrier would necessarily have to be acquired. Since the carrier tariffs prohibit customer resale of communications services, and hybrid communications offerings would involve such resale, the carriers themselves were expected simply to refuse to supply or to continue to supply communications to anyone planning to resell the same as a component of a hybrid communications offering, unless the customer in question had been authorized by the FCC to offer such service as a communications common carrier.

In recent years pursuant to the principles outlined in the *Computer Inquiry,* the Commission has authorized three so-called value added carriers to offer "packet switched" data service employing lines leased from other carriers combined with their own computers and software to transmit small groups (packets) of digitized data using store and forward methods to take advantage of the best available path through the network.[40]

Telenet v. Tymshare.

In early August of 1975, the tariffs of one of these newly authorized value added carriers, Telenet Communications Corporation, became effective. Five weeks later Telenet filed a complaint against Tymshare, Inc., a time-sharing concern, alleging that Tymshare's Tymnet data communications network, which also utilizes store and forward switching computers and leased communication channels, is physically and functionally separate from Tymshare's data processing computers which are connected to Tymnet. It charged that Tymshare, Inc. is in reality engaged in two separate profit making businesses: first, a hybrid *data processing* service using the Tymnet network as a means of communications between customer terminals and Tymshare's host computers; and, second, a hybrid *communications* service whereby it offers use of Tymnet as a means of communications between customers' terminals and the customers' own host computers. Tymshare, Inc. has answered this complaint alleging that it is not purely coincidental that Telenet filed only a few weeks after its tariffs went into effect. It suggests that Telenet really hopes to use FCC procedures to advance what it conceives to be its own competitive interests, and points out that the question whether, and to what extent, value-added carriers and others may be permitted to lease and resell or enter into joint user arrangements so as to provide value added services to others is presently under consideration and the Commission's inquiry in the *Resale and Shared Use Proceeding,* Docket No. 20097.[41] Tymshare argues that its Tymnet system is operated pursuant to the so-called joint user provisions of relevant tariffs, i.e., Tymshare leases lines from AT&T and other carriers for internal telecommunications and makes unused capacity available to others under joint user tariff provisions. In general, these require that the customer (Tymshare) have its own communications needs over and above those arising from management of the joint use arrangement, and that the customer and the joint users share the cost of the common carrier service by each paying part of the rates to the common carrier. Tymshare further states that the FCC in its order in initiating Docket No. 20097, expressly recognized that sharing arrangements could involve a complex computer switched network.

Tymshare also asserts that neither it nor even Telenet is in reality, or ought to be, considered a communications common carrier. This contention by Tymshare is squarely directed at the wisdom of the FCC's readiness to characterize value added services as communications because they involve circuit and message switching. At this writing, the FCC's staff has queried the carriers who are supplying communications circuits to Tymshare for their views as to whether Tymshare is indeed in full compliance with their tariff provisions prohibiting resale except under bona fide sharing arrangements. In short, for the time being the staff is following the FCC's suggestion in the *Computer Inquiry* that the carriers should first make the difficult decision whether a hybrid communications service is involved. But it seems inevitable that the FCC will ultimately have to decide this tough question as well, and the Tymshare case bears close watching.[42]

Other FCC cases

A similar situation where a carrier is asserting that a purported data processing service is in reality a communication service, involves ITT-Worldcom's pending challenge of the Telepost computerized message service being provided by TII Corporation. A customer signals Telepost that certain prewritten messages are to be sent to persons listed on various pre-established customer lists and the Telepost computer automatically interprets these signals and sends out the desired messages to the desired recipients via MAILGRAM. ITT-Worldcom claims in a petition in the proceeding that this service is a hybrid communications service which should be subject to regulation.

New developments in the service business are also putting to the test the *Computer Inquiry* definition of hybrid data processing and hybrid communications. Western Union has recently petitioned to offer a collateral processing service in conjunction with its SICOM message service for the securities industry. Under the proposed collateral service, Western Union's computers would perform order matching based on information gleaned from the handling of buy and sell messages. Western Union contends that this is a hybrid data communications service, since the data processing functions of order matching are both incidental to an integral with the SICOM message service. But this interpretation is being challenged by CBEMA and ADAPSO. The latter say that the proposed service is a data processing service that is neither incidental nor integral to Western Union's SICOM communications service. The Commission is being called upon to interpret its *Computer Inquiry* rules to determine whether Western Union will be permitted to offer this service.

The pattern of competitive response by AT&T, followed by charges and inquiries whether the competitive response is in fact predatory and subsidized by monopoly profits, has held true in the terminal equipment area as well as in the specialized common carrier services area and others. Such matters are now at issue in the AT&T Data Modem Rate Investigation, Docket 19419, which is now in hearing before an FCC Administrative Law Judge.

AT&T DATASPEED 40 Ruling

Another instance of such a competitive response by AT&T, which also illustrates the importance of the *Computer Inquiry* to the terminal equipment field, as well as in the service field, is involved in AT&T's recent tariff filings relating to Dataspeed 40. In these filings, AT&T sought to provide, subject to FCC regulation, intelligent remote access terminals with cathode ray video display. These terminals were designed to be for use by customers in connection with AT&T's Dataphone Digital Service, and to be competitive with new terminals manufactured by unregulated computer and data processing manufacturers including IBM. In petitions to reject or suspend these filings, IBM, CBEMA and others contended that AT&T's Dataspeed 40 terminals were plainly data processing equipment since they are in direct competition with IBM terminals which are not and should not be subject to tariffs at all. They argued further that AT&T is prohibited from competing in the data processing field in this manner by a 1956 antitrust consent decree which limits AT&T to common carrier communication services and services "incidental" thereto.[43] They argued that AT&T's filings were unlawful since they did not demonstrate conclusively that the new terminal was not being cross-subsidized by AT&T. They suggested further that if AT&T is, nevertheless to be permitted to offer data processing equipment, a revision of the 1956 antitrust decree would be required, and AT&T would have to offer the equipment on an untariffed basis through a separate subsidiary in accordance with the FCC's ruling in its *Computer Inquiry* respecting data processing services offered by regulated carriers.

The FCC's staff recently rejected the Dataspeed 40 offering, concluding in essence that it amounted to a data processing, not a communications service.[44] AT&T had argued the new terminals were merely evolutionary improvements of teletypewriter terminals which it has provided for many years as communications devices. It argued that if a computer—which consists of input, output, arithmetic and logic, memory and control units—is used to execute a program that involves data processing, the data processing takes place only in the arithmetic and logic units of the computer. The input and output devices perform no data processing since they do not operate on information to increase its worth to the user through changing its inherent informational content; instead the input and output devices merely permit outside entities to converse with the central processing unit and are required because of inherent limitations of the central processing unit. AT&T argued, therefore, that the Dataspeed 40 terminal performs the same communications function as that performed by telephones when two human beings converse remotely.

The staff rejected AT&T's arguments, however stating that it was clear that the primary function, design, and marketing of the Dataspeed 40 terminal was as an integral part of a data processing service involving the programmed interconnection of the terminal device and a central computer processing and/or storage unit. The FCC staff pointed out, and laid emphasis on the fact, that the terminals cannot communicate with themselves without the use of external data processing equipment.

If the staff's rejection of Dataspeed 40 is upheld, this bodes ill for AT&T's recently announced plans to offer, in the latter part of this decade, a new end-to-end, value added "communications processing" service designed to provide an alternative to the systems network architecture to be offered by IBM. Under this plan AT&T's computer controlled No. 4 ESS switch, located at the telephone company's central office, would function for users, on a shared basis, as a substitute for central processor front ends, multiplexors, concentrators, remote controllers and intelligent terminals. Users could bypass the profusion of separate systems for different on-line applications, and disparate outputs could be loaded into a single system capable of rearranging each set of bits without changing informational content, to meet requirements of receiving terminals. AT&T recently introduced "Dimension PBX" as the prototype for an on site controller which will be used for some applications of the new centralized communications processor.

AT&T will have to fight back contentions that its alleged "communications processing" service is in reality data processing, and a recent AT&T announcement gave a preview of what its position will be on this issue. It stated that data processing involves altering informational content of bits, something the centralized communications processing system will not do. Instead, AT&T said, the new system will perform network control, speed conversion, area control, terminal polling, message routing and rerouting (to effect priorities and avoid busy or down links), formatting, editing, and checking of input and output data. The announcement further explained that "communications processing" is but one of three elements of "data communications." The other two are transmission/switching/modulation/demodulation, and media conversion (e.g., transformation of bit stream to hard copy, cathode ray tube display (CRT display) or punched cards).

CONCLUSION

In a speech made by Walter R. Hinchman, Chief of the Common Carrier Bureau at the FCC, before the Computer Industry Association (CIA) in Washington, D. C. on February 25, 1976, Mr. Hinchman stated that problems posed by some of the cases discussed above are causing the FCC to have to focus closely on some of the ambiguities in its *Computer Inquiry* rules and, he said, might lead to a reexamination of these rules to make them more relevant in the context of changing conditions in 1976.[45]

It appears likely that a new Computer Inquiry will be launched. And this time it will be considered in a totally new environment—one with EFTS, privacy, and technology issues quite different from those dealt with previously.

ABSTRACT

Public packet switching networks are at various stages of development around the world, notably in the U.S., Canada, France, the United Kingdom and Japan. The success of these networks is highly dependent on the use of an agreed-upon standard device-independent interface between the packet networks and the user devices operating in the packet-mode. This interface consists of far more than the data link control procedure (i.e., HDLC), which administers the physical transmission medium between the data terminal equipment (DTE) and the network. The specification of the packet-mode interface defines a set of conventions governing the manner in which DTEs establish, maintain and clear calls, format control information and data into packets and manage the flow of data for many calls over a single circuit to and from the packet network.

This paper describes the International Packet-Mode Interface, developed jointly by Telenet Communications Corp., the Trans-Canada Telephone System (TCTS), the United Kingdom Post Office and the French PTT. This interface has been designed to enable DTEs such as computers, programmable terminal controllers and intelligent terminals to gain access to public packet networks throughout the world. The present status of international standardization of this interface within the CCITT is also covered.

Standardization of the International Packet-Mode Interface is to the advantage of teleprocessing users, manufacturers of data processing and terminal equipment and common carriers.

INTRODUCTION

Telenet has been commercially available in the U. S. since August 1975; Datapac will start commercial operation in Canada next month; the French experimental RCP network started operation in 1975 and Transpac development has been contracted out and will start providing service in France in 1978; the Experimental Packet Switching Service of the United Kingdom Post Office is well into the evaluation stage; and other public data networks are being planned and developed in both Japan and the Nordic countries.

The fundamental technology used in all of these networks is packet switching. In packet switching, all user data is formed into discrete units called packets. In addition to the data to be transferred (typically part of a message), each packet includes a header specifying control functions and the destination to which the data is to be delivered. Packets are routed through the network on a store and forward basis and travel very rapidly and accurately through the network, experiencing only a fraction of a second delay from source to destination. Additionally, the network performs buffering functions so that the speed and format of the data sent into the network can be different from those of the data received at the destination.

The packet switching technology described briefly in the preceding paragraph is actually of little direct concern here, since the sophisticated routing, monitoring and error correction techniques internal to packet networks are invisible to users of the networks. (Readers are referred to a book edited by Chu[1] for a discussion of packet network design considerations). Rather, the user's primary interests are the characteristics of the service provided by a network and of the interface between him and the network.

The public data networks listed above are supporting packet-mode services based on the *virtual circuit* concept. A virtual circuit is a bi-directional association between a pair of DTEs over which all data transfer takes the form of packets. Transmission facilities are only assigned when data or control packets are actually being transferred. The virtual circuit concept permits a DTE (data terminal equipment) to establish concurrent communications paths to many other DTEs over a single physical access circuit (Figure 1). The high degree of sharing made possible by the use of virtual circuits enables communication savings to be passed on to the user. The virtual circuit concept minimizes the impact of new packet switching services on existing user systems.

Two types of interfaces may exist on any packet switching network. The first type may be called a device-dependent interface such as would be required at present for most hard-wired terminals (e.g., point-of-sale terminals, teletype machines). The second type may be called a device-independent interface which is applicable to most programmable devices (e.g., computers, programmable controllers, concentrators, intelligent terminals). Because of the large number of terminals that require device-dependent interfaces and because of the large incompatibilities that presently exist among these terminals, a large number of interface specifications are required. On the other hand, only a single specification of a device-independent interface is necessary.

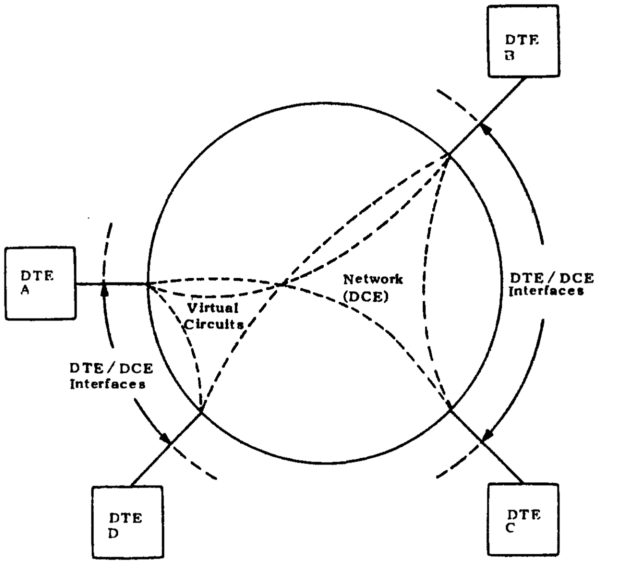

Figure 1—Use of virtual circuits

The International Telephone and Telegraph Consultative Committee (CCITT) in Geneva has recognized the need for these two types of interfaces and has put priority on the development of a recommendation for the second type of interface; that is, a device-independent interface between what it calls a packet-terminal and the packet switching network. A similar conclusion has been drawn by an Ad Hoc Group of U. S. ANSI Task Group X3S37 (Public Data Networks).[2]

Likewise, TCTS, the French PTT, Telenet, the Japanese NTT, and the United Kingdom Post Office have put high priority on the development and standardization of the International Packet-Mode Interface. The specification of the International Packet-Mode Interface was submitted as draft Recommendation X.25[3] to the CCITT Secretariat for consideration by the Study Group VII Plenary.

The purpose of specifying the International Packet-Mode Interface is to provide an efficient means by which a large set of characteristically different teleprocessing systems can gain access to the services and related technical and economic benefits of packet switching networks.

GENERAL DESCRIPTION

Interface requirements

The basic requirements imposed upon the architecture of the interface are introduced below:

1. The interface shall provide a full duplex transmission path between the DTE and the network.
2. It shall ensure the integrity and accuracy of the data transmitted between the DTE and the network.
3. It shall provide the DTE with switched and permanent virtual circuits.
4. It shall be capable of efficiently supporting concurrent communication between a packet mode DTE and numerous other DTEs over a single physical circuit to the network.
5. It shall allow both DTE and network to control the flow of data over the access circuit so that one does not overload the other.
6. It shall provide supervisory and control functions to administer calls satisfactorily.
7. It shall do all of above using existing standards wherever possible.

Interface characteristics

The International Packet-Mode Interface consists of three distinct levels of control procedures as illustrated in Figure 2:

1. the Physical Interface
2. the Frame Level Logical Interface
3. the Packet Level Logical Interface

Each of these levels functions independently of the other levels, with the exception that failures at a level may affect the operation of higher levels.

The Physical Interface specifies the use of a duplex, point-to-point synchronous circuit, thus providing a physical transmission path between the DTE and the Network. It also specifies the use of an existing physical interface (i.e., EIA RS-232-C standard) between the DTE and a data set or modem. Therefore, no changes to the interface hardware of the DTE are required.

The Frame Level Logical Interface specifies the use of a data link control procedure which is compatible with the High-Level Data Link Control (HDLC) procedures being standardized by ISO and with the Advanced Data Communications Control Procedure (ADCCP) being standardized by U. S. ANSI. The Frame Level Interface uses the principles of a new ISO Class of Procedure for a point-to-point balanced system, whereby the DTE and the network node each have a primary and a secondary function. The Frame Level Interface is defined in terms of primary and secondary responsibilities, and may be thought of as two independent but complementary transmission paths superimposed on a single physical circuit. The use of this data link control procedure ensures that packets provided by the packet level and contained in HDLC information frames are accurately exchanged between the DTE and the Network. The functions performed by the Frame Level Interface are:

1. transfer of data in an efficient and timely fashion;
2. synchronizing the link to ensure that the receiver is in step with the transmitter;
3. detecting transmission errors and taking steps to recover from such errors;
4. identifying and reporting procedural errors to higher levels for recovery.

The major significance of the Frame Level Interface is that it provides the Packet Level Logical Interface with an error-free, variable delay link between the DTE and the Network.

Frame Level Logical Interface (single data link)
Network
Physical Level Procedures
Physical Interface (4-wire point-to-point synchronous circuit)
DTE (customer side of DTE/DCE interface)
DTE/DCE INTERFACE
DCE (network side of DTE/DCE interface)

Note: Network is transparent to process-to-process communication.

DCE = Data Circuit-Terminating Equipment (e.g. data set)

Figure 2—International packet-mode interface architecture

The *Packet Level Logical Interface* is the highest level of the International Packet-Mode Interface and specifies the manner in which control information and user data are structured into packets. The control information including addressing information is contained in the packet header field and allows the network to identify the DTE for which the packet is destined. It also allows a single physical circuit to support a number of virtual circuits to numerous other DTEs concurrently.

The Packet Level Logical Interface is further described in the next section.

THE PACKET LEVEL LOGICAL INTERFACE

Multiplexing at the packet level

The Packet Level Logical Interface accommodates both permanent and switched virtual circuits. A permanent virtual circuit is a permanent association existing between two DTEs which is analogous to a point-to-point private line. Thus, it requires no call set up or call clearing action by the DTE. A switched virtual circuit is a temporary association between two DTEs and is initiated by a DTE sending a call request packet to the network. Call establishment and clearing is described in the next section.

In order to allow a DTE to establish concurrent virtual circuits with a number of DTEs over a single physical access circuit, the Packet Level Logical Interface employs packet-interleaved Statistical Multiplexing. This multiplexing technique is used to exploit the fact that a typical virtual circuit to a remote DTE may actually be carrying data for only a small percentage of the time. Each packet contains a logical channel number which identifies the packet with a switched or permanent virtual circuit for both directions of transmission. A packet that contains user data for example has a three octet header identifying it as a data packet and specifying its logical channel number as illustrated in Figure 3.

Call establishment and clearing

A signalling method is provided to allow a DTE to establish switched virtual circuits to other DTEs using logical channel numbers at each end to locally designate these switched virtual circuits.

A DTE initiates a call by sending a call request packet, Figure 4, to the Network. The call request packet includes the logical channel number chosen by the DTE to be used to identify all packets associated with that call. It also includes the network address of the called DTE. A facility field is present only when the DTE wishes to request an optional user facility (i.e., network feature) requiring some indication at call set up. Reverse charging is an example of such a facility. User data may follow the facility field and may contain any number of bits up to a maximum of 16 octets.

The calling DTE will receive a response indicating whether or not the called DTE accepts the call. When a switched virtual circuit cannot be established, the network will transfer clearing call progress signals to the DTE indicating the reason why the call was not established; call progress signals are listed in Table I. Either DTE may clear an established call with this information being conveyed to the opposite DTE.

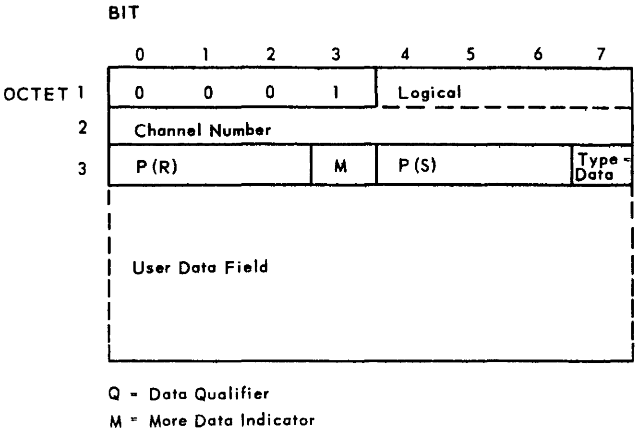

Figure 3—Data packet format

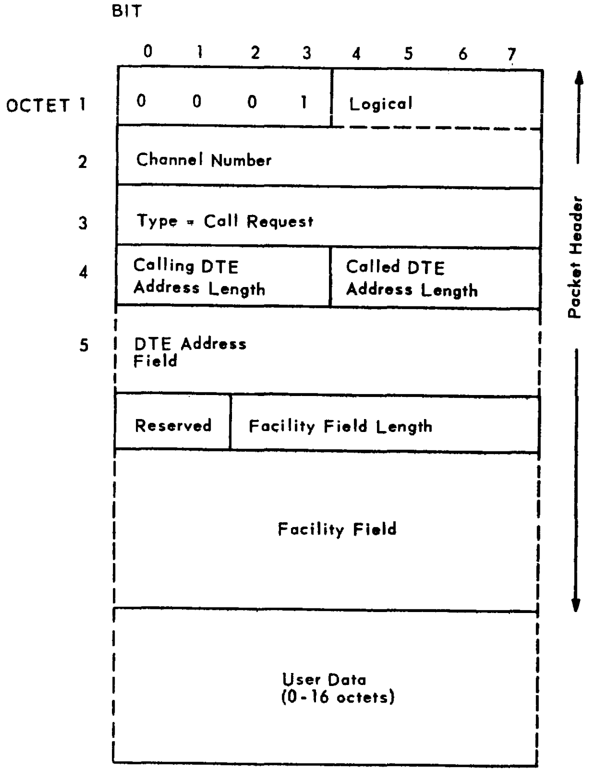

Bits of an octet are numbered 0 to 7, where bit 7 is the low order bit and is transmitted first. Octets of a packet are numbered consecutively starting from 1 and are transmitted in this order.

Every packet header has a 4-bit field which is effectively reserved for future use, a 12-bit logical channel number and an 8-bit field used for packet type information and control. This latter field is intentionally kept very similar to the control field of HDLC.

Figure 4—Call request packet format

Figure 5 is an illustration of call establishment, data transfer and call clearing.

Data transfer on a virtual circuit

Data packets, illustrated in Figure 2, can only be transferred on a virtual circuit after the virtual circuit has been established *and* flow control constraints are not violated. The third octet of the data packet header is identical to the control byte of HDLC information frames except that the poll/final bit is replaced by the More Data bit discussed later.

TABLE I—Clearing Call Progress Signals

Clearing Call Progress Signal	Explanation
Number Busy	The called number is fully engaged and cannot accept another call.
Number Refusing Collect Calls	The called DTE does not accept collect calls.
Network Congestion	Congestion conditions within the network temporarily prevent the requested virtual circuit from being established.
Invalid Call	Invalid Facility requested.
Access Barred	The calling DTE is not permitted to obtain the connection to the called number. Possible reason is incompatible closed user group.
Local Procedure Error	The call is cleared because of a local procedure error.
Remote Procedure Error	The call is cleared because of a remote procedure error.
Not obtainable	The called number is not assigned or is no longer assigned.
Out of Order	The called number is out of order. Possible reasons include (1) DTE not functioning; (2) Subscriber link not functioning; (3) Frame level not in operation.

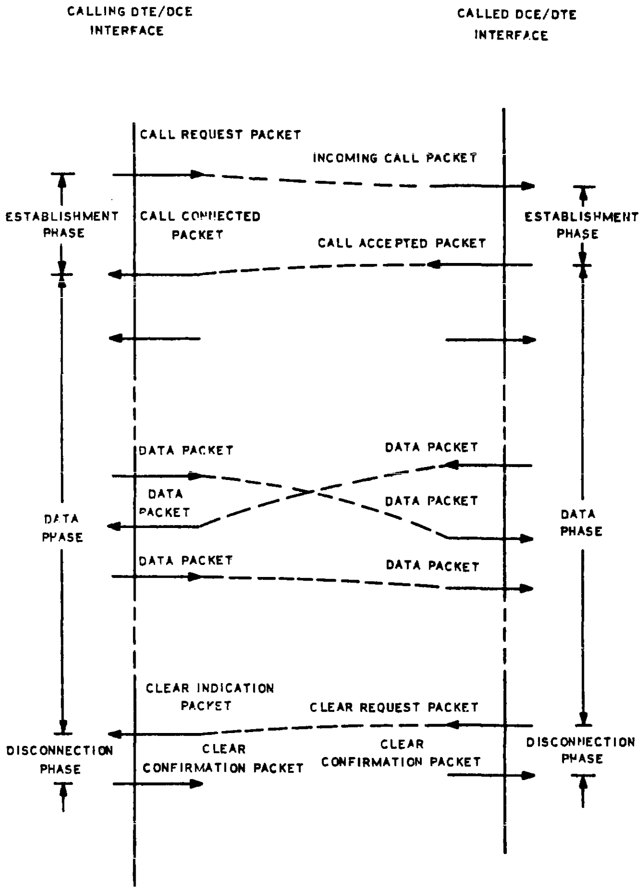

Figure 5—Illustration of call establishment, data transfer and call clearing

P(S) is the packet send sequence number of the packet. (Only data packets are numbered, modulo 8). The maximum number of sequentially numbered data packets that the DTE may be authorized to transmit, without further authorization from the network, may never exceed seven. The actual maximum value, called the window size W, is set for the virtual circuit either at subscription time or at call set up.

Each data packet also carries a packet receive sequence number P(R) which authorizes the transmission of W data packets on this virtual circuit starting with a send sequence number equal to the value of P(R). If the DTE or the network wishes to authorize the transmission of one or more data packets across the interface, but there is no data flow on a given virtual circuit in the reverse direction on which to piggyback this information, it can transmit a Receive Ready (RR) packet. Flow control based on the conveyance of P(R) numbers on a virtual circuit basis ensures that a sending DTE does not transmit data at an average rate which is greater than that at which the receiving DTE can accept that data.

The data field of a data packet to be transmitted on a virtual circuit may be any number of bits long up to some maximum value. The latter may be established independently at each end of a virtual circuit. Every network will support a maximum value of 128 octets. It may optionally support other values, possible values being 16, 32, 64, 255, 256, 512 and 1024. The governing principle is that a virtual circuit is used for the transfer of streams of user bits, where packet size may be chosen in such a way as to locally optimize: access line performance, cost, error rates, queuing delays, throughput, etc.

In order to facilitate the segmentation and grouping of the user's data stream into data packets, the user may indicate in a full data packet whether there is a logical continuation of his data in the next data packet on a particular virtual circuit. This he does with the More Data bit (M) indicated in Figure 3. Only a full data packet requires a More Data indication since a partially full packet is treated as if it had the M bit off. The use of the M bit ensures that two communicating DTEs can each operate at their locally selected packet sizes.

Two independent mechanisms are provided to transfer control information between a pair of DTEs outside the normal flow of data. The first mechanism transfers control data within the normal flow control and sequencing procedures on a virtual circuit. This is called the data qualifier procedure. The format used in this procedure is identical to the normal data transfer packet except that the "Q" bit is set (see Figure 3). The data transmitted is then interpreted by the receiving DTE. An example of the use of the data qualifier is to transfer device control information such as echoing or packet forwarding rules and transmission control parameters for device-dependent interfaces on the packet network.

The second mechanism bypasses the normal data packet transmission sequence providing non-sequenced interrupt packets. Interrupt packets consist of a short header identifying the logical channel number and a one octet data field. Interrupt packets will be transmitted by the network without waiting for all other packets to be delivered and will be delivered to a DTE even when it is not accepting data packets. They contain neither send nor receive sequence numbers. In this way, interrupt conditions, such as would be generated by the depression of a break key on a keyboard terminal, can be signalled between DTEs without being subject to the flow control imposed on data packets.

Error recovery

The reset procedure is used to reinitialize the flow control procedure on a given virtual circuit to the state it was in when the virtual circuit was established (i.e., all sequence numbers equal to zero and no data in transit). To reach this state, all data and interrupt packets which may be in transit at the time of resetting are discarded. Reset packets are used in the reset procedure.

The restart procedure is primarily used by the DTE and provides a mechanism to recover from major failures. The issuance of a restart request packet is equivalent to sending a clear request on all switched virtual circuits and a reset request on all permanent virtual circuits. Thus, the restarting procedure will bring the user/network interface to the state it was in when service was initiated.

CONCLUSIONS

This paper has presented a description of a new communications protocol for accessing packet switching networks. The International Packet-Mode Interface has been developed by a number of administrations and common carriers in cooperation with standards organizations, users and manufacturers. We strongly believe that it is to the advantage of teleprocessing users, manufacturers of data processing equipment and common carriers that standards and recommendations continue in this area. The benefits to accrue are simplified design and use of equipment, lower cost, higher transmission efficiency, interconnectivity and enhanced performance.

The International Packet-Mode Interface has already been implemented in a number of installations to give access to the Telenet, Datapac and experimental RCP networks. It has been specified for use on the French PTT's Transpac network and for the Euronet international network being developed by a large number of European administrations.

Virtual circuits vs. datagrams—Technical and political problems

by LOUIS POUZIN
Institut de Recherche d'Informatique et d'Automatique
(IRIA)
Rocquencourt, France

ABSTRACT

Public packet networks are becoming a reality, and call for interface standards. Two levels of facilities have been proposed, virtual circuit (VC), and datagram (DG). The concepts of VC and DG are already well developed within computer networks. Their properties are reviewed, along with typical issues such as out-of-sequence and congestion problems.

Usually DG's are a sub-layer used as a transport facility by a VC protocol. They also provide the ability to extend switching functions within user systems. The characteristics of VC's considered by CCITT are examined critically, and related to experimental networks and manufacturer softwares.

VC's and DG's are compared from the viewpoint of adapting customer systems to public networks. When the customer is interested in a transport facility, DG's appear to have an edge. When a network becomes a terminal handler, adaptations are more complex and require character stream interfaces. Intelligent terminals would make this problem disappear, as they can use a DG interface.

Although various groups call for a DG interface, the carriers are opposed to it. Four carriers are rushing a VC protocol through CCITT. The carrier's goal is to take over terminal handling, and gradually other processing functions. DG's would leave too much freedom to the customer. The political implications of the carrier policy suggest that better boundaries be drawn up between carriers and data processing.

THE COMMUNICATION INTERFACE

The development of large scale DP networks has pointed out the need for a well defined interface with a communication sub-system, which is termed here *a transport facility*. The term *transport* intends to emphasize the fact that this facility should move pieces of information from one place to another, without any alteration. Ideally, it should be error-free and carry data instantaneously. In practice, it introduces some transit delay and some errors.

In conventional systems, a widely used transport facility is a telephone line equipped with modems. The interface is standardized by CCITT (Comité Consultatif International Télégraphique et Téléphonique), and ISO (International Standard Organization). It is bit serial, at certain predefined speeds. New transport facilities such as *packet switching* are now becoming available. They are based on a combination of telephone lines and computers. The interface is more complex than for a simple modem. Typically it can be broken down into 3 components (Figure 1):

a—A modem interface, as usual;

b—A data link control procedure, such as HDLC[1] in charge of the transfer of packets between DP equipment and communication network equipment;

c—A packet protocol, in charge of sending and receiving packets according to a specific set of rules.

Components *a* and *b* do not raise any controversy. The modem interface is already widely available. The link control procedure is in the process of becoming an ISO standard. But component *c* turned out to be a tug of war.

Two approaches have been proposed for component *c*. One is a *virtual circuit protocol*, the other is a *datagram protocol.*

It is essential to note that the definition of a transport interface does not make any assumption on the

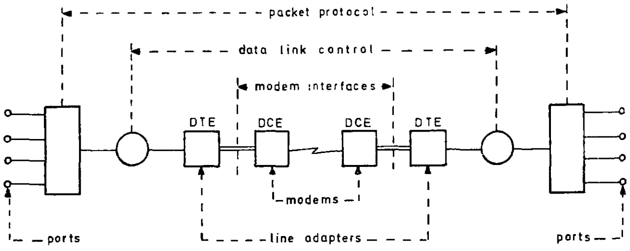

Figure 1—Packet network interface

specific techniques used to carry packets within the transport facility.

Even though some techniques may be more appropriate, with a certain technology, nothing prevents us from adopting widely different solutions, when new technologies become available. Changes need not, and must not, affect the transport interface.

VIRTUAL CIRCUITS IN GENERAL

A virtual circuit (VC) is a *logical path* between two end-entities for the purpose of exchanging data.

The terminology used in various groups is not stabilized, as is shown in Table I. In the following, end-entities are called *ports.*

Any computer network architecture embeds some form of VC, which is required to implement a *logical association* between a pair of correspondents. This is not so apparent when the pair of correspondents and their communication medium are represented by a dedicated set of resources, e.g., terminal control block, line adapter, telephone line, terminal. But it has become standard practice to share resources, such as a telephone line, between several pairs of correspondents. Thus, some machinery is required to segregate and control separately the traffic pertaining to each pair. This concept of *independent logical path,* along with an appropriate machinery, is what is called a VC, or many other things (Table I).

There has been a number of variations in the design of VC's. Since they are reviewed and discussed in a previous paper,[2] they are only given a short treatment here.

TABLE I—Virtual Circuit Characteristics

	COMPUTER NETWORKS				PACKET NETWORKS			
	ARPA Host net	CYCLADES EIN	IBM SNA	DECNET	EPSS PTT UK	TRANSPAC PTT FRANCE	TELENET USA	CCITT
VC name	connection	liaison	session	logical link	virtual call	circuit virtuel	virtual circuit	virtual call/ circuit
End-entity	socket	port	logical unit	object	customer label	voie logique	logical channel	logical channel
Sharable entity	no	yes	no	yes	no	no	no	no
Uni- or bi-directional	uni	bi	bi	bi	bi	bi	bi	bi
Error control	no	end	end	end	end	step	step	step
Flow control	end	end	end	end	step	step	step	step
Interrupt	yes	yes	yes	yes	no	no	yes	yes
Call Collision resolved	yes	yes	unknown	yes	no	no	unknown	no
Use DG's	no	yes	unknown	yes	yes	no	yes	not specified

Transit delay

Although delay presents no advantage, it is a built-in characteristic which cannot be eliminated. This is due to intrinsic response times and queueing always associated with resource sharing.

Uni- or bi-directional

It is the ability to transfer information in a single direction or in both simultaneously.

Permanent or transient

VC's may be set up permanently, or they may be opened and closed dynamically.

Sharable or busy ports

VC's are attached to ports bearing various names. In some systems several VC's may be anchored on a single port. In others, the port is busy when a single VC has been set up.

Call collision

In some systems, when two ports are attempting simultaneously to set up a VC with each other, one or both fail or two VC's are set up. This is a call collision. In other systems, which resolve collisions, this action results in a single VC being set up between the two ports.

Sequencing

VC's deliver information in the sequence it is sent. This may require a resequencing of fragments, when an underlying mechanism does not guarantee a sequenced delivery, e.g., a datagram network.

Error control

Most VC's perform error detection and recovery by retransmission. But there are two basic techniques:

—*step-wise,* in which control is applied onto successive legs of the physical path between ports (Figure 2). The reliability of the VC depends on intermediate mechanisms.

—*end-to-end,* in which control is applied by mechanisms located only at the two ends of the VC. Reliability is then independent of any intermediate mechanism.

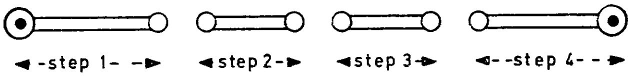

Figure 2—Step-wise error control

Both techniques may be applied simultaneously. Practically, end-to-end control always embeds some intermediate controlled legs. But there are step-controlled VC's without end-to-end control (Table I).

Flow control

It is the machinery in charge of keeping traffic within limits acceptable by the receiver, or any intermediate bottleneck. As for error control, two basic techniques are used:

—*step-wise,* in which feedback is applied on intermediate queues assigned to each VC;

—*end-to-end,* in which feedback is applied directly from the receiver to the sender. In this case, there is no need for handling intermediate queues per VC.

Again, both techniques may be applied simultaneously. However, when end-to-end flow control is used, intermediate legs are usually controlled in a more global manner (e.g., node-to-node, or network-to-network) rather than at the VC level. This saves a considerable overhead, and allows for *adaptive routing.*

Interrupt channel

It is used to by-pass the normal flow of information, when some signal must be transmitted even though error and flow controls may block up the VC.

Transport protocol

Sending and receiving information through VC's must follow a set of rules called a protocol. Basically, this protocol performs four types of functions:

(a) Implement a port name space in order to designate unambiguously sources and destinations at network level;
(b) Provide for the sending and the sequenced delivery of data, with error and flow control;
(c) If necessary, fragment items to be sent into

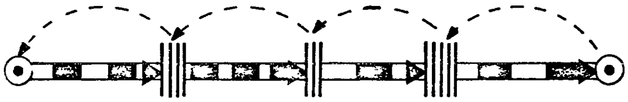

Figure 3—Step-wise flow control

pieces the size of the data field of a packet, and reassemble them at the receiver end;

(d) Multiplex the traffic of several VC's onto some common resources, e.g., a physical data link.

As may be inferred from the above, the sequencing functions require that all packets be routed through a minimum of two *focal points,* which insure numbering and sequenced delivery. Alternate routes can only appear in between the focal points, (Figure 4). The paths between ports and VC focal points must be unique and sequential. This creates a *reliability problem* when ports and focal points are not collocated in the same equipment.

DATAGRAMS

A datagram (DG) is a packet of information which is carried to its destination without reference to any other packet, or prior setting of a data path. In other words, a DG is a *self-contained* packet, in terms of switching.

As compared to VC's DG characteristics are considerably less diversified. The transit delay is of the same order of magnitude, or even shorter, since DG's do not have to wait for predecessors. All VC features, which are related to the concept of a logical path, are not applicable to DG's.

DG's can be sent to any port at any time. They are delivered in the sequence of arrival in the final queue to the destination port.

Since they are not related, they may be sent onto, and received from several physical data links in parallel.

The *DG protocol* consists only in formatting packets to be sent and dispatching received packets to specified ports. It may also include some conventions for flow control, when there exists a possibility of flooding some limited resource along the way.

Thus, DG's appear as a *very simple transport facility,* without mechanisms normally associated with an orderly and reliable transfer of information. An immediate question is whether DG's are useful.

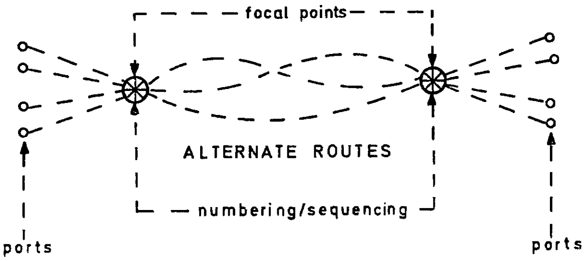

Figure 4—Focal points

At this point, it is interesting to quote a CCITT document[3] giving a definition for DG:

> "A user facility in which a message which can be contained in the data field of only one packet is delivered to the destination identified in its address field. No reference is noted by the network to any other datagram previously sent or likely to follow between the same two DTE's."

As long as the term *message* means everything or nothing, the definition is not incorrect, albeit meaningless. But if *message* is to have any correlation with a piece of data fit for processing, the definition is basically erroneous.

Indeed, neither VC's nor DG's can carry within a single packet messages longer than the maximum length of the data field (this is a tautology). Therefore, oversized messages are fragmented into pieces the size of a data field and sent as separate DG's.

At the destination, DG's are reassembled into a copy of the original message. Duplicates, if any, are discarded; missing DG's will be retransmitted if acknowledgment conventions have been established with the sender.

All this sounds very familiar, when compared to a VC protocol. But it is not a DG protocol. It is a user-oriented protocol interfacing the transport facility through a DG protocol. In other words, *DG's are not intended to be used as a self-contained transport facility.* On the contrary, they should normally be accessed through *an embedding higher level protocol.*

This higher level protocol may be a VC protocol, or *any other protocol* well suited to a specific class of applications. E.g., if user messages always fit within a DG, there is no need to invoke a fragmentation/reassembly machinery. This is likely to be the case of large scale applications, such as point-of-sale terminals.

The out-of-sequence issue

It is sometimes argued that DG's involve a substantial overhead at the receiver end to sort out packets, and put them back in the proper sequence. This is not the opinion of persons who have implemented protocols based on DG's. Indeed, in a sensible VC protocol using DG's, messages are broken down into labeled DG's carrying a message number and a DG number. All DG's of a message have the maximum length except the last one. On arrival, they are placed directly at their proper location in the message buffer, according to their number. This is utterly trivial, and needs no more comment.

It should be recalled also that resequencing is not peculiar to DG's. A sequential procedure, such as HDLC, delivers packets out of sequence when the command SREJ (selective reject) is used to trigger a retransmission.

Out-of-sequence packets could require more buffers than normally necessary if sequence shifts were frequent and had a large value. This is not the case in well designed networks. The reader may be interested in some simulation work[4] performed on this subject.

It certainly cannot be construed that out-of-sequence delivery carries an advantage per se. It is rather a non-issue. But the ability to accept out-of-sequence packets yields a major benefit in making *multiple physical links* a casual matter. This is indeed an essential ingredient if reliability is to be taken seriously.

The congestion issue

It has been recognized very early[5] that an excess of packets could use up all available buffers and result in deadlocks, or complete network jam, like cars in busy cities. Obviously, some mechanisms are necessary to prevent an overload of traffic. But the problem is not as simplistic as just keeping packets at bay. It breaks down into a number of sub-problems:

(a) Insure that packets do not enter the network when they would increase a developing congestion;
(b) Criteria to select acceptable packets when some of them must be held outside;
(c) What to do with packets that the receiver does not accept;
(d) What to do with packets that cannot reach their destination for any reason;
(e) How to anticipate congestion;
(f) How to optimize (?) network resources.

Most of these problems could apply to any resource sharing system, and it is well known that there is no general solution. But there are numerous partial solutions in a given environment.

It is often argued that a VC interface allows better traffic control. Actually, it only applies to *a*. No more.

Other schemes applicable to DG's have been studied and appear to be more effective, since they cope better with global congestion. The reader is referred to a very significant work accomplished at NPL.[6]

Every network designer cooks up some scheme coping with *a*, possibly at the cost of lowering the rate of resource sharing. E.g., in Transpac (French PTT), VC resources are dedicated all throughout the network.

Problem *b* requires some arbitrary policy including possibly tariff and marketing considerations. It has to be acceptable by the customer base. No general rule applies.

The most reasonable way to handle problems *c* and *d* is probably to destroy packets. As long as the destruction rate is lower than 10^{-3} or 10^{-4}, efficiency is not affected. End-to-end protocols handle easily DG loss. With a VC interface, the problem may require more extensive machinery, because VC's are not supposed to miss any packet.

Problems *e* and *f* are still a research area. They are independent of the network interface, be it VC or DG.

To sum up, there are a number of recipes to keep congestion under control regardless of which type of interface is used. Actually, carriers use DG's internally, which suggests that they are not so concerned. But making congestion control efficient is still an open question, for every network.

THE RELATIONSHIP BETWEEN VIRTUAL CIRCUIT AND DATAGRAM

As has been pointed out earlier, the DG is basically a low level transport facility at the disposal of higher level transport protocols, (Figure 5). It would be simplistic to oppose DG's and VC's, since they actually are complementary components in a hierarchical structure.

Indeed, computer networks such as CYCLADES[7,8] or EIN[9,10,25] use DG's as an underlayer of a VC protocol. This approach is in line with sound principles in system architecture, as it decouples the VC protocol from the characteristics of the transport facility. Thus, the VC protocol may operate as well over a thin wire, or a packet network, as long as they both transport packets.

Even the carriers have been able to understand the advantages of decoupling the VC protocol from the transport function proper. DATAPAC (Bell-Canada), EPSS (UK), TELENET (USA) are typical examples of packet networks based on this approach (Figure 6). Thus, it is all the more intriguing that carriers deny users the privilege to adopt the same principles.

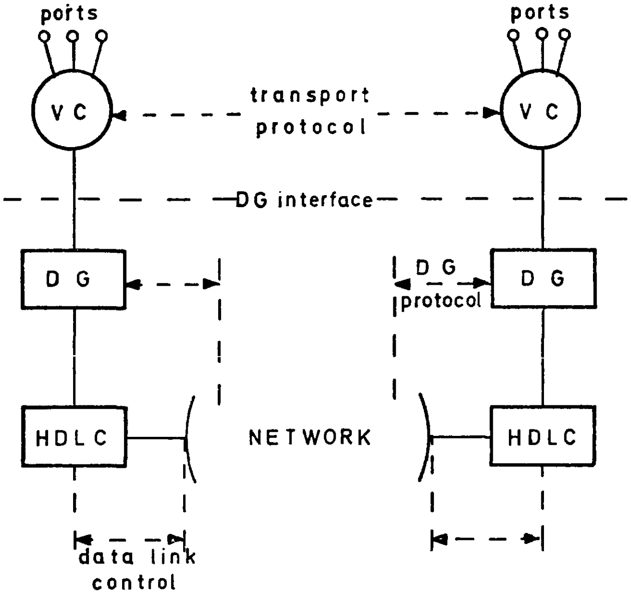

Figure 5—Protocol structure

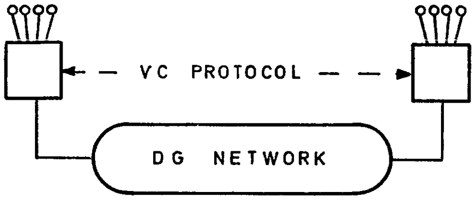

Figure 6—Two-level packet network

THE SWITCHING POTENTIAL OF DATAGRAMS

Another reason why carriers use DG's within their own packet networks is that switching DG's is much more efficient than handling logical paths all throughout a communication network. Intermediate nodes do not have to keep track of VC status; they only switch self-contained packets towards their destination. Error recovery and adaptive routing are much simplified.

Not surprisingly, the switching potential of DG's has also been put to an advantage by computer system designers. This stems from two simple remarks made earlier in this paper:

(a) DG's can be sent to, and received from several physical routes;
(b) DG's can be used as a transport sub-layer by several higher level protocols.

Therefore, the DG protocol acts as a *switch,* and interface converter, between user oriented protocols and transport facilities. It can also be used as an internal switch within a DP system. Nothing prevents us from putting several DG protocols, to deal with several transport facilities, public or private, or as internal relays within a distributed DP system, (Figure 7). This meshed structure provides for high flexibility and reliability, as it allows an arbitrary distribution of intelligence, without depending on a unique vulnerable component.

It can be verified easily that several recent computer system architectures include internal switching functions, carefully insulated from other parts of the system. They carry basic information units which are functionally equivalent to DG's. Interfacing with a DG network should require a minimum of adaptations.

Another benefit of the DG switching potential, is to simplify the interconnection of packet networks at DG level.[26] This approach has been extensively tested.[15] It allows multiple physical routes between networks. Interconnection at VC level requires additional focal points, which may render VC's inoperable in case of malfunctions.

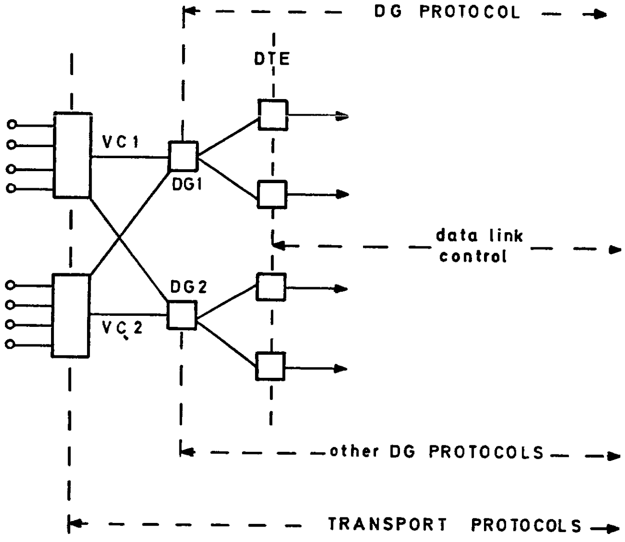

Figure 7—Multi-protocol Die

VIRTUAL CIRCUITS PROVIDED BY CARRIERS

During 1975, four carriers (France, UK, Bell Canada, and Telenet) evolved gradually a common proposal for a VC interface to public packet networks. Notwithstanding possible modifications, this proposal could become a CCITT *recommendation,* i.e., a standard, if it is agreed by a majority of carriers at the August 1976 plenary assembly.

At the present time, these four carriers have built, or are building, national packet networks with different interfaces. How and when they intend to migrate to the CCITT interface, is a moot question. Nevertheless, it seems more useful to concentrate on the CCITT draft,[11] instead of its ancestors. For ease of reference, we shall term CVC, (Carrier VC) the particular type of VC proposed to CCITT.

A subscriber equipment is called a DTE (Data Terminal Equipment) in CCITT terminology. A CVC may be summarized by its main characteristics:

(1) A DTE takes a subscription with the carrier for a certain number of bidirectional *logical channels* (LC) labeled 1 to N.
(2) In order to set up a CVC with another DTE, a calling DTE selects a local free LC number, and sends a calling packet to the carrier.
(3) Somehow, the calling packet reaches its destination within the carrier network (or another carrier network) to which the called DTE is physically linked.
(4) The carrier selects a supposedly free LC number and passes the calling packet to the called DTE.
(5) If the called DTE accepts the CVC, it returns an acknowledgment.

(6) The carrier propagates the acknowledgment back to the calling DTE.

(7) Both calling and called LC's are engaged for the time the CVC is set up.

(8) If two DTE's call each other simultaneously, two CVC's are set up, unless one of them (which one ?) rejects the call (unresolved call collision).

(9) Either DTE may decide to break the CVC at any moment.

(10) The physical link between DTE and carrier is controlled by an HDLC procedure (ISO standard). It must be full-duplex.

(11) The LC between DTE and carrier is controlled by a specific procedure that apes HDLC, without being identical.

(12) Packets sent by the DTE on an LC must not exceed a certain length agreed with the carrier.

(13) Packets delivered to the DTE on an LC do not exceed a certain length previously agreed with the carrier.

(14) Unless the maximum packet length used by both DTE's happens to be the same, there is no relationship between packets sent and received, except that they make up a continuous bit stream when concatenated by the receiving DTE.

(15) Message markers may be inserted by the sending DTE. This prevents the delivery of concatenated messages to the receiving DTE.

(16) Some CVC's may be set up permanently, subject to an agreement with the carrier.

It would be somewhat tedious to take into account all the various options anticipated. They do not alter substantially the general description presented here.

A few simple analogies may help to understand CVC's.

A DTE is like a PBX with one telephone number and a group of lines (LC's) to the public telephone exchange. A CVC is like a pipe, or a FIFO queue.

The CVC protocol provides only for interactions between DTE and carrier, not between DTE's. It is a *step-wise* protocol as far as error and flow control are concerned. This has strong implications:

(a) There is no way for a receiver to stop a sender, except by letting it fill up the CVC pipe;

(b) There is no way for a receiver to check that it has received its data completely, without alteration or duplication.

In other words: Thou shalt trust the carriers.

It is not clear why the CVC protocol comes on top of an HDLC procedure. They are both local protocols, controlling the transfer of data between the DTE and its nearest carrier office. If HDLC is presumed to work correctly, what is the purpose of a CVC protocol, and vice versa.

It may be argued that the CVC protocol needs more functions than HDLC. This is correct. But it would be perfectly adequate to control each LC with an HDLC procedure augmented with appropriate functions, for CVC set up, reset, and flow control. This is the way IBM does it in SNA. This would do away with one redundant layer, and bring the CVC protocol closer to an existing ISO standard.

However, due to the lack of DTE-to-DTE control, the *CVC protocol does not meet the qualification of a self-contained transport facility.*

As a consequence, users of CVC's will superimpose their own end-to-end protocol, such as a homemade VC protocol. Actually, this would happen anyway, because computer manufacturers and their customers must insure the reliability of their systems regardless of the vagaries of carrier facilities.

DATAGRAMS PROVIDED BY NON-CARRIERS

The concept of DG has been first experimented in the CYCLADES computer network, which uses a VC protocol[8] based on DG's. The CIGALE packet network[12] used in CYCLADES is a pure DG facility.

CYCLADES has been operational since early 1974. As opposed to Arpanet, the major part of the packet traffic is generated by remote batch jobs. At present, the bottleneck is the line printer, not CIGALE. This is an indication that DG's are an adequate transport facility in a remote batch environment. Conversational traffic is actually much less demanding.

The VC protocol has been implemented in various environments:

—in a user partition of a host computer,
—in a virtual machine under CP/CMS,
—within HASP,
—integrated with a telecommunication access method in manufacturer software,
—in a mini-computer as a host front-end,
—in a terminal concentrator,
—in a micro-programmed display controller.[13]

Another computer network, EIN, is being built on the same principles as CYCLADES. So far the participants have not identified any need for VC's at the packet network level.

An end-to-end VC protocol[14] based on DG's has been proposed by a working group of IFIP (WG 6.1). To date it is by far the best design which results from the largest exchange of ideas, and has received the widest acceptance. An early version[15] of this protocol has been in experimental use since mid 1974, between France and UK. Although the work accomplished in experimental networks has been generously disseminated, it has received little attention from the computer manufacturers, except for CII (Compagnie Internationale pour l'Informatique) in France, which has included VC's with a DG interface in its commercial software.

In addition, a packet switching software (i.e., DG) is available on a CII mini-computer.

Another computer manufacturer product, DECNET,[16,17] uses an end-to-end VC protocol independent of transport facilities, i.e., it can work with DG's.

IBM has released some documents on SNA,[18] in which there is an internal boundary with a transport facility. The transport interface appears to be of the DG type, but at the end of 1975, no information could be obtained on network structures allowing alternate paths. Furthermore, the transport functions are integrated in SNA. Facilities provided by carriers are limited to telephone lines.

VIRTUAL CIRCUITS VS. DATAGRAMS—TECHNICAL

As seen earlier, staging VC's against DG's in abstracto would be nonsensical, since they are independent layers. What is more relevant is to discuss the adequacy of either type of interface when provided by packet networks, namely public carriers. Thus, the discussion assumes CVC's.

It seems that all possible types of interfacing with public packet networks boil down to two classes:

—the carrier provides a transport facility in charge of transporting bits from one point to another;
—the carrier provides a device in charge of handling remote terminals.

This classification requires further elaboration.

Packet network as a transport facility

A typical situation is a private network in which dedicated lines and multiplexers are to be substituted with packet switching. What the customer is looking for is cheaper lines.

Only buffered equipment can send or receive packets. This rules out asynchronous character terminals, unless they are complemented with buffers. Normally, some kind of synchronous transmission procedure is used for the exchange of data.

First of all, delays introduced by a packet network may be unacceptable by application protocols. Assuming that this problem could be circumvented somehow, the customer would have to replace his transmission procedure with the one imposed by the network, i.e., HDLC, unless it is already there.

Then, the customer may subscribe for one or several CVC's for each piece of equipment, in keeping the same virtual topology. CVC's require the addition of the CVC protocol. If the customer is prepared to rely on the carrier for error and flow control, that's all he has to do. Otherwise, he would have to put yet another end-to-end protocol (E-E), which would give him complete control on the quality of the transmission on each CVC (Figure 8).

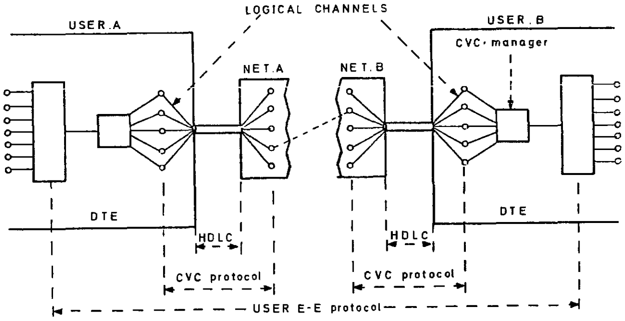

Figure 8—Virtual circuits as a transport facility

If the customer were using DG's, he would have to put an E-E protocol of his own choice, and a DG protocol.

To sum up, CVC's may have a minor advantage over DG's, when the customer agrees to trust the carrier, because a CVC protocol is perhaps a little more compact than an E-E plus a DG protocol. But this cannot be held true until it has been validated from experience for a number of protocols.

On the other hand, if the customer wants to insure his own E-E control, a DG interface would unquestionably take less overhead than CVC's.

As we have seen earlier, this latter situation is to become the rule rather than the exception, because computer manufacturers are introducing systematically E-E protocols in their network architectures. This approach has also been constantly advocated by users.[19,20,21,22,23,24] Unlike CVC's, E-E protocols within customer equipment are self-contained mechanisms. Furthermore, DG's provide for switching capabilities and multiple routes, which is a net improvement over CVC's in terms of flexibility and reliability.

Packet network as a terminal handler

This is the case where the customer wants to use a packet network to access non-intelligent character terminals. At one end he may have enough intelligence to implement whatever protocol would be required, but character terminals cannot transmit packets.

To that effect, carriers are providing functions to assist character terminals which they initially called packet assembling-disassembling (PAD). But a character terminal needs much more assistance than just PAD. E.g.,:

—character translation,
—recognition of break characters,
—timing of mechanical functions,
—translation of interrupt or error signals,
—recovery procedure,
—etc. . . .

It is no longer possible to control these functions over the packet network, since they are time dependent, and require a direct physical interface with the terminal. Therefore, the carrier has to do it. But terminals have a number of options, which the customer may want to use, or to vary. This requires some conventions whereby the customer, at either end, may set up his own menu. It is also nice to use different makes of terminals without having to develop special adaptations to the customer systems. Thus, terminals may access various computers. But a connect protocol and command language is necessary to specify the computer. And so on.

Step by step, the carrier is tempted to offer more and more facilities, which bear no relation to data transport whatsoever. These facilities are a set of functions which are logically at the level of an access method, such as VTAM. In a sound architecture, they should be matched by equivalent layers in the customer computer system. But, they are not. Flexibility has not yet reached that level.

Unless it is substantially modified, the customer system cannot communicate with the carrier as if it were dealing with a friendly terminal concentrator, because their access methods do not match. A typical scheme around this problem is to communicate with the carrier in terms of *character streams*, as if the carrier network were a terminal of a certain type, or a cluster of terminals.

Although this kind of interface is somewhat customized, some carriers appear to be willing to put the appropriate adaptation into their own networks, probably as the only way to get customers. Another variant is the customer developing a *gateway* between his main frame and the carrier.

With this approach, the customer delegates complete control of his terminals to the carrier. He has no way to check that things are running correctly save for hearsay from terminal users. This may be acceptable for certain classes of applications.

When the carrier provides the adaptation, the only interface visible to the customer is a character stream for a certain kind of terminal. Then, the question of using DG's or CVC's becomes an internal matter for the carrier. As we know, carriers use DG's internally to implement CVC's.

When the customer provides the gateway, he has to implement some protocol to exchange packets with the carrier. A simple DG interface would not be sufficient, as DG's assume an E-E protocol. Since the customer has no control on the other end, he has no choice but to use CVC's. Perhaps he would just wonder why the CVC protocol is that bungled.

But the real issue is not there. It is in the gateway itself. The hardware cost may be insignificant with large host computers. It certainly is significant when the host is a specialized mini. Furthermore, the largest part of the software is devoted to conversion chores, not to the CVC protocol. This means an inherent limitation in traffic throughput and a unique physical path to the carrier. Inter-computer communications become rather restricted if they have to mimic character terminal traffic.

A way out of that quagmire is intelligent terminals. If it turns out that they can be mass produced at a cost close to that of dumb terminals, there will be no need for terminal handling. Each terminal, or cluster, will contain enough intelligence to handle all necessary protocols, either locally or end-to-end. The most economic sub-layer to E-E protocols is a DG facility. As an illustration of that technique, a micro-programmable display[13] has been inserted in CYCLADES. It interfaces directly with the CIGALE packet network and contains all higher level protocols matching those in CYCLADES hosts. This puts terminal handling under complete user control, totally independent from the carrier. Thus, the packet network would revert to its initial destination: a transport facility.

VIRTUAL CIRCUITS VS. DATAGRAMS— POLITICAL

It should be apparent by now that there is something else than technical under the rug.

Indeed, manufacturers and users unanimously declare the view (as they say in CCITT) that there is a need for E-E protocols independent from transport facilities. This is an overwhelming position supported by scores of papers.[19,20,21,22,23,24,27,28] ISO has now started working on the standardization of an E-E protocol (TC 97/SC6/Project 17), which would allow data transfer between data processing equipments, *regardless of the transport facilities* used. IFIP-WG6.1 has already proposed such a protocol,[14] after extensive discussion and experimentation within network groups at international level. Therefore, one might think that the carriers would make every effort to take this approach into account in designing interfaces with public transport facilities, e.g., make it easy to superimpose E-E protocols on packet transport, and avoid the duplication of functions.

Some computer manufacturers have already expressed their preference for a specific transport facility: the DG. Others have not, and this includes IBM. Their position is that they cannot take a stand as long as specifications, quality of service, tariffs, are not known. Fair enough, because adaptation costs and effectiveness cannot be assessed without these essential parameters. But a certain number of institutions have already expressed a definite support for a DG facility. This includes IFIP-WG6.1,[27,28] the EIN community, the Industrial and Technological Directorate of the European Communities, the French Direction of Industry, and various users of large private networks.

Positions on CVC's are more polite. Everyone supports more or less CVC's without comment. It is not considered as a wise stand to antagonize the European PTT's when they are known to be ticklish (PTT's are telecommunications state monopolies). Manufacturers are even more cautious, since they always have some proposal hung up somewhere on a PTT desk. And after all, if CCITT standards are awkward, manufacturers will have a good excuse for selling their customers additional hardware. In case customers would then shy away from public packet networks, God bless the CCITT. Private networks are a bonanza.

Since carriers, and especially PTT's are primarily concerned with public interest, one would think that there are enough indications for providing both CVC and DG facilities. CVC's would be used by carriers as part of their terminal handling complex, and DG's would meet the requirements of a certain number of users. Actually, DG's are the only facility for which there has been real insistence coming from users and some manufacturers (not IBM). Software products using DG's are to be delivered in 1976.

A carrier's dream

As mentioned earlier, since mid 75, four carriers have been very busy coming to a consensus on a user interface with public packet networks (X25). (They are: French and UK PTT, Bell Canada and Telenet). They assume that CCITT, therefore the whole world, will buy up their common proposals at the next plenary assembly in August 1976. Due to administrative constraints, these proposals are practically firmed up at the beginning of 1976.

Conspicuously, the 4-tuple are adamant against DG's which they have downgraded from essential to optional, in opposition to the view of ECMA, IFIP, ISO,[30] and NTT.[29] Then, what is wrong with DG's?

Technical arguments are still used with non-experts, who may ignore that carriers use DG's for their own needs. The crux of the matter is elsewhere.

DG's call for E-E user protocols, which imply that the user is in control of both ends of the data path. In between, the carriers transport bits. But that is just a carrier business. Carriers do not want to be confined in carrier business any more. They want a more glamorous piece of the action: no less than a share of the computer market. According to their rationale, anything that goes on between a computer and a terminal is data transmission and switching. Since carriers have a monopoly in switching telephone circuits, they consider it a natural extension to demand the monopoly of virtual circuit switching for data. Terminals being a natural extension of circuits for testing, maintenance, and so on, should also belong to the carriers, like a phone set or a teletype.

Additional functions might be required, such as a command language, editing facilities, etc., but this is a natural extension to a dialing procedure. Carriers would standardize all that, and everyone would be happy. No less than a lion's share.

If the user were in control of both ends of the data path, nothing could ever happen, because he would keep buying total systems from his usual supplier. Therefore, it is essential for the carriers to be in control of at least one end of the data path. Clearly, working from the terminal up is a logical step. This is why such things as DG's, E-E protocols, are totally undesirable, unless they are completely under carrier control. In line with that approach, CVC's do not provide for E-E control at the user level.

An additional reason why DG's are outlawed is that they facilitate switching. That should be a carrier privilege. Therefore, it is essential that DG's do not spill away into the user domain. The CVC interface should be the Chinese Wall that contains DG's within carrier boundaries.

Once the carriers have secured terminal control in their networks, they will work at stealing more and more functions from the processing industry, to make them available within public networks. E.g., text handling, data banks,[31] data collection, software packages, about everything that is presently offered by service bureaus through private nets. Wherever possible, private nets will be outlawed or deterred with exorbitant line tariffs. State monopolies can do that.

Terminal manufacturers will have to queue up for months or years to get their products supported by public networks. Even if they conform to PTT specifications, a stamp of approval will likely be necessary. Innovation will be decided by PTT's.

Small computer manufacturers will be brought to compliance with CCITT standards and there will be no exception, because everyone else could put it up as a precedent. However, CCITT standards will not be incompatible with IBM, for practical reasons.

Carriers are huge bureaucracies. They have split viewpoints. Infighting goes on over issues like digital circuits vs. packet switching. Most carriers at top level are uncertain about choices made and would react negatively at the prospect of building a data processing empire, especially in Europe, where some of them cannot even cope with telephone. So, the packet clan has to walk a thin line, and tends to operate by political coups rather than by open policy. Occasionally, one of them is candid in telling the whole story.[32] Unfortunately, this is an exception. This is one of the reasons why discussions about public networks are somewhat eerie. In addition to the traditional secretive attitude of the European PTT's, there is a touch of deliberate covering up. It may explain such ludicrous documents where handling character terminals is just a matter of putting characters into packets, and vice versa. This is a model understatement for another Babel tower in the terminal jungle.

CONCLUSION

The controversy DG vs. VC in public packet networks should be placed in its proper context.

First, it is a technical issue, where each side has arguments. It is hard to tell objectively what a balanced opinion should be, since there is no unbiased expert. This paper argues in favor of DG's, but the author does not pretend being unbiased. Even if no compromise could be found, the implications would be limited to some additional cost in hardware and software at the network interface. So much resources are already wasted in computing and communications that the end result may not be affected dramatically.

Second, the political significance of the controversy is much more fundamental, as it signals initial ambushes in a power struggle between carriers and the computer industry. Everyone knows that in the end, it means IBM vs. Telecommunications, through mercenaries. It may be tempting for some governments to let their carrier monopolize the data processing market, as a way to control IBM. What may happen, is that they fail in checking IBM, but succeed in destroying smaller industries. Another possible outcome is underdevelopment, as for the telephone. It looks as if we need some kind of peacemaker to draw up boundary lines before we all get in trouble.

Network access techniques—A review*

by ROBERT ROSENTHAL
National Bureau of Standards
Washington, D. C.

ABSTRACT

The computer industry's ability to serve a diverse and expanding user community is evidenced by the rapid growth of computer network services. Computer service providers design and market their own offerings as they deem best, given their own market and their own set of resources. This has led to a proliferation of similar resources requiring different user access procedures. With emphasis on currently operating and planned systems that assist users in accessing available network services, this paper identifies the techniques used in network access devices. By examining these devices, the trend toward improving the interface between the user and the computer is brought more clearly into focus and up to date.

INTRODUCTION

Little over a decade ago, when people began to interact with computers in the routine performance of their jobs, few cared about the differences between similar service offerings—all were eager to learn and experiment with that new technology.

Today, with the advent and growth of computer networks, that modest size group of scientists, engineers, and researchers has grown to include professionals in all sciences—mathematical, physical, health, and social—as well as students, stock brokers, and reservation clerks from many fields. Just as the number of users has grown so has the number and diversity of computer services.

Trends in service growth, traceable through individual families of mainframes, operating systems, and service packages, lack direction and consistency from the user's point of view. The reason for this fragmented growth might be justified considering constraints imposed by telecommunications facilities, peculiarities imposed by mainframes and their operating systems, and the personal preferences of system developers. Unfortunately, many of these services are characterized by different implementations of the logically similar steps that users must take in order to accomplish productive work.

Today we have a situation in which more and more users are consuming more and more services while the services themselves perpetuate differing user procedures for access to the same logical services. A reasonable question to ask is "What can be done to help the user?" Standardization of access procedures is a possible solution. However, a procedure for access that makes one service more attractive than another through enhanced features should not be compromised by a premature effort to standardize such procedures—especially if the standard settles on "lowest common denominator" features. Encouraging competition among network service providers can be in the user's best interest if it leads to innovation in the amount and quality of service received and in the reduction of costs in providing the service. Rather than push for extensive user-oriented uniformity, it may be desirable to continue to permit and encourage such non-uniformity, but to compensate for it through network access assistance to the user.

ASSISTANCE

The concept of assisting users is not new to the computer industry. The notion of a compiler, for example, resulted from this kind of motivation. Unfortunately, compilers were soon accompanied by complex operating system control languages. Once again, assistance techniques in the form of a control language macro capability or a catalogued procedure capability were employed to help the user. With these techniques the inexperienced user easily performed complicated job steps and the experienced user worried less about detail in setting up job steps.

This type of assistance, extended beyond a single computer system and placed in the interactive computer network environment, lessens the wearisome burden faced by users contending with separate and

* This work was sponsored in part by NSF grant DCR 72-01206 A06.

different services that accomplish logically similar tasks. In such an environment, the user should have resources readily available from different computers without regard for the specifics of how to obtain them; the user should be more concerned with what services are required.

Early attempts to provide computer network assistance are still in use today. One interesting technique makes use of function buttons that produce character sequences. These sequences represent the appropriate user protocols that identify terminals, users, and services, thus alleviating the need for the user to key in the required protocol. The familiar "who-are-you" drum is an example of this kind of technique. Other devices—stunt boxes, automatic card dialers, and paper tape loops—have been used successfully to assist users, but all of these devices are usually applicable only on dedicated connections to specific computer systems and services. In a modern computer network other more general techniques can be employed.

INTERFACES AND PROTOCOLS
